ALL LIFE AHEAD . . . . Mileage is the measure of car life, and the real gauge of mileage is "Timken Bearing Equipped".

As wheels spin smoothly along; pinions run true; differentials are kept to dead silence; steering retains its original ease;—it becomes evident that prime performance is seemingly without end.

Search for the reason and you find behind it all these exclusive advantages—Timken tapered construction, Timken *POSITIVELY ALIGNED ROLLS* and Timken-made steel—defying advancing years, refusing to grow old

How long do you want your car to stay young? You can forecast its miles of usefulness by referring to the list on this page. Look for Timken Bearings. See just *where* they are.

Then, buy with the same judgment the engineers used in designing these cars for long life —"Timken Bearing Equipped".

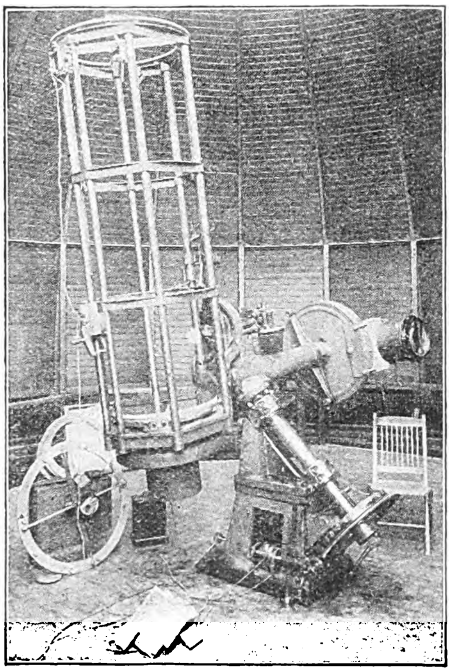
The Amateur Astronomer

AMATEUR telescope makers who recall the publication of the Reverend W. F. A. Ellison's picture in the March number, and the suggestion there made that it be clipped out and pasted in the instruction book, "Amateur Telescope Making," may wish to do as much with the photograph which appears at the right. This picture of Mr. Porter, which was taken by Dr. Clyde Fisher, president of the *Amateur Astronomer's Association,* (American Museum of Natural History, New York), is a much better likeness than the one on page 19 of "Amateur Telescope Making." Mr. Porter is still at Pasadena co-operating on various pieces of work, optical, mechanical, and architectural, preliminary to the final construction of the 200-inch reflecting telescope.

Russell W. Porter



24-inch at Yerkes

THIS month we shall discuss the merits of the open or skeleton tube reflector, in contradistinction to the more common closed or solid-sided tube, and two open-tube telescopes of this type are shown here. Of these the one below is a strictly professional job. The mirror was made some years ago by Ritchey, who also supervised the construction of the mounting. The figure of the mirror is very perfect, and extremely fine photographs of nebulae have been obtained with it, according to Director E. B. Frost of Yerkes Observatory, mainly by Ritchey, when the latter was connected with this Williams Bay, Wisconsin, institution. A detailed description of this reflector will be found in Volume 14 of the *Astrophysical Journal*, and a large photograph for those who care to study its structural detail may be had from the Observatory, for 50 cents.

The other skeleton tube telescope is one recently built by Professor Dinsmore Alter of the University of Kansas and Mr. William Pitt, retired manufacturer. As several requests for information have failed to bring forth much satisfaction (the photograph itself having been purchased from a news photograph agency), no details can be stated here, except that it has been known among astronomers for several years that Professor Alter was engaged in making the instrument. The 27-inch mirror was made from a 27-inch disk of Pyrex four inches thick.

OPEN-TUBE telescopes of the kind just mentioned are strongly advocated by the Reverend T. E. R. Phillips, M.A., F.R.A.S., and F. J. Hargreaves, F.R.A.S., in comment reproduced by kind permission from the *Journal of the British Astronomical Association* (London). The Reverend Phillips is Director of the Section on Jupiter, and Mr. Hargreaves of the Section on Photography, of that organization. They write:

"There is a widely held view that reflectors are much inferior to refractors in defining power, assuming equal optical quality, and there can be little doubt that in most cases this is so, especially when the reflector tube is of metal and closed on all sides. Experience over a long period at Headley with an 8-inch refractor and a 12¼-inch reflector in an iron tube shows that the number of nights when the image in the reflector is as good as that in the refractor is very small.

"A third instrument at Headley, the Association's 18-inch reflector, formerly the property of the late N. E. Green, has recently been remounted in the dome formerly occupied by the 12¼-inch, and its performance since remounting is worthy of record insofar as it affects the question of the relative merits of the two types of instrument.

"Before the remounting, the 18-inch mirror was carried by a square wooden tube, completely closed on all sides, and the image usually had the well-known reflector characteristics—unsteadiness, lack

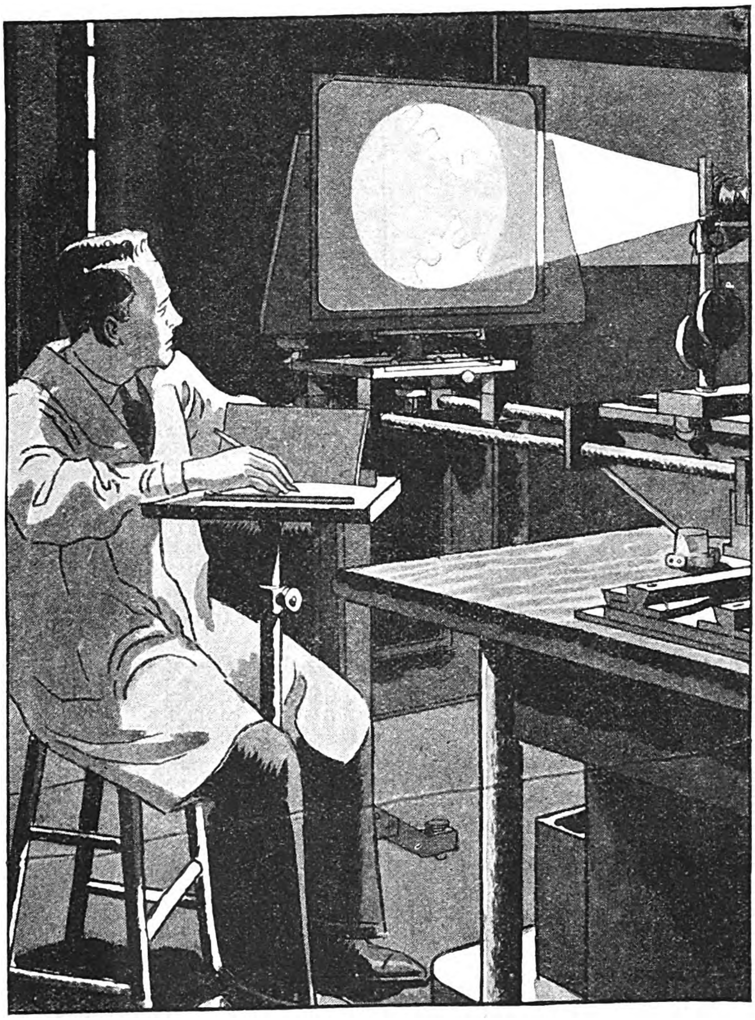
Alter-Pitt reflector

A RAINBOW

now helps to make Better Machines



Up the hill to the busy Westinghouse research laboratories in East Pittsburgh come engineers of a great industry asking, "What shape shall we make these machine parts to get the greatest strength from our materials?"

Light flashes on a snow-white screen. Outlines on the machine part appear. Then someone turns a loading screw and areas of color are seen changing their hues as the load on the test model increases. Black turns to gray, gray to yellow, yellow to red, brown, green and so on. In this manner the machine part appears in colors of a laboratory rainbow that tells its own story for keen eyes to read—a well-directed ray of light discloses where the heaviest stresses are.

"Photo-elastic tests" the engineers call them. And from tests like these slight changes in shape give vast gains in strength without added material. Sometimes even less material actually gives greater strength. A laboratory rainbow does what the most elaborate calculations could not do.

These tests are but one instance of the methods by which Westinghouse research is engaged in finding new ways to help dollars in industry, in business, in homes, obtain larger returns for those who spend them. In finding new facts, and new ways to use old facts for new gain, Westinghouse serves the modern electrical age in which you live.

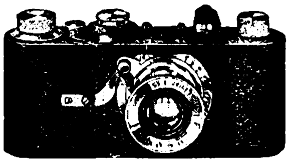
made with a Leica



Only an exceptional camera can do this

A SUDDEN flash out of a darkened sky—and the Leica records it with astonishing clarity and fidelity.

Here is a camera of true scientific precision. Mechanically and optically perfect. Its famous Elmar Anastigmat F 3.5 lens insures clear, sharp negatives under all conditions of light and weather. Ideal for snapshots, portraits or photomicrographic work.

If you want better pictures this Spring and Summer take a Leica wherever you go. Weighs less than a pound and fits vest pocket or purse. Each roll of standard cinema film gives 36 pictures, double frame size. And enlargements to 12 x 18 inches or more retain and amplify the smallest detail.

See this unusual camera at any high-grade photographic supply store. Or, if you prefer, send the coupon for illustrated catalog No. 1166. E. Leitz, Inc., Dept. S. A.-9, 60 E. 10th St., New York, N. Y.

Our Point of View

France and the Naval Conference

(*Continued from page* 349)

building program; and, thanks to their large additions to the cruiser strength made since 1921, they are in an excellent position to resume competitive building.

The economic position of France is better than at any time since the World War. There is no unemployment problem, her gold reserve is large, the reconquest of Alsace and Lorraine makes her self-sufficing for coal and iron, and as long as she controls the Mediterranean route to Algiers, her supply of foodstuffs is secure. So France faces the future with confidence, is encircling her land frontiers with modern fortifications, and purposes to provide sufficient naval force to secure her position in the Mediterranean. Tardieu's demand on Stimson and MacDonald for guarantees in exchange for naval limitation is suggestive of Clemenceau's demand on Wilson and Lloyd George for a security pact in exchange for the League of Nations. France pursues a consistent course in her foreign policy.

Italy stolidly reiterates her claim to absolute parity with France. England claims she must maintain a navy equal to the combined navies of the next highest European navies; and her agreement to reduce her tonnage to an amount acceptable to us is contingent on her tonnage being equal to the combined tonnage of France and Italy.

Britain is willing to give the guarantees required by France if we will countersign the guarantee, but our delegation well knows that though the American public is anxious for naval limitation, it will not purchase limitation by again involving the country in Europe's affairs. When the British delegation is asked to find a formula acceptable to France they point to their existing obligations under the Locarno and the Lausanne agreements to use their fleet to support the decisions of the League of Nations against an aggressor nation, pointedly remind us that we have not accepted any such obligation, and request us to share any further responsibilities Great Britain is called upon to assume. This part of the problem therefore is developing just as anticipated.

Great Britain and the United States could agree on a parity at a tonnage not in excess of that which the United States is willing to build, if France and Italy combined would not build a larger fleet than Britain's. If France insists on 700,000 tons, and Italy insists on as much, then Great Britain must have 1,400,000, which is more than the United States wants to build. Great Britain, on the other hand, is willing to build the larger tonnage and expresses a perfect willingness for us to achieve parity by building up to her requirements.

There is a small but influential section in Great Britain that rather welcomes the threatened impasse on the theory that the United States is unwilling to spend the money on its fleet necessary to achieve parity, and that Great Britain, having made its gesture of accepting parity with the United States, will, if the Conference fails, be free to continue its building program and once again achieve an overwhelming sea supremacy. For our part we believe that the American people are resolved to have a navy second to none and while they would prefer to spend their revenues on internal improvements, they are prepared to maintain their fleet if the complexities of European jealousies make this necessary. Ours are a busy people, more intent on their daily tasks than on world politics. They are a peaceful people, enjoying more prosperity than others and consequently unenvious of others, but they are fully aware that their prosperity is dependent on their sea-borne commerce, inter-coastal as well as foreign. In the World War, they saw the sea-borne commerce of Germany, who possessed the second best navy in the world, swept off the seas within 30 days and we are confident that never again will the United States be content with a navy that is not equal in every class of vessels to that of any other nation.

Japan and the United States are discussing the ratio of cruisers, destroyers, and submarines; Japan demands 70 percent but the United States claims that Japan is morally committed to a 60 percent ratio, the same as in capital ships. Japan has the legal right on her side, but unquestionably it was the understanding of this country when it agreed to restrict the fortifications of its Far East posses-

The Scientific American Digest

(Continued from page 394)

on a wet soil is prevented. Water will sink through that kind of a furrow several times faster than from a shallow furrow.

The advantages of the deep-tillage system (with sub-soiling and without plowing) and cover crop culture have been summarized by the Agricultural Extension Division, University of California, as follows:

(1) The cost, as compared to plowing and ordinary tillage methods is reduced in some cases as much as 50 percent. (2) All cultural operations are speeded up, making it possible to take advantage of favorable weather conditions. (3) Incorporation of the organic matter (cover-crop) throughout the entire area of the soil, is facilitated. (4) The humus content of the soil is increased. (5) The soil is given greater water-holding capacity. (6) The soil (especially in orchards) is more easily kept level. This is important in irrigated districts. (7) By conservation of moisture, the number of necessary irrigations is lessened. (8) More complete aeration of the soil results, with consequent increase in the beneficial activity of soil bacteria and fungi. (9) Roots (of fruit trees) are pruned, with the result that fine feeder roots are put out, increasing the assimilation of moisture and plant food. (10) The friability and general physical condition of the soil are improved.

Strange Stone Head Discovered in Texas

A GREAT stone, naturally shaped like a human head and carved with teeth, ears, eyes, and flattened chin, is a strange new discovery from Texas, unearthed from its resting place beneath 16 feet of undisturbed gravel.

Dr. E. H. Sellards, geologist of the University of Texas, brought news of the discovery to the Paleontological Society. The stone head appears to be a new piece of evidence that man existed in America in ancient times.

Judging by the geological conditions of the region, the stone must have lain in place while the gravel from nearby streams washed over it forming finally a layer more than 16 feet deep, Dr. Sellards said. The streams have long since ceased to wash gravel over the site. The stone weighs at least 75 pounds, possibly 100, he reported. —*Science Service.*

Ford Adopts New Alloy

WHEN the redesigned Model A Ford was announced late last December, the official description stated that exterior metal parts were made of rustless steel. It is now learned that the metal referred to is not the usual rustless steel, but an entirely new alloy never before used in automobiles. The Ford company's adoption of the product has more than doubled its output in this country.

The new alloy is known as Allegheny metal. The original formula for its manufacture was developed in Germany during the war, when armament plants were seeking the hardest possible substance suitable for gun lining. At about the same time, the English also worked out the formula. It was not until after the war, however,

Industry's Mainstay
—and yours

Few realize how the individual, as well as industry, is dependent upon wire rope—the great flexible "handler" of practically everything.

The illustration shows a great slab of concrete bridge flooring being lifted onto a freight car.

All the material in a modern skyscraper is handled with wire rope—in the "raw"; in shipping; in the actual building erection.

Oil wells are drilled with wire rope; mines are mined and quarries quarried with it. Your furniture and the evening newspaper both originated in logs taken from the forests with wire rope.

Yellow Strand Wire Rope will usually be found where real stamina is demanded. Not mere strength, but strength so nicely balanced with elasticity, flexibility and resistance to the crystallizing effect of vibration, that long life under severest conditions is assured.

One *strand of yellow* distinguishes this high quality rope from all others.

Broderick & Bascom Rope Co.
St. Louis, Missouri

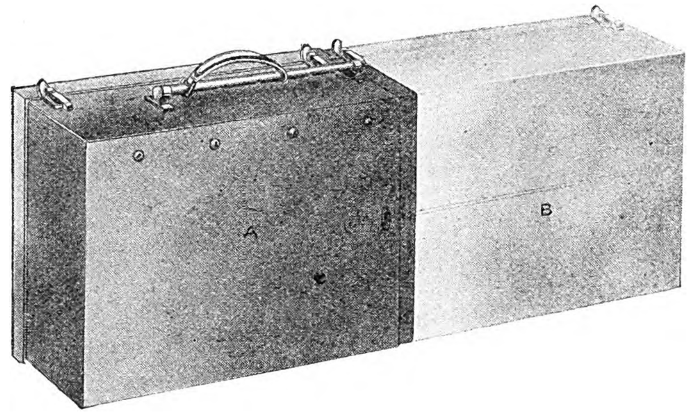
Manufacturers of nothing but wire rope for over half a century

Yellow Strand
WIRE ROPE

Aerial Wire Rope Tramways designed by this company have features that insure economical operation.

Luggage Manufacturers

I wish to interest buyers in purchasing license or royalty contracts of patent rights on the patent number 1748024.



Here is an opportunity to acquire the manufacturing rights to an invention relating to collapsible cases which telescope lengthwise. The telescoping parts lock solid when the case is closed, the lid may be opened in any position, and a movable handle establishes balance for carrying. These principles can be applied to any type of carrier from a personal hand bag to a trunk. Any material could be used for construction, wood, canvas, leather, cane, fiber, composition, papier mache, metal, etc. One of the most popular and useful applications of this invention would be to bags such as the one illustrated.

The possibilities of this telescoping principle as applied to industrial shipping cases should not be overlooked. Such a case made of unbreakable waterproof papier mache would institute a tremendous saving in shipping certain types of products since they could be used repeatedly and are adaptable to the size of the shipment.

Manufacturers interested in this device should write the inventor,

that the commercial production of the alloy was contemplated and it was only a few years ago that methods for its economical manufacture in large tonnage were developed.

The Ford requirements are said to be about 1000 tons a month. This represents two thirds of the entire output of the American factories and one third of the output of the world, which is now about 3000 tons. When he adopted the alloy, Mr. Ford had to scrap several million dollars' worth of equipment originally installed for fabricating and polishing the nickel used in the original Model A.

Allegheny metal is said to be nonrusting, untarnishable, non-corrosive, and not affected by weather in any way. It is also one of the hardest metals known to the steel industry. It is an alloy of refined steel combined with about 18 percent of chromium, 8 percent of nickel and smaller proportions of carbon, manganese, silicon, phosphorus, and sulfur. It is the complicated method of combining these elements that gives the alloy its properties, it is explained.

Before its adoption by the Ford Company, production of the alloy was limited, because it was used only for building trim, cooking utensils, dairy equipment, and other articles for which it met special requirements. It is now being considered for use in the bars of State penitentiaries, according to report, because it is so hard that it cannot be sawed or otherwise cut by any hand tool.—*The New York Times*

Measure Wind Passing Through Brick Walls

WIND blows right through brick walls. A well-laid 13-inch wall in the face of a 30-mile-an-hour wind will allow 14.75 cubic feet of air to pass through it every hour, G. L. Larson, D. W. Nelson, and C. Braatz reported to the International Heating and Ventilating Exposition in Philadelphia recently. This data is obtained from researches they have conducted at the University of Wisconsin.

But proper plastering with gypsum directly on brick, they find, will stop 96 percent of the leakage. Less air will leak through a wall which has been well constructed and in which all spaces between bricks are filled with mortar.—*Science Service*

Test Shows Efficacy of Auto Oil Filter

IF automobiles are equipped with oil filters, frequent changes of oil in crankcases are unnecessary, a test trip across the continent by A. H. Hoffman, associate agricultural engineer at the University of California agricultural experiment station, tends to show.

On the trip, during which the speedometer showed 10,025 miles of travel, Mr. Hoffman found that after a change of oil, the viscosity dropped rapidly for about 200 miles, and then changed little for 5000 miles.

The tests on acidity were much the same, the acidity rapidly rising for about 200 or 300 miles, then showing small variation.

Only one machine was used in the experiment. In addition to the oil filter it had a crankcase ventilator, and both carbureter and breather were protected against dust. The test was made in warm weather.—*Science Service.*

The Amateur Astronomer

(*Continued from page* 400)

of crispness, and inability to bear high magnification.

"The sides of this wooden tube were made after the manner of a door, with stiles, rails, and panels. The panels having for the most part rotted, they were removed prior to the re-mounting of the instrument, and it was decided not to close in at once the large openings left by their removal, in order to observe the effect of allowing the air to circulate freely through the tube. In brief, the effect is to remove completely the characteristic defects of the reflector, so far as planetary images are concerned.

"The performance of this instrument has surpassed all expectations—so much so that in spite of the great disparity of aperture it is now rare to find, on occasions of poor seeing, that the refractor image is steadier or better-defined than that of the reflector.

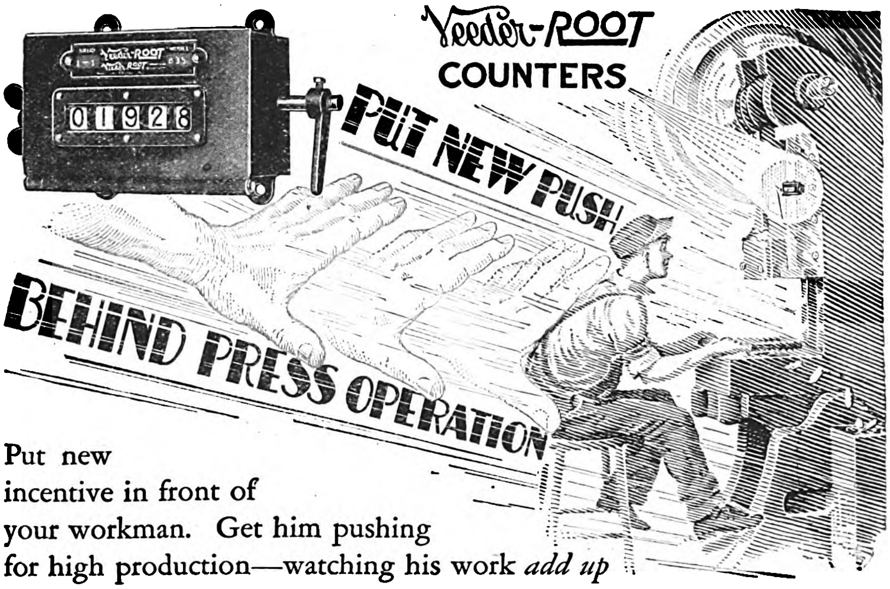
"It should be understood that no claim is made for novelty in the idea of the skeleton tube, which, of course, is used for all the very large reflectors; it is only desired to point out the very great benefits to be obtained by adopting this type of tube for the smaller instruments, for which it has not hitherto been generally used.

"Experiments have shown that when the external temperature is falling, as of course is the general rule at night, it is impossible to keep the temperature of the air inside a "closed" tube uniform and equal to that of the external air. An electric blower sending a current of air up the tube is a help in the smaller sizes, but the trouble begins again as soon as the blower is stopped. In the case of a metal tube, the upper wall becomes colder than the lower wall by radiation, thus setting up convection currents within the tube. If the tube is lagged with felt, or if it is of wood, this trouble is avoided in part, but the tube and the air within it will then remain warmer than the external air during the whole time that the temperature is falling, and for some time after.

"The presence of this mass of relatively warm air can be made visible readily when the conditions are suitable. The telescope should be directed to a bright star and the eye-piece racked out considerably to give a large out-of-focus disk, which will be seen to be irregularly in motion. If an assistant then opens the door near the bottom of the tube and flaps a piece of cardboard vigorously in front of the opening, the out-of-focus disk will "boil," owing to the inrush of the cooler air. The air within the tube can be readily set in rotation by this means, and the rotation is visible in the eyepiece; but no amount of flapping will bring about uniform conditions."

So much for one side of the question. In a long article entitled "Reflectors versus Refractors," in the March number of *Popular Astronomy* (Northfield, Minn.) Prof. W. H. Pickering discusses both sides.

STILL another telescope, a 19-inch reflector having an open tube, is described in the January, 1930, number of the *Journal of the Royal Astronomical Society of Canada*, by its maker, Professor R. K. Young, of the Department of Astronomy at the University of Toronto. The illustrated article is detailed (16 pages) and ought to be obtained by every amateur who aspires to



Put new incentive in front of your workman. Get him pushing for high production—watching his work *add up* on a Veeder-Root Counter. Let him see his efforts COUNT in pieces per day or hour. So he'll be encouraged to do more, *earn* more—and you'll know you get all you pay for. Saving over-runs and under-runs by counting the work *as produced.*

make a fairly large telescope at some future date. The address is *Journal of the R. A. S. C.*, Mr. H. W. Baker, Treasurer, 198 College Street, Toronto, and the price is 25 cents.

Another current scientific journal which those who are especially interested in the Hale spectroheliosope should not miss is the December, 1929, number of the *Astrophysical Journal* (5750 Ellis Avenue, Chicago; 75 cents), containing a 46-page article on that instrument written by Dr. Hale and strikingly illustrated by R. W. Porter. Since the publication of "Amateur Telescope Making" with its description of the spectroheliosope, numerous alterations in design have been made.

Professor Charles W. Woodworth of the University of California, is making a mosaic type of telescope containing 400 mirrors, each 15 inches in diameter, and all attached to a single rigid backing. Each is to be adjusted, if possible, to the position called for by theory. Dr. Woodworth submitted his idea to this journal a year or more ago and the opinion given through one of its corresponding editors was that the theory was correct but in practice the difficulties would probably prove insuperable (see "A. T. M.", page 242, near bottom). He is now trying it out, and this is the correct procedure in cases where there is any doubt. Dr. Woodworth is an entomologist who has specialized on microscope theory, with which telescope theory has much in common. The amateur fraternity will wish him success.

At 10½ o'clock: May 15.
At 10 o'clock: May 22.
At 9½ o'clock: May 30.
At 9 o'clock: June 7.
At 8½ o'clock: June 14.
At 8 o'clock: June 22.

The hours given are in Standard Time. When local summer time is in effect, they must be made one hour later: 12 o'clock on May 7, etc.

NIGHT SKY: MAY AND JUNE

MERCURY is an evening star till the 20th and then a morning star, but can be well seen only during the first few days of the month. Venus is an evening star, growing more and more conspicuous as she comes north and gets farther from the sun. She sets at 8:30 when the month begins and 9:30 at its close. Mars rises in the neighborhood of 3 A.M. but is still almost 200,000,000 miles away and in consequence looks but little brighter than a star of the second magnitude. Jupiter is still an evening star but is getting low in the west. By the end of the month he sets a little after 8 P.M. and can hardly be seen. Saturn is in Sagittarius and rises at 10:30 P.M. in the middle of the month. Uranus is a morning star rising at 3 A.M. in the middle of the month, while Neptune is in quadrature on the 22nd and becomes an evening star.

The moon is in her first quarter at noon on the 5th; full at noon on the 12th; in her last quarter at 11 A.M. on the 20th; and new at 1 A.M. on the 28th. She is nearest us on the 4th, farthest off on the 19th, and nearest again on the 31st. As she circles the sky she passes near Jupiter on the 1st, Neptune on the 6th, Saturn on the 16th, Uranus on the 24th, Mars on the 25th, Mercury on the 27th, Jupiter again on the 29th, and finally Venus on the 30th of the month.

"You'll be ALL RIGHT at a Statler"

In these hotels you can be sure, in advance, of the up-to-date attractiveness of your room — and of such comforts as radio which awaits the turn of a switch, running ice water, bed-head reading lamp, your own private bath, a morning paper under the door when you wake; and excellent restaurants, in a variety which ranges from formal service to a lunch-room or cafeteria.

You can be sure of "Statler Service," and that every Statler guest's satisfaction is guaranteed.

Depend upon the experience of thousands of travelers who'll tell you, if you inquire in a Pullman, or a ship's lounge, or wherever travelers congregate, that "you'll be *all right* at a Statler."

Our Point of View

France and the Naval Program

(Continued from page 402)

sions that the 5 : 5 : 3 ratio applied to all classes. Australia, New Zealand, and Canada object as decidedly as we to an increase in Japan's auxiliary craft, but Great Britain is permitting our delegation to do the negotiating with Japan. If Japan proves obdurate, our only recourse will be to refuse to extend the agreement in the Far East in 1931.

Unquestionably both Great Britain and Japan are relying somewhat on our reluctance to spend the money necessary to create a navy, and they have some reason because of the ship-building program from 1921–1929 of the three countries, of cruisers, destroyers, and submarines, as shown in th table on page 402.

Thus since 1921, in the types of naval vessels not limited by the Washington Conference, Great Britain has built practically twice as many cruisers and Japan 40 percent more cruisers than the United States; in destroyers we have built none, while Great Britain has added 38,000 and Japan 74,000 tons. It should be added, however, that in 1921 we had a considerably larger number of modern destroyers than either Japan or Great Britain. In submarines, Japan has built over twice as many as Great Britain and 40 percent more than the United States. For eight years we practically refrained from adding to our fleet, with the result that except in capital ships we have been outbuilt by both Great Britain and Japan. If the Conference succeeds we will have to build to catch up with Great Britain and to regain the 5 : 3 ratio with Japan; if the Conference fails we will have to build still more or expose our commerce to the not over tender mercies of belligerent cruisers when we are neutral, or to the hostile action of enemy cruisers when we are a belligerent. As we go to press it looks as if the action of France would eventually decide the size of our Navy; to such curious results do international agreements lead.

Chemistry in Industry

(Continued from page 397)

M. R. Tern, of Zinnowitz, has lately been developing a process whereby the production of the sulfate is carried out without the use of sulfuric acid, and the process is said to have been successfully tried out on the large scale in Germany, where it has been attracting a good deal of attention.

The production of ammonium sulfate by passing ammonia gas through dilute sulfuric acid is such an old established process that no one but a German chemist would have thought it feasible to revolutionize the process. Dr. Tern's invention brings two gases together to form a shower of crystals, completely eliminating the saturators in which the ammonia gas is bubbled through acid. He produces sulfur dioxide gas by roasting the spent oxide, which is a waste product of the gas plant. Then he passes this gas through an electric arc, oxidizing it to sulfur trioxide. This gas then mixes with ammonia gas in an

ELECTRIC STARTING ON EVINRUDE Elto LOCKWOOD OUTBOARD MOTORS
SIMPLY touch a switch. Instantly your motor whirls . . . . ten times faster than strongest human hands could spin it. Starting is immediate, positive. Start and stop as often as you wish, for the powerful 12 volt battery is automatically recharged. Have spot and running lights — have every boating convenience and luxury at amazingly low prices.

electro-filter and crystalline ammonium sulfate rains down, ready to be put in bags for sale as fertilizer. The amount of current used in the process (which is known as the Tern "Elektrostickstoff" system) is so small that by its use the saving through the elimination of sulfuric acid is sufficient to pay in a short time for the installation of the simple apparatus required. The ammonium sulfate obtained, known as "Elektroammon," is pure white, and contains about 20 percent of nitrogen. Installations having an annual output of 37,000 tons per annum are projected in Germany, where a large plant is already in operation.

Chemicals Do Not Fool Chickens

THE United States Department of Agriculture warns that no known drug or combination of drugs when fed to poultry will increase egg production. It has objected repeatedly to the use of any label on drug preparations for fowls which indicates that the preparations will increase egg production, and will continue actively its action against any preparations appearing in interstate commerce violating the law in this manner.

Enzyme in Bleaching Flour

GIVE us our daily bread and give it to us white, say Mr. and Mrs. American Public; wherefore flour millers, at the insistence of bakers, bleach the flour with chemicals before it goes on the market. This demand for white flour is largely a psychological one, for the carotin in wheat which normally colors it is entirely harmless and the bleached flour is neither purer nor more nutritious.

Until recently all flour-bleaching processes were based on rather potent oxidizing agents. Chemicals such as chlorine gas, nitrogen tri-chloride, nitrogen peroxide, and benzoyl peroxide are the oxidizing agents generally employed by flour millers for bleaching flour. Three of these are used in gaseous form, the fourth being a powder. In addition to their bleaching effect, all these bleaching agents effect an alteration in the baking characteristics (volume, grain, and texture) of the flour so treated. The chemicals effect the desired whitening of the color of the bread, but they also act on the flour protein, which forms the gluten of the dough. It follows that the flour is not only bleached by the bleaching agents but is also more or less modified in its other characteristics. Moderate treatment seems to improve the baking quality of the flour; over-treatment (overbleaching) may have undesirable effects in terms of its adaptability to yeast-bread production.

The latest development in the field of flour bleaching is the utilization of color-removing enzymes. The first compound containing these enzymes in activated form has just been announced under the trade name of "Do-White," a finely-ground, white-colored powder with a pleasing leguminous taste. Do-White is a pure, edible, plant product, containing no added chemical salts. It is partially soluble in water; in a small quantity of water it has a tendency to form a stiff jelly. Its active principle is an enzyme that has the ability to destroy or decolorize the natural, carotinoid pigment of flour. One half to one pound of it will completely

Wall Street Ventures and Adventures

RICHARD D. WYCKOFF'S
New Book Gives Invaluable Advice for All Speculators

Founder of "Magazine of Wall Street" Tells How Livermore Trades at a Profit

Richard D. Wyckoff

NEW YORK, APRIL 18

HOW Livermore reads the tape, avoids "danger spots", judges the merits of a stock, takes profits, decides when trading conditions are favorable—as told personally to the author—are invaluable features of this fascinating picture of the inner workings of Wall Street.

The book also gives inside descriptions of how other great traders—Morgan, Keene, Durant, Rogers, Harriman — have actually formed pools, influenced prices, taken profits; and tells how *everyone* who wishes to speculate can follow the methods of the experts.

Here is the real "low down" on Wall Street, and on the speculative tactics which bring success there, written by a conspicuously successful advisor, broker, and financial publisher. "Filled with practical information of great interest to all traders!" — *Chicago Journal of Commerce.*

Dr. Stemmerman's Great New Book
INTESTINAL MANAGEMENT
Will Bring You Longer and Happier Life

If you seek freedom from the results of constipation, high blood pressure, acidosis, rheumatism, kidney troubles, headaches, nervousness, inability to concentrate, sleeplessness, etc.—if you would be free from the slavery of constant dieting, pill taking and the enema habit, begin thus: Send for our free brochure. It reviews "Intestinal Management" fully, contains three full chapters (to give you an idea of its readability and good sense) viz., "Insomnia," "Is Exercise Worth While?" "Shall We Eat Fruits and Vegetables?" and includes a biographical sketch of its internationally known author, William H. Stemmerman, M. D. (New York University and Bellevue Hospital Medical College).

He tells you, in simple language, how to permanently banish constipation and its serious consequences; how to flush the bowels daily without the use of drugs, minerals, oils or enema. He gives you the fruitful results of 35 years' active experience as a regular medical practitioner and as a specialist in intestinal hygiene.

EVERYONE who values health and longevity should SEND TODAY for this free brochure, to

ARDEN PUBLISHERS

bleach 100 pounds of unbleached flour when added to the ingredients in the dough mixer. Action is very rapid, the dough as it leaves the mixers being already considerably whitened. Bleaching continues throughout the fermentation, until the high heat of the oven during baking kills the enzyme. Like other enzymes, it is more active at high temperatures below its death-point, as in pan-proof, than it is at lower temperatures.

New Plastic Material from Cornstalks

OUT in the "corn belt," chemists have dreamed of converting the useless cornstalks into a useful article of commerce. Indeed, the dreams have been realized to a certain extent by the recent perfection of a process for making wall board from the stalks that were formerly useful only as Hallowe'en decorations. The most obvious use however, namely their conversion into paper, has thwarted the efforts of chemists, mainly because of the difficulty of overcoming the tendency of the pulp to hydrate, a property which seems characteristic of this material.

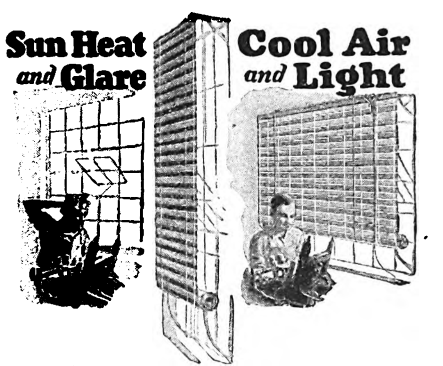
Scientists at Iowa State College finally hit upon the idea of turning this stumbling block into a benefit, and have produced a new material known as "maizolith." This material is somewhat like hard rubber in appearance and properties. It is believed that cornstalks may eventually find their way into the manufacture of insulating material, noiseless gears, and similar products. It has been found rather easy by severe chemical and mechanical treatment to hydrate the cornstalk completely so that the product is a jellylike mass with no vestige of fibrous structure. Maizolith is prepared by drying this jelly and then machining the finished piece into the desired shape.

Russian Chewing Gum Proves to be Rubber

A PLANT having a larval parasite which produces cocoons of a rubber-like substance has been discovered in Soviet Russia, following the search in that country for new sources of rubber, according to information obtained by the Department of Commerce from a Soviet publication. These cocoons have long been known to the local population and are used as a sort of chewing gum, but in the opinion of Soviet investigators they are thought to consist of rubber.

The constant development of the rubber industry in Soviet Russia has involved an increasing expenditure of foreign currency for the purchase of raw materials. Two methods have been suggested to remedy this situation: the manufacture of synthetic rubber and the cultivation of rubber-bearing plants. The Rezinotrest (the Russian rubber trust) has experimented in cultivating guayule shrubs in several of the southern regions of the Soviet Union, but these experiments cannot as yet be pronounced successful. Attempts have been made also to find other plants capable of producing rubber.

In Kazakstan, in the sands of Barkhan, several varieties of Chondrilla are found, which secrete a sort of rubber and which also is used by the Kazaks for chewing gum. This material has been examined by the Supreme Council of National Economy and Rezinotrest chemists, who classify the gum as rubber.



RA-TOX Shades keep out sun-glare and heat but admit from 30% to 40% more light and air than ordinary shades. They reduce room temperature from 10 to 20 degrees—ventilate without drafts—allow for independent operation of center-swing ventilators in steel sash. Made of attractively colored, permanently stained or aluminum finished wood strips woven parallel. They are practically wear-proof and will serve you for twenty years or more. Brackets and fixtures that perfectly adapt this shade to all types of sash have been developed.

Our Choice of Recent Books

New Frontiers of Physics

By Paul R. Heyl, Ph.D., Physicist U. S. Bur. Standards

THIS brilliant thought-provoking work by an outstanding thinker among American physicists fairly boxes the compass in the new physics of the present period. Matter, energy, space, time, non-Euclidean geometry, gravitation, cosmology, relativity, wave atoms, ether, the quantum theory and, finally, the biggest question of all, that of the real ultimate physical basis or nature of the universe—these high points will indicate the scope of this new work. In it physics is shown to be *the* fundamental, basic science of all the other sciences. There have been other books covering nominally the same ground as this one—why, then, one more? All we can say is this: he who reads it will see why. The book has influenced our own point of view more than any work on physics we have ever read, and we regard it so highly that we are rereading it and giving it permanent place on our editorial desk. In scope it is broad; in length medium because concise and to the point; and in depth medium as, it is no "tabloid" for the unintelligent but contains much solid, lean meat, no fat, no padding, and almost no mathematics. $2.15 postpaid

The New World of Physical Discovery

By Floyd L. Darrow

THE fact that the Editorial Committee of the "Scientific Book Club" (a new scientific-book-of-the-month-club composed of five of the "biggest guns" in all American science) has chosen this book, is far from remarkable. Had they passed it up they would have merited boiling in red ink. Darrow, the author, has performed another of his periodic miracles of popularization, the best known previous "miracle" being his "Story of Chemistry" (1927) which in next to no time became a scientific best seller and roundly deserved that distinction. "The New World of Physical Discovery" is just as good as the other book (it couldn't be better). Darrow writes for a wide, not a special, audience, and his books are "comfortable" for the average mortal who wants instruction—yes—but interest also, and now and then some brightness, rather than a headache. The present book (358 pages) covers the whole of physics, both old and new, not merely the new. From it the reader will learn how physical science started; how it grew; what it is today; and *why* it is what it is. Authenticity, instruction, interest, legitimate romance, and again authenticity—these are its earmarks.

$3.70 postpaid

Auditing

By R. H. Montgomery, Prof. Accounting, Columbia
W. J. Graham, Instr. Dept. Commerce, Chicago

TREMENDOUSLY increasing in extent over a few years ago, this subject interests the executive particularly, for without some knowledge of the fundamentals the reports with which he must acquaint himself will not have full significance. Just such information as he will need will be found in the 221 pages of this concise and informative work.

$2.15 postpaid

Merck's Index

Fourth Edition

THIS new edition is most welcome, for there is no more useful reference book for the chemist, pharmacist, and physician. It gives the names and synonyms, source, origin or mode of manufacture of all chemicals and drugs used in chemistry, medicine, and the arts. Chemical formulas, molecular weights, physical characteristics, et cetera, are given in most succinct style No other work of which we know, covers such extended ground. In fact we consider it one of the most valued references in our library. $5.00 postpaid To members of and those affiliated with the chemical, pharmaceutical, medical, and allied professions— $2.50 postpaid

America Conquers Britain

By Ludwell Denny

AN honest appraisal of a developing international crisis that we can no longer ignore. The great economic war we are now waging may bring on the "unthinkable" war, which will be open or a surrender to material superiority. Sane analysis is our only resource and this the author earnestly strives to present. The format is particularly good and appropriate and in a number of ways differs from the usual. Reference notes do not clutter up the pages but are all placed at the end of the volume under serial numbers. A thoughtful, impartial work of power and definiteness. $4.20 postpaid

The North Pole of the Winds

By W. H. Hobbs, Prof. Geology, Univ. Michigan

PROF. HOBBS has led three scientific expeditions to the Arctic under the auspices of the University of Michigan. His findings have proved of the utmost value to meterology. Here is the story of hardy adventure which made possible the first Arctic weather observatory; further extension of such stations will bring to civilization much needed accurate weather reports, for the Atlantic Ocean particularly.

$5.20 postpaid

Principles of Property Insurance

By F. E. Wolfe, Ph.D.

RISK-BEARING organizations in the field of fire and other property insurance and the part they play in modern social economy, are lucidly described in an interesting style, easy to understand, suggesting present tendencies in development which challenge consideration of this fundamentally business institution. $3.20 postpaid

Insect Ways

By Clarence Weed

IN most interesting style is shown what remarkable means the ants, bees, butterflies, grasshoppers, wasps, et cetera, fit themselves for the conditions under which they live, their devices for securing food and providing for their young, their surprising craft in self-protection, and the part they play in human affairs. $2.65 postpaid

The Wright Brothers

Fathers of Flight

By J. R. McMahon

HERE for the first time is the complete story of Wilbur and Orville Wright based on unpublished letters and diaries of the two men and from data obtained from Orville and his family. Strong stress is laid on the personal and human side. An entrancing story ably told. $2.65 postpaid

Sky-High—The Story of Aviation

By Eric Hodgins and F. A. Magoun

GOING back 150 years, the story of man's attempt to conquer the air is detailed with painstaking and exhaustive conclusiveness. Throughout the long list of attempts the groping toward bigger ideas and the fascination of adventure is brought out in this lively chronicle which is lucid and instructive in its scientific detail. Both authors are graduates of M. I. T. and friends of long standing.
$2.65 postpaid

Inventions and Society

By Waldemar Kaempffert, Dir. Rosenwald Museum Science and Industry

NO more inclusively cultural set of books has appeared than the series of "Reading with a Purpose" of which this is Vol. 56. The author is especially qualified both by taste and accomplishment to write on this particular subject, which he does in most entertaining style, weaving in the historical data in readily comprehendible manner. You will read it at a sitting and value it for reference. Further interest titles with outlines are also appended.

The Sea

By H. A. Marmer, U. S. Coast and Geodetic Survey

A POPULAR survey of all that oceanography has discovered about the vast areas covered by the oceans, together with various other correlated matters which ordinarily fall outside the scope of the usual text. The science and the romance of the sea by one who has made it a lifetime study.
$3.20 postpaid

The Great Meadow

By Elizabeth Madox Roberts

SAID by qualified critics to be one of the three eminent novels which have recently appeared. Early Kentucky history is the background and in fidelity to characterization, as well as to event, this enthralling story leaves nothing to be desired. Born and raised in the district which her ancestors settled in 1803, the author preserves the independent and rugged character of the pioneer, while developing the display of the various strains inherent in the individuals. A most excellent book which has been denominated "singing prose." $2.65 postpaid

Phantom Walls

By Sir Oliver Lodge

THAT the soul *does* survive the material body and that there are proofs, this distinguished scientist and scholar of psychic phenomena contends in his most complete statement to date. With that charm of presentation which he has ever maintained even in his expansion of abstruse or indefinite theories, one is compelled to follow on even when unconvinced. This will be a widely read book for it represents most profound thought by a brilliant intellect.
$2.65 postpaid

The Woman of Andros

By Thornton Wilder

IF one could use the denomination "lyric prose" it would seem a fitting characterization for this most exceptional work. Classical in its structure, the theme of life and death is none the less developed with the passionate intensity of the present, in a smooth flowing, absorbing style that fascinates. Much the best of the author's three books.
$2.65 postpaid

Exile

Warwick Deeping

WE anticipate each new book from this author for we know a novel will emerge in its most attractive form. With incomparable style he always has a most human story to tell. This is a fine portrait of a young woman who, in the library of the Italian town of Tindaro, finds employment, experience, and romance. A theme and a setting which is used with characteristic enthusiasm. $2.50 postpaid

Land of the Lion

By Cherry Kearton

FOR twenty-five years the author has roamed Central Africa studying and photographing wild life. Here are presented some of his conclusions based on the facts noted in his various expeditions covering practically all the various animals commonly found. It might well be called an animal lover's note-book. $3.70 postpaid

Commercial Property News

Facts and Notes of Interest to Inventors, Patentees, and Owners of Trademark Rights

American Corporations in Mexico

THE Supreme Court of Mexico has recently decided in a suit instituted by The Palmolive Company against an infringer of its trademark registrations in Mexico, that a foreign corporation, whether it be doing business in Mexico or not, is precluded from bringing suit in the Mexican Courts unless and until it is registered in the Commercial Registry. Such registration might be rather expensive, the fee depending largely on the amount of the capital of the corporation; thus, a corporation capitalized for 100,000 dollars would be required to pay from approximately 1000 to 1500 dollars for recording and legal fees. The registration referred to is not the registration of trademarks in Mexico but the registration of the corporation as doing business in Mexico.

The suit by The Palmolive Company was on its trademark, which had been duly registered in Mexico; actual infringement had been established but nevertheless the Supreme Court held that the plaintiff corporation has no standing in the Mexican Courts, because not being registered as doing business in Mexico, it has no existence in Mexico. This decision unless modified will have a far-reaching effect on the rights of American corporations in connection with their trademarks and other industrial property in Mexico. Although clearly erroneous, it will nevertheless be the law of Mexico unless it shall be set aside. The Department of Commerce has already laid the matter before our State Department.

Such a condition of affairs should not be permitted to continue. The Courts of every land should be open to afford complete relief to the owner of a registered trademark, and to prevent infringement thereof and imposition on the purchasing public by the substitution of the infringer's merchandise for that of the owner of the trademark.

Patents and Taxes

A RECENT decision of the Court of Claims in the matter of the claim of the Westclox Company for recovery of excess taxes paid by that company, reported in the *United States Daily* of February 6, 1930, is of considerable interest, not alone in showing that in computing income-and-profits taxes due consideration must be given to the advantages accruing to an industry because of patent protection, but also as outlining a rule for estimating the value of the savings resulting from the employment of the patented invention as compared with other processes and machines employed by competitors in the same line of business.

The patents covered a machine for automatically producing pinions and wheels, and also other patents for the design of the clocks manufactured by the claimant. Using as a basis the cost of producing ten thousand such wheels by the patented machine as compared with the machines and processes in use by others, the Court finally estimates the savings attributable to the patents; this is multiplied by the remaining life of the patents, in order to estimate the deduction which should have been made by the tax payer before computing the amount of its income-and-profits taxes.

In addition to the patents which were discussed, the value of the trademarks under which the clocks were sold was considered, and on the whole case as presented, the Court ordered that the parties compute the amount of the recovery and come to some stipulation with regard thereto.

This was a case where the patented inventions were not manufactured and sold, but offered protection only for the exclusive use of the machines employed in producing certain parts of the clocks. This is true, of course, excepting as to the Design Patents which covered the ornamental appearance of the clocks themselves.

If the protection of the exclusive right to use a certain machine, as compared with what one's competitor is compelled to use, is of so much value, it must follow that the exclusive patent protection for something that is manufactured and sold is of far more value. The theory on which the claim was allowed was that these protective patents were gradually expiring and that in time they would no longer be a source of profit to the owner, as upon their expiration the subject-matter thereof would be free to competitors.

Agreements Voided for Pooling Patents

THE United States District Court for the Northern District of Illinois has entered a decree in the so-called "oil-cracking case" by which agreements between several oil companies for pooling certain patents have been declared void. The case, as reported by the *United States Daily*, concerns agreements made between the Standard Oil Company of Indiana, the Texas Company, the Standard Oil Company of New Jersey, the Gasoline Products Company, *et al.* The patents involved covered processes and apparatus for producing gasoline by "cracking" petroleum. The agreements dealt with royalties for the use of such processes, as well as with the various patents. The suit was brought by the United States against the oil companies for alleged violation of the Sherman Antitrust Law.

In addition to holding the agreements null and void, the court said: "It is further ordered, adjudged, and decreed that the primary defendants and the secondary defendants and each and all of their respective officers, directors, agents, servants, and employees, and all persons acting or claiming to act on behalf of them, or any of them, be, and they are perpetually enjoined and restrained from further executing and performing said agreements.

"It is further ordered, adjudged, and decreed that jurisdiction of this cause be retained by this court for the purpose of carrying out the terms of this decree."

Junior Applicant Wins Stoker Patent

RULING that the patent application of Chauncey L. C. Magee, covering certain improvements in mechanical stokers or grates, was filed after the invention had been disclosed to Magee by John C. Heavey, the Court of Customs and Patent Appeals has sustained the latter's claims. This decision confirms the opinion of the Commissioner of Patents, which had affirmed the decision of the examiners-in-chief, which in turn affirmed the decision of the examiner of interferences. All of the tribunals found that the junior party had disclosed the invention to the senior party, who had then filed application for a patent covering the device.

The appellant contended that the invention had originated with him, that the testimony of the junior applicant had failed to establish disclosure of the invention to him, and that the junior applicant's testimony had failed to overcome the prior record date of the Magee application. The courts, after investigating the facts involved, decided that Heavey had invented the device in question and had persuaded the manager of a large building in Chicago to have the apparatus installed by Magee, who was engaged in such work. It was disclosed that Magee had sent one of his draftsmen to Heavey to obtain the details of the apparatus. The equipment was made and installed, and Magee filed application for patent on the apparatus soon thereafter. Heavey filed application for patent some six months later, with the result that the Patent Office declared an interference to determine which of the claimants deserved the patent.

The invention relates to certain improvements in stokers or grates for furnaces of the type in which the grate bars travel through the furnace, supporting the fuel. The fuel is consumed as the grate moves. The particular improvement claimed consists of certain provisions for dividing the area of the moving grates into zones or sections for the purpose of supplying air upwardly through the different sections of the moving grate. This arrangement enables the air to be cut off from one section or zone and to be supplied to another by means of sliding dampers.

Court Finds Copyrighted Maps Were Copied

BECAUSE the maker of a composite map entitled, "Cleartype Road Map, Featuring Main Travel Routes within the Greater Metropolitan Area," had reproduced many errors, misspellings, and other peculiarities of certain maps copyrighted by the General Drafting Company, Inc., the District Court for the Southern District of New York ruled the defendant guilty of infringement. The case in suit was General Drafting Company, Inc., *versus* Lews H. Andrews, *et al.*

After pointing out that automobile road maps similar to those in suit are clearly the subject of copyright, the court appraised the method by which the maps had been prepared. It was found that the plaintiff had gone to considerable trouble and expense to prepare its maps, and had shown a noteworthy amount of originality in their preparation. The elements of the copyright consist, according to the court, in the selection, arrangement, and presentation of the component parts. The plaintiff's maps are sold in great numbers to the highway departments of several states, and to a number of the larger oil companies, for distribution to motorists.

The court ruled that if the defendant's map had been constructed after an independent investigation of the original sources in the public domain, without copying, the plaintiff would have no complaint. It was found, however, that the differences between the defendant's composite map and the several maps of the plaintiff were superficial. The defendant rested its case on the testimony of one Tudor, who described the manner in which he made the composite map. The testimony of this witness was shown to be of doubtful credibility, upon cross examination.

The case of the plaintiff was based upon the *prima facie* evidence showing the similarity, in unimportant and almost minute details, between the maps. Some 20 common misspellings were introduced, as well as 17 common errors in population symbols, the inadvertent misplacing of part of a river, arbitrary endings for roads at points actually not their endings, and the meanderings of highways, which in maps of this type are rather freely drawn. The court ruled that the defendant should pay damages and attorney's fees.

"Back of the Brawn, the Brain"

FROM a recent article in the *Journal of the Royal Society of Arts* (London), we are reprinting a tribute in verse to the world's inventors, and all those who design, build, and operate machinery.

"Back of the motors humming,
Back of the belts that sing,
Back of the hammers drumming,
Back of the cranes that swing,

"There is an eye which scans them,
Watching through stress and strain,
There is the Mind which plans them,
Back of the Brawn, the Brain."
—Berton Braley.

Wood Preservative Process Patented

ALTHOUGH the use of oil and sugar in treating wood is not new, patent has been awarded to George Elton Rice (Number 1732420) for a process of treating wood with oil and sugar which involves a function not present in the prior art and eliminates one step from the prior art processes. This decision of the Board of Appeals of the Patent Office, *ex parte* George Elton Rice, held that the examiner improperly rejected claims in an application for patent, because none of the references cited anticipate the process claims which cover the dehydrating as well as the impregnating of wood by treatment with a solution which contains oil and sugar.

Although it is old to preserve wood by impregnating it with preservatives carried in oil, and it is also old to preserve it by impregnating it with sugar in aqueous solution, the applicant had substituted oil for water with sugar and in so doing eliminated the necessity of drying the wood either before or after the impregnation process. This process involves more than the mere substitution of one preservative for another, in view of the fact that the drying process or step is eliminated. In the absence of any showing by the examiner that the result urged by the appellant is old or obvious, the claims were considered valid and allowable.

Patent Holder Must Give Notice of Alleged Infringement

THE owner of a patented article must give notice of his right therein, either to the public by marking his article "patented" or to the particular defendant by informing him of its infringement. Unless this is done, according to the District Court for the Western District of Pennsylvania in General Electric Company *versus* George J. Hagan Company, the owner of the patent may not obtain an accounting for damages and profits, even though the infringer had knowledge of the patent for several years and had built the devices for a time under a license.

The suit was tried on submission of decree for profits and damages for infringement of claims 7 to 11 of patent Number 1310060 to Collins for an electric resistance furnace. The court found that the defendant had knowledge of plaintiff's patent in 1919. Under an oral license from the plaintiff, the defendant built furnaces from 1919 to 1923, then conducted negotiations about a renewal license. It was found that at no time did the plaintiff comply with the statutory provisions of notice to the public by marking, and at no time did the plaintiff either verbally or in writing notify the defendant that it was infringing the patent in suit. It was held, therefore, that the plaintiff was not entitled to an accounting for profits and damages.

Section 4900 of the Revised Statutes, title 35, section 49, reads: "Patented articles marked as such; notice of infringement.—It shall be the duty of all patentees, and their assigns and legal representatives, and of all persons making or vending any patented article for or under them, to give sufficient notice to the public that the same is patented; either by fixing thereon the word "patented," together with the day and year the patent was granted; or when, from the character of the article, this can not be done, by fixing to it, or to the package wherein one or more of them is inclosed, a label containing the like notice; and in any suit for infringement, by the party failing so to mark, no damages shall be recovered by the plaintiff, except on proof that the defendant was duly notified of the infringement, and continued, after such notice, to make, use, or vend the article so patented."

Pertaining to Aeronautics

AIRPLANE WING—The surface of which is made in a plurality of sections arranged in stepped relation affording air passages between the sections which, incident to the velocity of the plane, creates a maximum vacuum over the entire wing surface. Patent 1746140. Jarrot Bobo.

AEROPLANE STEERING MECHANISM—A combined steering mechanism and joy stick whereby an aeroplane may be controlled in flight in the usual manner or steered on the ground, and manually operable means for locking the wheels in landing position. Patent 1747344. Harry S. Bell.

AEROPLANE—Having a water tight fuselage, and equipped with a parachute and means for releasing the forepart of the plane from the fuselage so that the latter will be permitted to slowly descend in case of trouble. Patent 1748811. Charles C. Warren.

PONTOON FOR AIRPLANES—Providing means whereby an airplane may be used as a hydroplane, the pontoons being equipped with retractable wheels, which may be drawn for travel on the ground surface, thus combining several body units in one assembly. Patent 1747563. Joseph G. Yonkese.

CONTROL MECHANISM FOR AIRCRAFT—Whereby a slight movement of the joy stick will enable the pilot to handle and control the elevators, rudders and ailerons of a large passenger carrying plane as easily as a small scout machine. Patent 1747564. Joseph G. Yonkese.

EMPENNAGE STRUCTURE FOR AIRCRAFT—More particularly adapted for large double bodied aircraft, wherein means is provided for guiding the craft when rising or alighting, the operating mechanism being particularly strong, and enclosed in such manner as to present a smooth stream-line box-tail construction. Patent 1747565. Joseph G. Yonkese.

Pertaining to Apparel

HEEL GRIP—Of resilient material, shaped to the contour of the heel so that in its movement it will cause the boot or shoe to move almost as if it formed an integral part of the foot. Patent 1745726. Chester R. Snow.

Chemical Processes

PROCESS OF MAKING FUEL MIXTURES—Which comprises passing acetylene gas through pentane, whereby the acetylene gas will act as a vehicle for carrying predetermined quantities of the pentane, and so modify the mixture that the flame will give off no carbon monoxide. Patent 1746172. Paul E. and Frank A. Webb.

Process for Retting Textile Fibers—Consisting in agitating raw fibers from flax, or other vascular fibers, for about fifteen minutes in water and nitrogen fixing bacteria at 100 degrees Fahrenheit, letting the fibers remain immersed for three hours, draining, and drying the fibers. Patent 1746316. Morris Marcus.

Designs

Design for a Key Tag—Patent 80435. Benjamin C. Da Shiell.

Design for a Doll Head or Similar Article—Patent 80481. Adolph Gramlich.

Design for a Goblet—Patent 80512. George Dougherty.

Design for a Toy Soldier—Patent 80531. Peter J. Hemmer.

Design for Dish or Similar Article—The inventor has been granted four patents for ornamental designs of a similar nature. Patents 80520, 80521, 80522 and 80523. William P. Graham.

Design for a Dress—Patent 80574. Dorothy Long.

Design for a Coaster—Patent 80591. Albert S. Valchek.

Electrical Devices

Dynamic Radio Receiver and Amplifier—A transformer especially adapted for radio, providing a simple and efficient receiving circuit in conjunction with an amplifier which does away with the use of a battery and vacuum tubes and gives greater amplification. Patent 1747137. George Wald.

Electrostatic Loud-Speaker—Wherein a soft ductile membrane co-operates with a rigid perforated metallic plate, the perforations being parabolic so that even with large amplitude vibrations the electrostatic forces upon the membrane remain proportional to the applied electrical amplitudes. Patent 1747952. Eugen Reisz.

Membrane for Electrostatic Loud-Speaker—A process for manufacturing a metallic coated insulating membrane which includes the step of sticking metallic foil coating upon the rubber or other insulating membrane by means of a vegetable or castor oil. Patent 1748901. Eugen Reisz.

Of Interest to Farmers

Cultivator Attachment—Having a plurality of rotatable earth working elements which may be simultaneously adjusted to various angles with respect to the path of travel, particularly adapted for side hill cultivation. Patent 1747058. Daniel W. Duellman.

Cultivator—Having an angularly disposed wing at the side, by means of which grass and other vegetation may be uprooted from the ground in close proximity to the roots of growing plants, while the row is being cultivated. Patent 1747059. George F. Dugger.

Stock Muzzle—Having means whereby the size of the central feeding opening may be quickly adjusted to permit the animal to bite off more or less grass, according to the height, and thus prevent dangerous bloating. Patent 1748027. Chris M. Rasmussen.

Of General Interest

Jeweler's Tag—Of bendable material, which may be easily connected with an article of jewelery, and if desired easily removed for use on another article, a button structure securing the tag in folded position. Patent 1742982. Charles T. Wittstein.

Road and Street Construction—In which the road base is covered with bituminous rock, or a mixture of bituminous rock and clean hard stone, forming a levelling course, after which the wearing surface is formed of ground bituminus rock rolled cold. Patent 1747125. Guy F. Murphy.

Structural Form for Concrete Work—A metal form framing and retaining unit of general application and use in the building of walls, stairs, columns and the like, wherein the form serves as molds within which the concrete is poured and held until set. Patent 1747036. John H. Sullivan.

Refrigerating System — Particularly adapted for cooling syrup cans in soda fountains, the cooling mechanism taking up a minimum space, high pressure in one refrigerant being utilized to force the liquid through an additional cooling line to other containers. Patent 1746896. Franklin B. Hunt.

Card Holder—Which may be permanently fixed to a trunk, box or package, in such a manner that a card may be inserted or removed at will, a holding means retaining the card against accidental displacement. Patent 1747077. Irwin M. Ikelheimer.

Ice-Cream Holder—Which can be conveniently handled without soiling the hands from the melting cream, and which will be edible constituting in effect an ice-cream sandwich having a handle for holding the same. Patent 1747112. Warren E. Good.

Hand Protector—A covering guard particularly designed as a shield for the hand when manipulating a spoon in basting meat, or a fork or other culinary implement in the presence of hot grease or steam. Patent 1747097. Alvah D. Young.

Rack for Piece Goods—Especially designed for holding bolts of cloth or goods on shelving in the aisles of stores so that the goods may be conveniently displayed to prospective customers, thereby reducing to a minimum the handling of the goods. Patent 1747026. William W. Phillips.

Collapsible Case—Simulating the commonly known suit case, having a plurality of sections which enable the case to be enlarged or contracted, operating with equal facility at any adjustment, the handle being positioned according to the weight within the case. Patent 1748024. William W. Machemer

Combined Soap Holder and Massaging Device—Functioning as a soap cup of sponge rubber, having in addition one face with projections and the other face formed as a receptacle for soap with a pair of spaced handles permitting a secure grip for massaging. Patent 1748008. Harry Barnowitz.

Curtain and Shade Guard—In the form of a rod and brackets whereby curtains and shades may be kept from being soiled by the action of rain and dirt, and to tearing action on being blown outside of the room. Patent 1746269. Henry W. and Margaret Lupton.

Vacuum Cleaner Attachment—Whereby one of the two hooks, usually attached to the handle for holding the electric cord when not extended in use, may be swingable, so that the cord may be instantly released without unwinding Patent 1746246. Frederick W. Elworthy.

Tie Wire and Spreader—An elongated member having eyelets which may be secured to forms for concrete, and the like, at a number of points, thereby strengthening the connections between the inside form and the outside form. Patent 1746298. Charles M. Ally.

Plant Protector—For protecting young plants against destructive insect and worm life, as well as against injurious cold weather or frost, designed to hold more moisture in the soil about the roots that is usually possible. Patent 1747967. Robert B. Bell.

Expansion Plug for Pipes—Having an expansion head adapted to effect a closure of the pipe, and in which ample clearance, irrespective of elbow bends, is provided for the operation involved in expanding the head. Patent 1747933. Patrick Goodman and Beni Leone.

Fire Hose—Characterized by properties of high resistance, reinforced against permanent creasing which results in rapid deterioration and cracking, and reinforced against wear while being drawn over the ground or conveyed within the hose wagon. Patent 1747584. Russell P. Howard.

Juice Extractor—Embodying a cutter for dividing the fruit and a receptacle in which the extracted juice and pulp of oranges, lemons or limes is collected, and the juice strained from the pulp before being discharged. Patent 1747641. Robert C. Morris.

Vacuum Cleaner—Including a wheeled carriage constituting a solid base for electric motor and blower, is relatively small and compact, can be conveniently carried from place to place or may be readily stored within the carriage. Patent 1748853. Etta M. Squires.

Hardware and Tools

Pivot-Straightening Device—Particularly adapted for straightening the balance staff pivots and train pivots of watches, a tool with which accurate temperatures are assured, and which may be manipulated with the thumb and fingers without burning the hand. Patent 1747136. George F. Putnam.

Can Opener—Comprising a pair of handles, a cutter and a can-moving wheel, the cutter being riveted at two points will not work loose, and the movement of the can-moving wheel away from the cutter is limited. Patent 1744573. Axel W. Peterson.

Bed-Rail Connecter—So constructed as to render the side bed rails reversible to accommodate flat bed springs or coil or box bed springs, each being supported at the same level on the bed frame. Patent 1745653. Adolf Weston.

Trunk Lock—Comprising threaded means adapted to be secured to the trunk body in spanning relation to its door opening, for providing a fluid tight joint between the closure and the truck body and effectively lock the closure. Patent 1745422. Charles Hinde.

Vise—A portable tool with means for attachment to a bench, a pair of jaws of the screw adjustable type to function as a wrench when detached from its support, thereby being usable under varying conditions. Patent 1748886. Abelardo Linares.

Screw Adjustable Mechanism—A combination tool, combining a wrench structure with a support for its fixed jaw, and a hanger or jacking element for its movable jaw, to form a jack, the parts being separable for storage or shipment. Patent 1748888. Abelardo Linares.

Intermittent-Grip Device—A rotatable element having a ratchet wheel thereon, and a detachably mounted handle and co-operating pawl element, said member being demountable for convenience in storage or shipment, and being reversible for effecting reverse rotation. Patent 1748887. Abelardo Linares.

Heating and Lighting

Grate—Wherein a maximum natural draught will keep the interchangeable grate elements in a cool state, the construction being such as to give a maximum life to the grate, and a more perfect combustion to the fuel. Patent 1746126. Morton K. Moore.

Apparatus for Making Illuminating and Heating Gas—In which compressed air is forced through gasoline or oil, whereby a combustible gas is produced and stored in confined space, before being conducted to the burners or any form of motor power operated by gas. Patent 1747094. John Whikehart.

Machines and Mechanical Devices

Slip Flask—For molds, wherein the alignment and holding of the cope in proper position on the drag receives special attention, the planks of the flask being so clamped and reinforced as to prolong their period of usefulness. Patent 1746146. Adam Diehl.

Snowplow—Of the type adapted for use with tractors, whereby the necessary parts may be controlled by the operator from his seat, effective means being provided for gathering and delivering snow on either or both sides. Patent 1746167. Richard Robertson.

Cotton-Feeder Mechanism—For cotton cleaners, burr extractors, boll breakers, etc., which is entirely automatic, the speed of the feed being regulated with extreme accuracy by the pressure of the cotton in the roll box. Patent 1746135. Jackson L. Walker.

Paint Stirring and Mixing Device—Including a rotary blade and manipulating crank, adapted to be attached to a paint can for facilitating the stirring and remixing of the liquid and solid ingredients, after they have settled in the container. Patent 1747032. Frederick Schlageter and Fabian Maletsky.

Mechanism for Cutting and Facilitating the Removal of Material from Machines—A machine for manufacturing noodles, which insures the separation and cutting of the noodles into uniform quantities, thus obviating the necessity of weighing, means being provided for their removal without physical contact, whereby sanitation is insured. Patent 1747075. Joseph Horowitz.

Ball-and Socket Joint—Which is simple in construction, easy to assemble and effective in operation, and is particularly useful in lubricating systems in lieu of flexible tubing. Patent 1745755. Coy C. Goodrich.

Glass-Gob Cutter—Adapted to be positioned near the outflow of glass from a melting tank, for cutting the glass gobs, at right or various angles by a liquid or gaseous substance, without leaving any visable mark. Patent 1747087. Charles H. Schlalz.

Surfacing Machine—For finishing the interior of manhole casings, a portable machine which is rotatably supported on the work, and incident to its rotation about the same, automatically feeds a cutting element evenly over the entire surface. Patent 1747944. Charles H. Lyne.

Wave Motor—Which is characterized by its responsiveness to record every impulse of the water due to wave motion, roll, weight of water and undertow, and to convert such impulses into power to perform useful work. Patent 1746613. Chester E. Shuler.

Developing Rack—A manually rotatable disk support, whereon photographic films may be detachably held without contacting with each other, and may be passed through the developing, washing, fixing, and washing processes, and eventually dried by centrifugal action. Patent 1747930. Irving L. Cook.

Harness-Tape-Selvage Motion for Looms—A salvage harness so constructed that it may be used with the heddles used in connection with the usual harness, reducing wear of the parts to a minimum, and is readily removable for retying warps. Patent 1748001. Edward P. Taft, Payton L. Videtto, and James A. Gaddy.

Automatic Control for Well-Flowing Devices—Wherein no delicate springs or other unsubstantial elements are used to urge the plunger or valve element to an open position or to resist its action in closing, the action being governed by the velocity of the liquid column, is therefore positive in operation. The inventor has been granted three patents of a simular nature, Nos. 1747570, 1747571 and 1747572. Alexander Boynton.

Current Motor—Particularly adapted for use in bodies of flowing water, such as rivers or streams, is capable of being adjusted with respect to the direction of the water, whereby the power of the flow may be utilized. Patent 1745356. William H. Crofton.

Valve Mechanism—For air compressors, functioning as either an inlet or outlet valve means, comprising a cup shaped element having an axially disposed duct there through and a flat annular valve seat surrounding the inner end of the duct. Patent 1746612. Elmer F. Seager.

Gas-Orifice Meter-Chart Calculating Machine—By which the pressure and differential curves of such charts are employed as indices for the production of a computation of the quantity of fuel that has passed through an orifice during any determined period. Patent 1748783. John B. McGaughy.

Graduated Magnetic Control of Brakes or Clutches—A brake mechanism having means for controlling the same, whereby the brake may be either gradually or quickly applied and held at any degree of application, by combined electromagnetic and fluid operated means. Patent 1748773. Frank L. Johnston.

Margin-Adjusting Device for Writing Machines—Adapted for open front paper carriage machines, whereby the margin may be set and fixed by displacing the carriage as a whole, or may be locked on the carriage or left free to slide. Patent 1748896. Camillo Olivetti.

Apparatus for Applying Soft-Metal Linings to Hard-Metal Tubes—Which facilitates the application of soft metal, such as lead, to hard metal tubes, the lining operation being continuous, and the lining uniform, without necessitating subsequent finishing operations. Patent 1748851. Warren R. Smith.

Dish-Washing Machine—By means of which dishes of various sizes, as well as table silver, may be washed and rinsed thoroughly and rapidly, the soiled dishes being continuously fed to the machine. Patent 1748530. Aurelio R. Torres.

Musical Devices

Piano—Wherein the percussion strokes of the hammers are automatically shortened or lengthened correspondingly with the actuation of the soft pedal control, and a greater range of volume and tone is obtained, with precision not heretofore possible. Patent 1748777. Bernhard F. Laukandt.

Plumbing and Fittings

Faucet Fitting—Comprising a pipe divided interiorly into passages, and outlet ports for separately conducting hot and cold water to a single nozzle, the valve seats are readily accessible for replacement when necessary. Patent 1747640. George J. Morris.

Prime Movers and Their Accessories

Safety Device for Liquid-Supply Lines—Adapted for use in preventing failure of a supply of fuel for internal combustion engines, in the event of a break or other source of leakage in the supply line, particularly adapted for air craft. Patent 1746095. Frank E. Tugwell.

Valve Construction—Which has means for receiving the general formation of carbon and directing the same so that it will not interfere with the valve operation, the contacting portions being out of the path of the exhaust gases may be lubricated. Patent 1746927. Carl F. Burgmann.

Railways and their Accessories

Railroad Tie—A tie structure in which both sections are identical, whereby any two sections may be properly mated, eliminating the number of operations required for the production of a complete tie, thereby effecting economy in labor. Patent 1747054. George B. Cox.

Wheel-Flange Lubricator—Using grease in stick form for lubricating the flanges of railway cars, locomotives, street cars or other vehicles running on rails, whereby the lubricant will be constantly applied, and the stick easily replenished. Patent 1748028. Lester J. Rickard.

Hinged Top for Box Cars—By means of which the entire top of the car may be opened, permitting the use of cranes, instead of human effort, for unloading, resulting in cheaper handling, the construction forms an entirely watertight closure. Patent 1747423. Blair B. Campbell.

Pertaining to Recreation

Toy—A combat device in the form of two boxers or fencers, the arms of the figures being manually operable to deliver or parry blows, and to automatically become inoperative when the target portion of the body has been struck. Patent 1745434. John F. McIntosh.

Swimming Appliance—In the form of a glove with rubber webbing, or the like between the fingers and thumb, as an aid in swimming, and to increase the effectiveness of the propelling stroke. Patent 1748317. Thomas B. Sykes.

Pertaining to Vehicles

Visor for Motor Vehicles—Having a window and a shutter, and means within reach of the driver for regulating the vision area of the window whereby an unobstructed view of elevated traffic signals may be had. Patent 1745197. Joseph E. Tirpak.

Cylinder Grinder—Which may be secured to the engine block, and has means for automatically centering the mechanism within the cylinder for grinding automobile motor cylinders, without removing the motor from the chassis. Patent 1745015. John Johnson.

Brake Equalizing and Operating Mechanism—For vehicles, comprising a plurality of brake actuating members and a wedge-shaped member contacting therewith, the wedge-shaped member having a slight rotative motion and means for imparting endwise motion for operating the brake members. Patent 1744643. Nicholas A. Kristmann.

Method of Making Tires—A built up tread portion for pneumatic tires comprising a central section of annular fabric rings and alternate annular rubber tread webs, their edges forming a wearing surface which will prevent lateral slipping. Patent 1744025. Virgil C. Anderson.

Oil-Gauge-Rod Wiper—For use in connection with cleaning automobile gauge rods, before use in testing the amount of oil in a crank case, whereby the wiping may be accomplished by a single stroke, without the operator handling the wiper. Patent 1747100. Alton W. Ashworth.

Foot Control for Motor Cars—Adjustable to a given point in a range of settings for the throttle valve of the carburetor, and when adjusted may be left at that point so that the speed of the car will be substantially held. Patent 1747083. Henry J. Ries.

Blow-Off Gauge—Adapted to be applied to the valve stem of an inflated tire for allowing only a predetermined amount of air under pressure to pass the valve stem, having a novel means for forming an air-tight connection. Patent 1746923. Esten B. Beeler.

Water Gauge for Automobile Radiators—Having a supportng plate and a floating member with signs indicating the water level, the entire formation covering only a part of the radiator opening, thereby permitting water to be inserted while the gauge is in use. Patent 1747022. Albrecht zur Nieden.

Collapsible Wheel Chuck—A block which will be strong, yet can be carried in a relatively small space, opened and placed in operative position under and at the rear of a wheel, to prevent any possible movement of the wheel. Patent 1746415. Joseph A. Burkart.

Three-Wheel Vehicle Chassis—Having means for moving the front wheel slightly to one side when turning to carry the weight directly to the ball bearings removing the strain from the chassis and preventing the device from turning over. Patent 1747526. Ernest L. Pearson.

Antiglare Device—Which is applicable to automobiles of the closed or open type, and when in applied position may be adjusted to effectively intercept glare producing lights, yet permit an unobstructed vision of the roadway. Patent 1745695. William O. Hunter.

Rumble-Seat Top—Wherein a top and sides are provided and so arranged that the top may be used alone or in connection with the sides, thereby providing a complete enclosure, the cover is removably connected. Patent 1748031. Julius N. Wiener and Henry Aretsky.

Bus Seat Switch—A double deck bus, wherein the operator may act as driver and conductor, all passengers being compelled to pass him in entering and leaving, and a signalling device indicating the vacant seats on the upper deck. Patent 1747960. Charles Weiss.

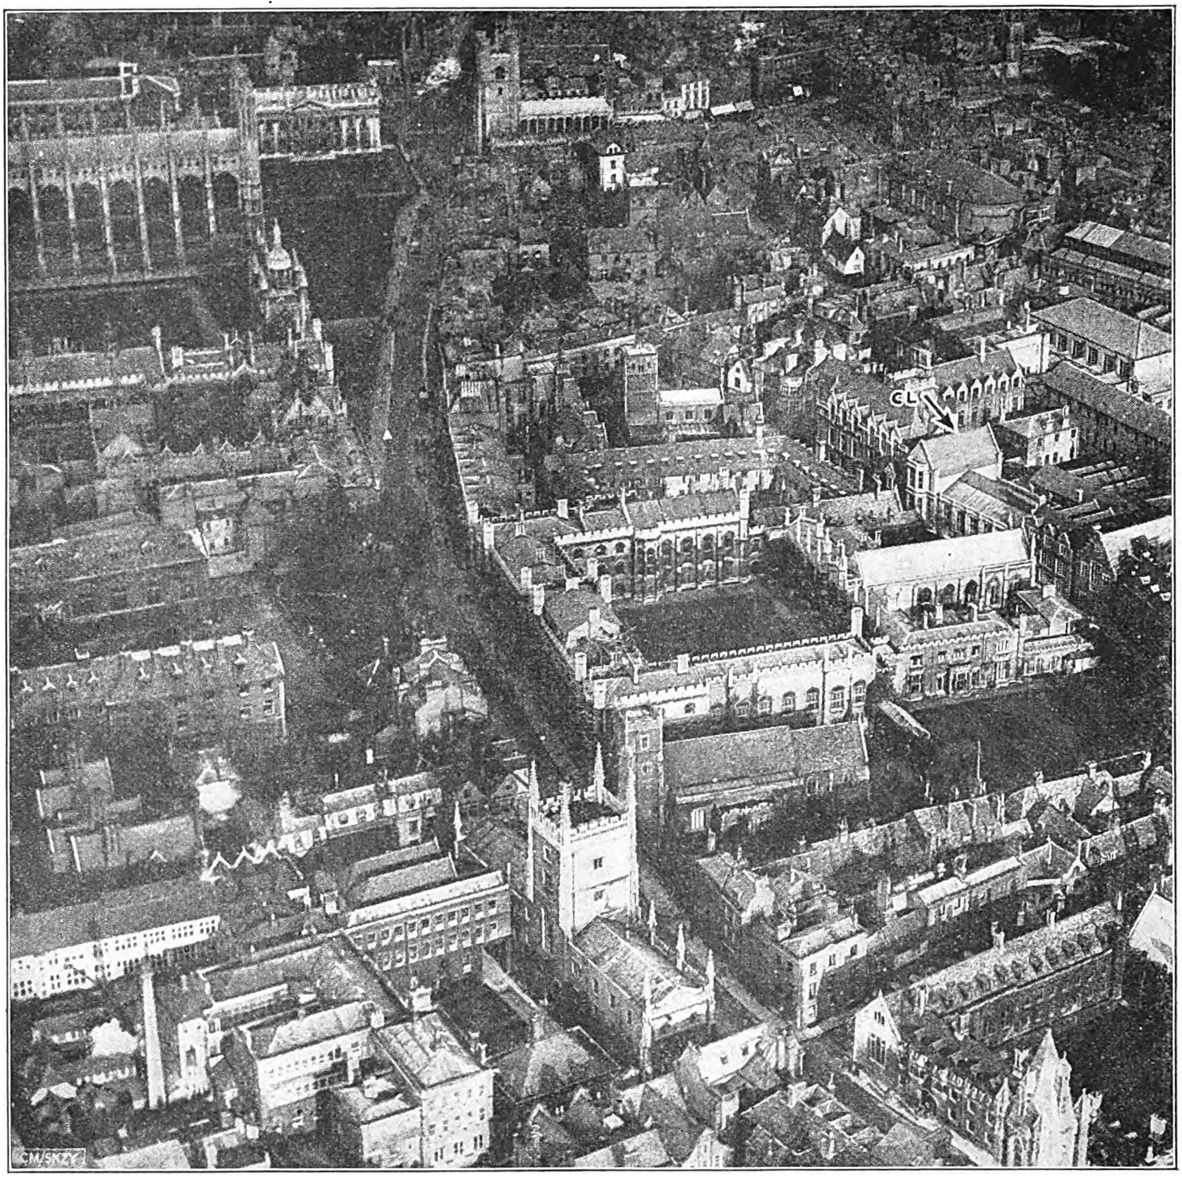
Sir Ernest Rutherford

SIR ERNEST RUTHERFORD was born and reared a New Zealander; he was professor of physics at McGill University in Canada for nine years; and in 1919 he succeeded Sir J. J. Thomson as Director of the Cavendish Physical Laboratory at Cambridge in England. His fame is founded mainly on his basic researches in radioactivity; the new student of that domain of physics may scarce turn a page without encountering his name, linked in many cases with those of Soddy, C. T. R. Wilson, and others who about two decades ago were pioneering in work which has since been seen to be of the utmost significance in physics. His is the discovery, for example, of the alpha rays or alpha particles. Honors too numerous to mention have been heaped upon him—degrees from European and American universities, and coveted medals, including the Franklin Medal of the Franklin Institute in Philadelphia. At present he is President of the Royal Society (properly The Royal Society of London for the Improvement of Natural Knowledge), the highest honor at the disposal of British science.



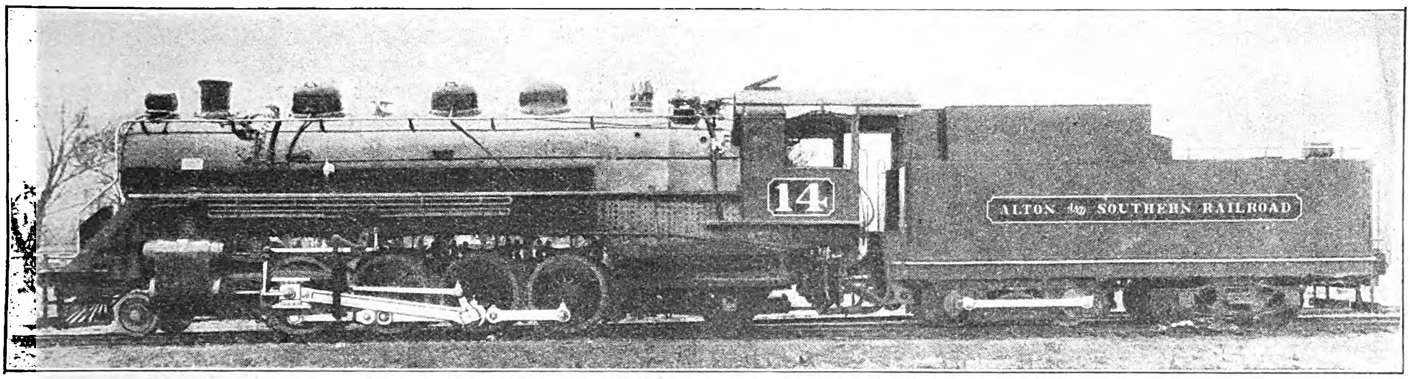
Great Britain's Foremost Physical Laboratory

In the April number, on this page, we presented a photograph of Ryerson Laboratory at the University of Chicago, which was there characterized as "America's foremost physical laboratory." Now is shown a picture of a part of Cambridge University in England, including the famous Cavendish Laboratory of Physics (marked "CL" on the picture) which men of science regard as Great Britain's foremost physical laboratory.

Cambridge University as a whole is British headquarters for science, and has been so for centuries. It was here that Newton, profoundest intellect of the ages, performed his classic experiments on light and gravitation; and that Darwin, whose concepts of general evolution have had stronger impact on thought than those of any modern human being, obtained his education. Jeffreys the geophysicist, and Eddington the widely know astrophysicist, are Cambridge professors.

Cavendish Laboratory of Physics was organized by the great physicist Clerk Maxwell.

Just as, in Chicago, the Ryerson Laboratory's achievements have mainly been derived from Michelson's inspired leadership, so those made at Cavendish Laboratory have been the resultant largely of the personality of its former director and leading spirit, Sir J. J. Thomson, discoverer of the electron. Among Thomson's students now risen to eminence in physics are Sir Ernest Rutherford, the present Director of the Laboratory, Sir William Bragg, Charles G. Barkla, C. T. R. Wilson, F. W. Aston, and O. W. Richardson. "This," as Professor Arthur H. Compton, of Ryerson Laboratory, puts it, "is the largest group of Nobel Prize men that can be boasted by any laboratory. Under Sir Ernest Rutherford it continues to carry on with increasing vigor the work which Thomson started. To this laboratory can go the credit for having established the existence of both the electron and the proton, largely through the work of J. J. Thomson and Rutherford."



LOCOMOTIVE PARTS OF STRONG ALUMINUM ALLOYS

Aluminum alloys are now being used on some railroads in place of steel for cross-head assemblies, valve motion parts, main rods, and side rods. Aluminum is used to improve the general balance, to increase the boiler power, and to obtain the required durability

Aluminum and Its 'Hard-Boiled' Alloys

How a Chemical Curiosity Became a 225,000,000-Pound Industry in Forty-Three Years

By ALBERT A. HOPKINS

INVENTIONS are not all made in woodsheds, although it seems rather a logical place for a shop. Given a shop and an inquisitive mind, who knows what may happen? There is, however, one woodshed which Mr. Ford will never have for his Dearborn collection, although he uses large quantities of the product that was born there. Unfortunately, this particular woodshed in Oberlin, Ohio, will also never be marked by a tablet, as it has been removed, but there is one on the house which adjoined it that reads: "In This House Charles Martin Hall Discovered the Electrolytic Process of Making Aluminum, February 23, 1886, the Year Following his Graduation from Oberlin College, Thus Making Available for Industry a Metal Long Known but Little Used." The tablet tersely describes the invention of a process vitally necessary for the commercial production of one of our most useful metals, particularly when alloyed.

ALUMINUM was separated from its chloride in 1825 by Oersted. Wöhler continued the Danish scientist's experiments but it remained for the French chemist, St. Claire Deville, to produce the first aluminum commercially. This was approximately 25 years after Oersted's discovery. In 1852 the metal was worth 545 dollars a pound but in five years the price had dropped to 27 dollars a pound. Thirty years later an Oberlin College student was destined to shake the metallurgical world with an epoch-making discovery and in a short time thereafter aluminum sold for two dollars a pound in 1000-pound lots, a remarkable decrease.

Professor Jewett, of Oberlin College, was lecturing one day and said that if anyone should invent a process by which aluminum could be made on a commercial scale that he would not only be a benefactor to the world but would amass a fortune as well. Charles Hall turned to a classmate and said, "I'm going for that metal." Six months later he came into Professor Jewett's office and said: "Professor, I've got it!" In his hand were little globules of aluminum. Inventor at the age of 23, this young man had carved his way to fame and fortune.

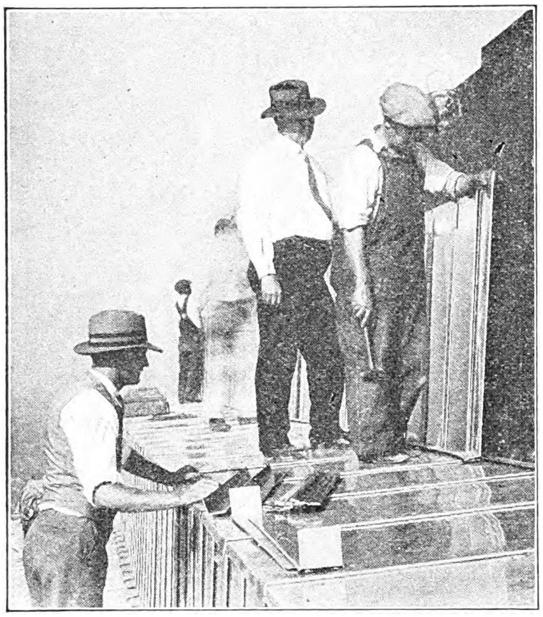
26 1/2 POUNDS

This is not a feather weight, but is certainly light, weighing 3 1/3 pounds a foot

A month or two later a French chemist, Heroult, of the same age, made the same discovery independently. On the occasion of the award of the "Perkin Medal" to Hall in 1911, Heroult crossed the Atlantic to congratulate him.

A COMMERCIAL plant was established in Pittsburgh in 1888 by a company called the Pittsburgh Reduction Company, which was the forerunner of the Aluminum Company of America. The first week's production was 100 pounds and it was kept in a safe, as aluminum was still a more or less semi-precious metal. But nobody wanted the product, so the company had to go out and make a market. They succeeded so well that the production of aluminum in the United States in 1928 as given by the American Metal Market was 198,414,000 pounds. In 1929 the production showed an increase but definite figures are not yet available. The average price of virgin aluminum has fallen to 24.3 cents per pound, a far cry from something that had to be kept in a safe and which nobody wanted.

It must not be supposed that Hall's invention did not thrive uncontested. The Cowles Electric Smelting and Refining Company, of Lockport, New York, reduced aluminum oxide with carbon in electric furnaces but only a copper-aluminum alloy was produced; it was a high-temperature reaction, and not electrolytic. The late Judge Taft who was destined to be President and Chief Justice of the Supreme Court, rendered a decision in the United States Circuit Court of Northern Ohio in which he said: "Hall was a pioneer, and is entitled to the advantages which that



ALUMINUM IN BUILDING

The pyramidal roof of the St. Louis, Missouri, Civil Court House was all fabricated from aluminum

fact gives him in the patent law." Other litigation followed, but finally all obstructions were swept away. With the cheap water power at Niagara and elsewhere we are able to obtain vast quantities of aluminum, which is gradually entering more and more into our daily life. It is used in our automobiles, airplanes, buildings, locomotives, and kitchens. It is used so much in everything to do with locomotion that it is interesting to note that its use in bicycles really brought aluminum into prominence. The war helped the aluminum industry; the light weight aluminum alloys dictated their use in aeronautical parts and today aluminum propellers, forged under huge air hammers, are standard on many of the finer planes. The dirigible depends largely upon aluminum alloys and aluminum sheet has even been used in place of a fabric as an outer shell for the ship.

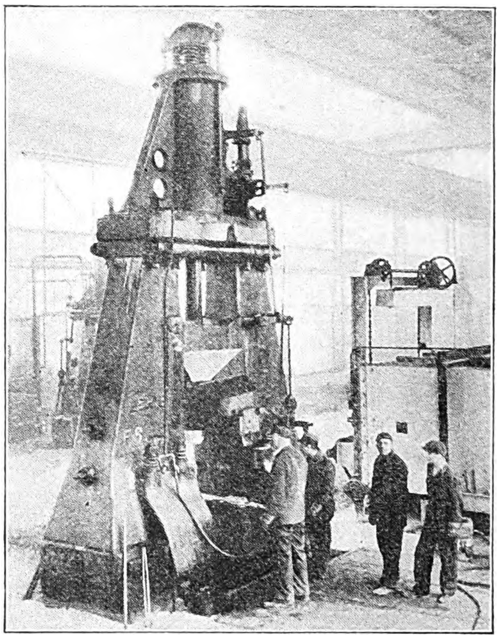
Because of the fact that manufacturers did not have uses for the new metal when it was first made commercially available, the Aluminum Company of America was really forced into designing and making all kinds of things such as bottle caps and seals, foil, and so forth, as well as plates, sheets, bars, castings, forgings and articles fabricated from them. The writer well remembers as a boy seeing the Cowles electric furnaces in "Lower Town" in Lockport, New York. These were under open sheds and it was a puny affair compared with the immense "pot room" at Niagara Falls, where the ingots are now produced.

The aluminum comes to the mills and shops in the form of "pigs" or ingots which weigh about 50 pounds. While large quantities of aluminum are used without alloying for consumption in foil, bottle caps, kitchen utensils, and hundreds of other uses, much of the aluminum of commerce is consumed in the form of alloys. The aluminum and the alloying metal, copper for example, are melted under the most precise pyrometric control, and cast into ingots weighing between one and 30 pounds. The alloys thus made are subsequently remelted and cast into rolling ingots or castings.

IN the case of sheet, tubing, and forgings, the ingots generally weigh between 50 and 300 pounds, but for structural shapes these ingots may weigh upward to 3000 pounds.

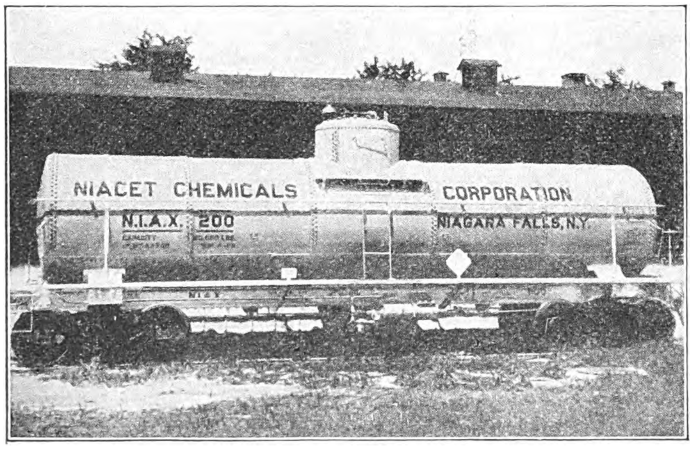
Aluminum and its alloys are cast in a number of ways—by gravity in sand molds; by gravity in accurately made fixed molds (permanent mold process) and by die casting under great pressure. The alloys can be forged under a steam or air hammer just as are iron and steel; airplane propellers are so forged. Remarkable effects are produced by heat-treating aluminum alloys. The end is to secure the best possible distribution of the alloying element and then to fix it. The heat treatment is conducted in electrical furnaces and steam-pressure tanks. Aging of alloys, both natural and artificial, also enters the case, but here we are treading on a metallurgical morass so we had better retreat while there is time. Alloys have been developed which can be forged from one piece without reheating. Strong alloys are also made proof against corrosion. Pure, comparatively weak, aluminum is used as a protective coating over strong aluminum alloys. Indeed, the results obtained by heat treatment are so peculiar that it is sometimes called "voodoo" treatment by the scornful. The more you see of the processes of manufacture, the more respect you have for the magnificent laboratories which control it all.

Strong aluminum alloys have been developed to supply engineering materials, having mechanical properties comparable with those of steel, and,



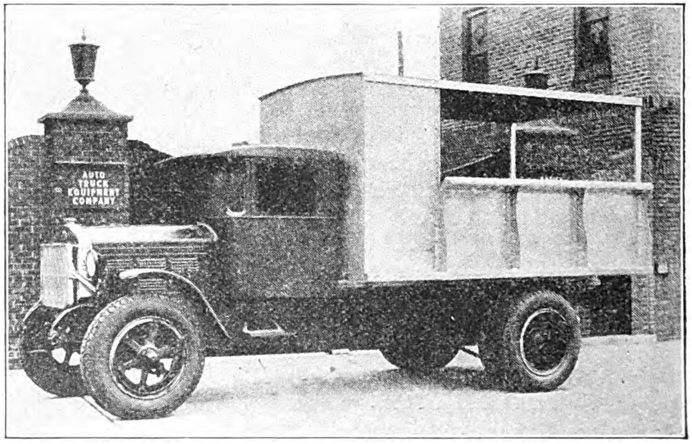
FORGING ALUMINUM

An 18,000-pound hammer is forging an airplane propeller. Some aluminum alloys can be forged



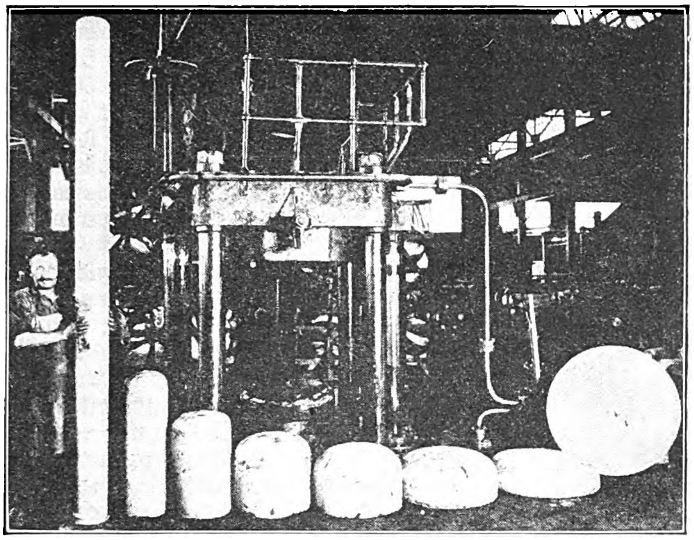
FOR ACETIC ACID

An all-aluminum tank of riveted construction is used for acetic acid, which does not affect aluminum. Capacity is 80,000 pounds



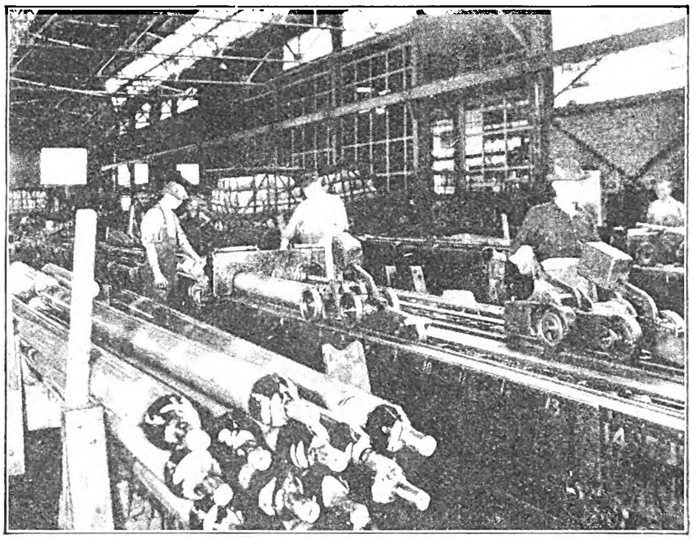
ALUMINUM TRUCK BODY

Every pound of weight that can be saved in the construction of the body of a heavy-duty truck is a pound added to the pay load



ALUMINUM TUBES BY CUPPING

An aluminum sheet is drawn on a cupping press into the form of a tube. Tubes thus produced may be further reduced by drawing



DRAWING TUBES

Round and square aluminum tubing has many uses. Tubes are also produced from the billet by means of an extrusion process

at the same time, retaining the well-known characteristic properties of the parent metal. Briefly summarized, these include low specific gravity, good resistance to corrosion, high thermal and electrical conductivities, and pleasing appearance. Pure aluminum has a tensile strength only about one sixth that of mild steel but "17ST" has a tensile strength of 55,000 to 63,000 pounds per square inch and a yield point of 30,000 to 40,000 pounds per square inch, fully comparable with low-carbon nickel and carbon steels.

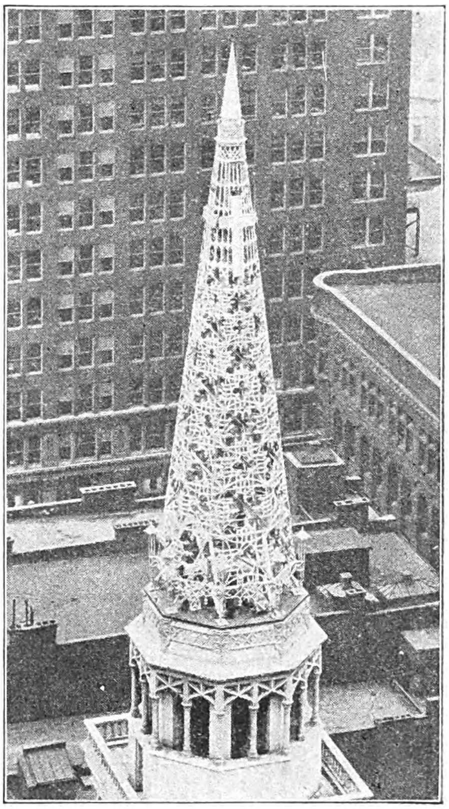
These aluminum alloys are of rather recent development, but they have found immediate application in the aircraft and automotive industries, and their use has rapidly spread to other fields. From the truck and the bus, where the light alloys have already proved their worth, it is only a step to the electric and steam railway car, and this step has already been taken. Here the strong aluminum alloys have replaced steel. Such a substitution is not possible on the basis of first cost alone, even when it is considered that the low specific gravity of these alloys results in a very much lower metal requirement for any given part.

ALUMINUM HELPED

Over 100,000 pounds of aluminum sand-cast spandrels were used in the Koppers Building

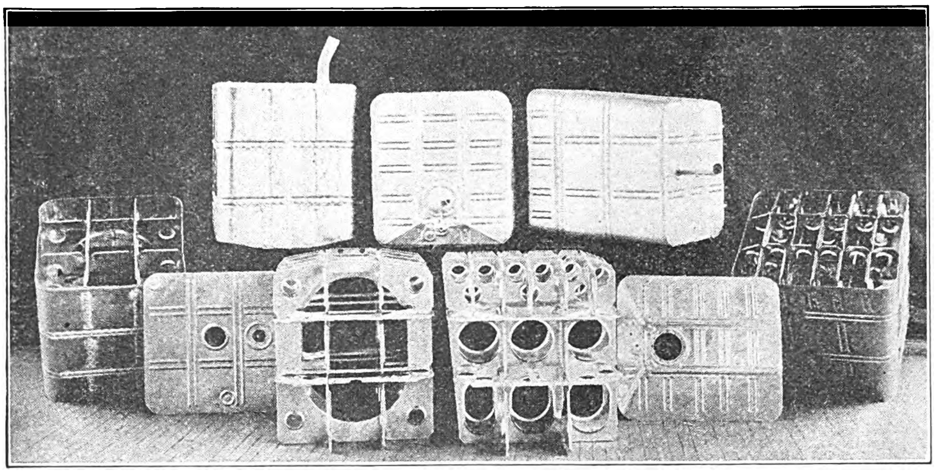
WHEN, however, the saving in power during the life of the assembly is considered, and also the lower maintenance cost resulting from the decreased inertia and vibrational stresses, as well as the increased resistance to corrosion, the advantage of the aluminum alloys becomes apparent. When, however, the strong aluminum alloys are substituted for other non-ferrous alloys, there is frequently an actual saving in metal cost.

Almost at the birth of the automobile industry aluminum was recognized as an important material of construction and the automobile manufacturer is aluminum's largest customer. Aluminum is ideal for truck bodies in that it increases the pay-load or decreases the dead weight of the truck. Fuel consumption and wear and tear on the chassis are also lessened. Even if an aluminum body costs 600 dollars more, the revenue is increased some 800 dollars a year and the scrapped body can be sold for around 300 dollars. Trolley cars with aluminum bodies are giving excellent service and show the way to increased economies. The Navy's metal-clad dirigible *"ZMC-2"* not only has an aluminum framework but is enclosed in aluminum sheeting. The use of aluminum in airplanes is almost an old story now. Aluminum is ideal for many parts of the radial motors and forged aluminum propellers are largely used. Outboard marine motors afford a fine field for the use of aluminum. In washing machines, vacuum cleaners, and other household appliances aluminum enters the house as well as via the kitchen. Seals for bottles are made at New Kensington, Pennsylvania, by the hundreds of millions and are used on products packed in various places all over the globe. Aluminum foil is largely used in place of tin foil and can be obtained in all the colors of the rainbow. Aluminum tanks make good oil storage containers and aluminum tank cars carry acetic acid safely.



ALUMINUM CHURCH SPIRE

Two hundred and twenty castings were used in the spire in this new church



AIRCRAFT TANKS

Here we have finished and semi-finished gasoline tanks for aircraft. Lightness is essential in such parts, and for this reason they are fabricated from aluminum sheet. Note the baffles

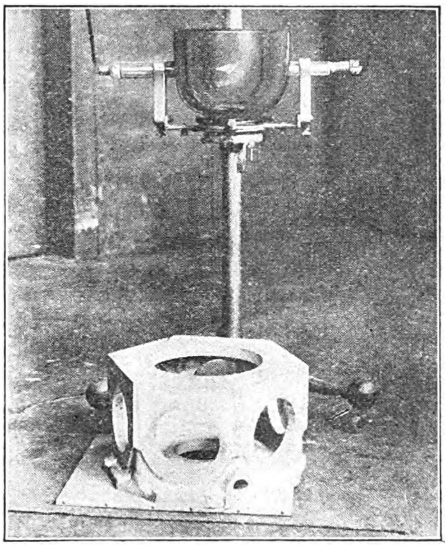
Aluminum furniture has come into its own. An average aluminum chair weighs only about seven pounds.

Aluminum is very successful in the building field. Over 900 aluminum spandrels were used in the Koppers Building in Pittsburgh, while in the new Chrysler Building in New York the spandrels, copings, and sills are of aluminum. Aluminum shingles and cast aluminum ornaments and crestings are being largely adopted.

Shingles made of aluminum have many points of excellence due to the inherent properties and qualities of the metal itself. They are wind, water, and weather tight. They are unbreakable and non-inflammable. They are frost proof; they cannot crack nor leak, because they are flexible. They are, of course, non-rusting and are light in weight, thus relieving the roof framing timbers of excess weight. These shingles are laid from the top downwards, so no scaffolding is laid over them and they are not injured by being walked on. Sheets of aluminum have been exposed to the ravages of the elements for over 25 years and at the end of that time they show no appreciable deterioration. This is worthy of note, when considering various shingle materials for building.

One of the most striking uses of aluminum for architectural purposes will be found in a church in Pittsburgh in the downtown section, surrounded by lofty office buildings. This church is the German Evangelical Protestant Church which is built in a modification of the French Gothic style. The spire is made up of aluminum castings. There are 221 castings used in this striking edifice which towers 259 feet above the level of the street. The spire is octagonal and is 80 feet in height. It rests on a concrete base 179 feet above the street. The crosses on both sides are also made of aluminum and are illuminated at night. The extreme tip of the spire is a single casting weighing 201 pounds. This spire will never have to be painted and it stands out brightly under Pittsburgh's rather trying climate. Aluminum also caps the Washington monument. The capstone weighs 3300 pounds and is finished off by a small pyramid of aluminum 5.6 inches at its base and 8.9 inches high. It weighed 100 ounces, being the "largest piece of this metal ever cast in any country." This was in 1884; recently a 3800-pound base for a Diesel engine was cast.

Aluminum paint is used in many industries. The pigment base is "albron," which is made by stamping pure aluminum into small, flat, and very thin *flakes*, which, when mixed with a suitable oil or varnish vehicle form aluminum paint. These tiny flat flakes overlap one another when applied. They arrange themselves layer on layer much like falling leaves. Thus there is formed a metallic sheath that can be readily washed. One coat will completely hide a black surface.

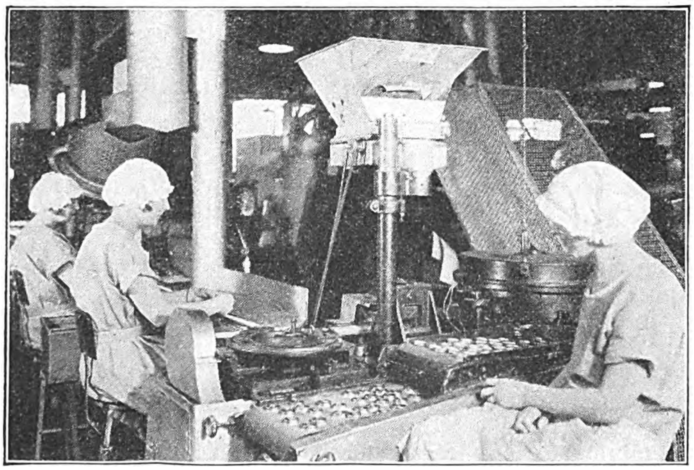


LOOKING FOR DEFECTS

X-raying a crankcase. Heat treatment and forgings necessitate such inspection

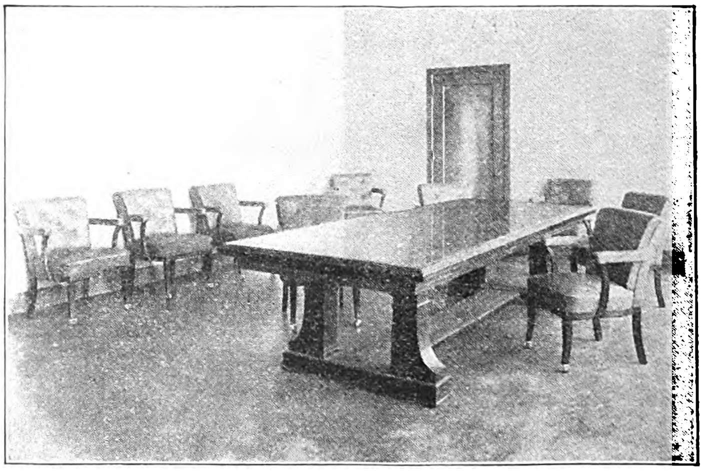
ONE more example of the application of strong aluminum alloys, in this case to locomotives, and we are through. It has been found advantageous to provide reciprocating parts of aluminum alloy. Any weight saving in the reciprocating or rotating parts can be put into boiler capacity without increasing the weight on the drivers. The saving in rail hammer is very great.

So here we must take leave of this very light and versatile metal and its useful "hard-boiled" alloys, to mill out new uses in our machine world.



BOTTLE SEALS

Girls place tin disks in the aluminum capsules as they pass by on a conveyor. A cork liner is dropped in and a groove secures it



ALUMINUM CHAIRS

Here is a director's room entirely equipped with aluminum chairs. Having no dowels they are especially valuable for dining cars

OUR POINT OF VIEW

The Rights of the Governed

PROBABLY no one will dispute the affirmation that the Constitution of the United States was promulgated with the inherent idea that, insofar as it is possible, the people shall have a direct voice in their own government.

As the years have passed, the practical operation of law-making and law enforcement has been more and more delegated to representatives, which though a proper procedure in itself, has resulted, in many cases, in the evolution of a situation where representatives do not always represent the opinions and beliefs of their constituents. This is evident in the agitations for the "referendum and recall"; by the pressure of public opinion which forced the passage of the XVII Amendment, the election of United States Senators by direct popular vote; by direct primary nomination in certain states, and so forth.

Even these reversions to older tradition of self-government have not entirely ameliorated the conditions, for we still find some of our representatives being governed by the opinions of a close coterie who are accessible and whose influence has weight with them, or by a part of their constituency who are most vociferous. It is true that when the situation becomes flagrant, the people will correct it by the removal of such misrepresentation, but in the ordinary run of events a representative can continue to misrepresent the majority of his constituents for long periods before retaliating wrath can be organized to overthrow and punish by elimination.

If popular vote can make, it surely has the same right to unmake. The aphorism that because a law is on the statute books it must remain and be enforced regardless of popular will, is as fallacious as that a man should continue to do something injurious to himself simply because it is a custom or a fad.

Criticism appears in some quarters of the nation-wide poll on the prohibition amendment now being taken by the *Literary Digest*. Yet, fundamentally, what is censurable in any honest effort to learn what the public really wants? Without a doubt this effort is an honest one, and to our mind it is representative, although as to the latter there is a basis for argument.

If the XVIII Amendment was put through as a war-time measure, at a time when we were ready to agree to anything that might help us to victory, and we now wish to reconsider that action in the light of present peace-time prosperity, who can gainsay us such a right?

It's Not the Cost

CRITICISMS of the increased rates for American naturalization papers seem partly justified by statistics. For the July-December, 1929, period as compared with the same period of 1928, the number of first-paper applications fell from 114,469 to 79,346, and second-paper applications fell from 106,028 to 65,887. Under the old rates, first papers cost one dollar and second papers four dollars; under the new, five and ten dollars respectively.

Unregenerate Criminals

IN a letter to *The New York Times*, Ranulph Kingsley, of New York, declares that we have become too good-natured and easy-going in our dealings with criminals. He believes that "Even if we have to pock-mark the state with prisons, we should put every confirmed criminal in one and keep him there." Mr. Kingsley states that since holding up the United States mail with gunplay was made punishable by life imprisonment some years ago, that kind of crime has noticeably decreased. He would have the states adopt laws as stringent as this federal law; and, further, he believes it inadvisable to take pistols away from honest people yet very necessary to teach the criminal that when he goes out at night with a pistol, "he goes to his own swift and inevitable imprisonment for life."

We heartily agree with Mr. Kingsley. Under the present lax system, too many politicians are working hand-in-glove with the underworld, too many murderers are brought in simply for questioning and then are let go with a smirk on their faces, too many foreign-born are conducting rackets that terrorize honest citizens. It is all very well to philosophize about the exploitation of human beings that leads them to become criminals, to prattle of reforming them, to pity them for their supposed lack of advantages, but that is not enough. All this is the fault of the system; therefore the system should be changed. Many years will elapse, however, before we have made a start in this direction and, in the meantime, confirmed criminals, with minds warped irreparably, continue their depredations on society. What we need right now is a Mussolini to round up our "Mafia" and a few jurors who are not too chicken-hearted to send the criminal up long enough to pay fully for his crime.

The drop in the number of applications has been laid to the increased cost, and the principal criticism of this increase seems to be that the tendency will be "to perpetuate an alien group." It is contended that the alien most often belongs to the low-income class and finds it exceedingly difficult to spare the money for naturalization papers while maintaining himself and his family, building a home, and educating his children. To some extent, then, the criticisms are justified, but—

The alien, as a rule, comes to this country because of his intolerable poverty in some other. If he belongs to this class, citizenship should be cheap at any price. There are some, of course, for whom the expenditure of the few extra dollars would work a hardship but the amount is so small even under the new rates that they can and will manage somehow if they seriously desire to share the benefits and prestige of American citizenship. As for those who can afford the price and will not because of indifference or lack of appreciation of what it means to them, and those who cannot because their earning power is too low, we do not want them. They are not the stuff of which good American citizens are made.

Questionable Success in London

A THREE-POWER Pact has been agreed upon by Great Britain, Japan, and the United States. For the present the differences between France and Italy have proved irreconciliable; but it is the intention of Great Britain, France, and Italy to continue negotiations in the hope of developing a formula that will enable the two Mediterranean powers to join the pact. We have a direct interest in the solution of the problem between Italy and France, because it may affect the number of cruisers considered necessary by Great Britain.

If the tentative agreement is carried out, the fleets of Great Britain, Japan, and the United States would be as follows:

	United States	Great Britain	Japan
Capital Ships	15	15	9
Cruisers (tons)	323,500	339,600	208,900
8″ Cruisers	18	15	12
6″ Cruisers	19 or 20	34 or 35	12 or 13
Destroyers (tons)	150,000	150,000	105,000
Submarines (tons)	52,000	52,000	52,000

Super Magnetic Fields

Some Remarkable Experiments in England—"The Most Interesting in the World"—Promise New Revelations in Physics

By J. G. CROWTHER*

THE behavior of the compass needle is described by saying that a magnetic field of force exists on the earth's surface. The magnetic force turns the needle to the north. Clearly this field of force must have a definite strength at any particular place; it must be at least strong enough to deflect the compass needle. The strength of the earth's magnetic field is in fact about one half of the unit used for measuring such fields, that is, half a gauss. It is known that the sun has a surface field of about 50 gausses, and in sun-spots the field may rise to 5000 gausses. Very strong electro-magnets can generate fields of upwards of 100,000 gausses, though 30,000 or 40,000 is about their usual manageable limit.

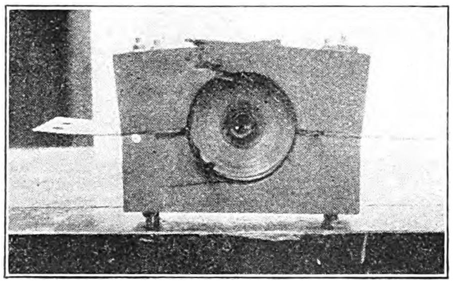
One wonders what will happen in more intense magnetic fields. Superficially, it looks quite easy to discover. You take a bar of iron and wind copper wire around it. You run current through the wire. This produces a magnetic field within the coil and in the iron. The iron concentrates the field around its ends, called the pole-pieces. Put more current through the coil, and the field in the interior becomes stronger.

But this phenomenon occurs only up to a certain point. Iron has only a limited appetite for magnetic fields; it can not absorb them beyond a certain strength. So very strong fields must be made without the assistance of concentrating iron poles. This means that still higher currents must be put through the coil, since the iron will not be there to assist in the concentration.

BUT copper wires heat when currents are passed through them. When the currents are above a certain volume, the wire is heated above its melting point. Thus, seemingly, there is a limit beyond which the field inside a copper wire coil can not be raised—the limit determined by the melting point of the coil.

Dr. Kapitza, working at the Cavendish Laboratory at Cambridge University, has shown how this limitation can be evaded. Suppose an enormous current is sent through the coil, but only for a tiny fraction of a second. Even the most powerful current takes some time to heat up the wire. May it not be possible to get the enormous current through the coil and cut it off again before it has had time to melt the copper wire? This is Dr. Kapitza's method. He sends the current through the coil for not more than 1/100th of a second.

Although this sounds simple, the execution of the method bristles with difficulties. Obviously, everything has to be done in less than 1/100th of a second. Even after the apparatus itself is successfully designed, all the experiments have to be carried out and measurements made within periods of 1/100th of a second. The fields exist for a period of 1/100th of a second. If their duration has to be accurately defined, they must be started and stopped almost instantaneously. Dr. Kapitza's switch for making and breaking the circuit can operate in 1/10,000th of a second.



AN EXPLODED COIL

The magnetic field, 600,000 times as strong as the earth's, is produced at the center

The powerful currents are obtained by short-circuiting a dynamo. The machine Dr. Kapitza uses is of a special design. It is wound so that the current alternates its direction during a revolution, that is, it has a single phase winding. At the beginning of a revolution the current is zero. It rises to a maximum at the quarter revolution and then declines to zero again at the half revolution. The current then changes its direction, rising to a maximum in the new direction at the three quarter revolution, and declining to zero again at the full turn. With such a machine, the current will be zero at the beginning, the middle and the end of a revolution. The volume of the current at the maxima will depend on the size of the machine. In Dr. Kapitza's machine the maxima are about 30,000 amperes. By special winding the maxima can be reduced but spread out a little. In this way, he obtains a steady 30,000 amperes for 1/100th of a second, instead of, say, 72,000 amperes for a far shorter fraction of a second.

We now come to one of the many highly ingenious features of this machine. Dr. Kapitza has his source of 30,000-ampere current; how can he tap it?

We all know that when a current is broken, sparks occur; for instance, when a street car trolley jumps off the wire. Will we not get a tremendous spark if we try to break a current of 30,000 amperes? And will not a big spark at each end of the 1/100th of a second period rather blur the definition of the interval? We can avoid all that, says Dr. Kapitza, by seeing that the current is tapped from the machine when it is at one of its zeros.

So the coil for producing the magnetic field is switched on to the dynamo in 1/10,000th of a second when it is producing zero current. As there are limits to mechanical accuracy, the current may not be quite zero, but perhaps a mere 3000 amperes. So the switch must be capable anyway of breaking a current of a few thousand amperes in 1/10,000th of a second. That is why it has to be so large and complicated. Dr. Kapitza considers that the switch was the hardest to design of all the parts of his apparatus.

THE coil has now been switched into the current when the current was comparatively feeble. In a small fraction of a second it rises to 30,000 amperes and remains at that strength for the next 100th of a second. All the experimenting has to be done in this short interval.

For the small fraction of a second when it is short-circuited, the dynamo develops about 50,000 horsepower, and the energy discharged into the coil is about equal to that discharged when a field gun is fired.

The machine was made to Dr. Kapitza's design, in consultation with Professor Miles Walker, of the College of Technology at Manchester, by Metropolitan Vickers at Old Trafford, in England.

The magnetic coil for producing the magnetic field consists of layers of square copper wire, or copper-cadmium alloy. When a current is sent through the wire the opposite sides of the coil repel each other. If the current is small the repulsion is not great but if the current is large the force on the coil tending to make it expand can amount to several tons per square inch of copper.

In his earlier designs, Dr. Kapitza

---

*See "Among Our Contributors," page 421.

found that the metal of the coil spread like putty under these repulsive forces. But it is possible to design the coil so that these forces cancel out, except directly outward. So this was done, and a strong steel strap was clamped around the coil to bear the resultant outward thrust. By using copper-cadmium alloy, the coil itself can be made four times as strong as when copper is used, and yet retain 90 percent of the conductivity of copper.

Then a worse snag arose. The repulsive forces tending to make the coil expand made the coil unwind itself a little. Its ends were torn away from their terminals. Coil after coil burst in this way, and the experimenter had the unnerving experience of seeing his experiments failing after all the labor and expense on the dynamo and other apparatus.

After some months of disappointment, the experimenter devised a solution of the bursting coil trouble, and it was possible to proceed with these epic experiments. He designed coils which "breathed," that is, expanded automatically. The central winding in the coil was made out of a piece of copper-cadmium tubing with a helical saw cut. A ring was made to slide around this tube, and then the end of the wire was brazed to the ring. When the coil expanded, the wire just slid the ring around the tube. After being used once, the coil settled into a permanent position cramped against the outer steel strap and the trouble was overcome.

Another difficulty was caused by earthquakes. When a dynamo about to produce 50,000 horsepower is short circuited, it suffers a severe shock which it communicates to its foundations. A small earthquake travels through the laboratory at the rate of about two miles a second. Measuring apparatus, spectrographs, and so on, are thrown out of adjustment. Now these magnetic field experiments last one 1/100th of a second. So, if the coil is placed some distance away from the dynamo, the whole experiment will be over before the earthquake shock has had time to reach the measuring instruments, and so Dr. Kapitza has arranged it. All the photographs and observations are taken before the shock arrives, even though it is traveling at two miles a second.

The unleashing of energy at the rate of 50,000 horsepower for a fraction of a second, has been calculated to produce an exceedingly high momentary temperature inside the coil, possibly the highest temperature the earth has known since it condensed out of solar material. This calculation, and Professor Rutherford's disintegration of atoms at Cambridge, prompted Professor Eddington to remark humorously that, though the interior of a star may be at a temperature of millions of degrees, centigrade, it is quite a mild place compared with the Cavendish Laboratory.

Dr. Kapitza has already made two discoveries of great interest, besides extending magnetic field technique ten times beyond its previous limit. The late Kamerlingh Onnes, the Dutch scientist, discovered that when certain metals were reduced to a very low temperature their electrical resistance decreased almost to zero. Other metals decreased steadily until a low temperature was reached, after which there was a sudden drop in resistance. Still other metals were always left with a certain residual amount.

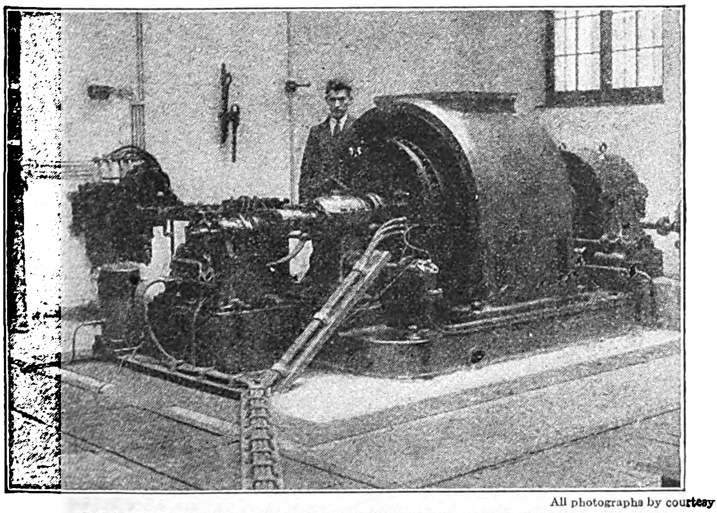
NOW the resistance of metals increases in strong magnetic fields. With the range of field strength at his command, Dr. Kapitza has shown that the residual resistance is due to internal disturbances in the metals. If the temperature could be lowered sufficiently, these disturbances would disappear. Thus he has shown that the same laws of variation of resistance control all metals under undisturbed conditions; the exceptions are due only to disturbances which can be removed by adequate technique. A jumble of varied data has been reduced to order.

His next remarkable result was published recently. He has discovered the phenomenon of atomic magnetostriction; that is, the stretching in a magnetic field of the bonds between atoms. It has long been known that metal rods change their length when placed in magnetic fields. This old phenomenon is completely describable in terms of the elasticity of the metal and what is known as its magnetic susceptibility. It is due to slipping or rearrangement of the polar crystal units of which the rod is built up.

Kapitza's phenomenon is quite different. The crystal units themselves are distorted under the enormous stresses of his intense magnetic fields. He finds that the strong fields tend to increase the strength of strong short bonds between close atoms, and to weaken the weaker bonds between atoms farther apart. Thus Kapitza has started a completely new line of attack on the nature of certain of the forces acting between the atoms of magnetic solids.

The greatest achievement in science consists in the invention of new methods. Once a new method is devised, it can be applied to hosts of objects, and must almost necessarily reveal new facts, many of which must be important. Dr. Kapitza has devised a new method. It is not at all unlikely that the next great advance will be the outcome of applications of this method.

For many years the study of magnetism has been in a jumble. Straightening the jumble will almost certainly reveal an atomic design of the profoundest significance. It looks as if Dr. Kapitza is in a fair way to do this straightening. At the moment, no one in the world is making more interesting experiments in physics.



MACHINERY FOR PRODUCING THE FIELDS

The dynamo gives electrical energy at the rate of 50,000 horsepower during a period of about 1/100th of a second. It has a special single phase winding, which is described in the text

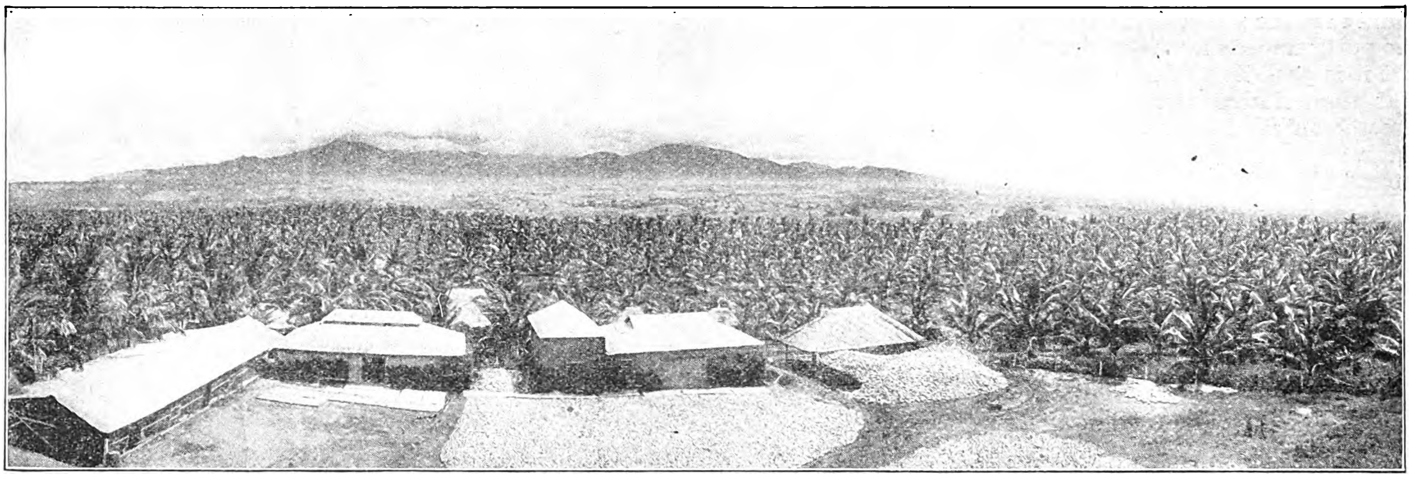
THE SWITCH, AN UNUSUAL PIECE OF DESIGN

This must be capable of cutting off a current of about 5000 amperes in 1/10,000th of a second; the maximum is 30,000 amperes, which flows through the circuit for 1/100th of a second



A COCONUT PLANTATION IN THE PHILIPPINE ISLANDS

Piled against the side of the thatched hut to the right of the center of this photograph are thousands of coconuts. In the center foreground is a large area covered with coconuts that have been broken open and exposed to the sun to dry. The resulting dried meat is called copra

From Coco Palms to Coconut Oil

The Coconut Has Exerted a Tremendous Influence in the Industrial Life of the Philippine Islands

By CHARLES W. GEIGER and RUTH SABICHI

COPRA, the dried meat of the coconut, has figured in the romance of world trade since the days of Magellan. The story of the coconut is the story of the economic progress of the Philippine Islands, to which it has contributed more than any other product, with the possible exception of hemp. Few plants, if any, are as serviceable to primitive man as is the coconut. The nut meat is eaten as food; the oil is useful in making edible fats and soap, and is also used for illumination; the tree roots provide a dye, and the trunks, building material; the leaves are employed for thatching roofs; the midrib of the leaf is used for making baskets, brooms, and brushes; the fiber from the nut husk is woven into ropes and mats; and the nut shells, in addition to providing fuel, are shaped into cups, ladles, spoons, and other utensils.

UNDER primitive conditions, the production of coconuts, copra, and coconut oil was confined to the groves of wild palms that skirted tropical shores. These wild or uncultivated trees still constitute a considerable source of supply when the market price is sufficiently attractive to the natives. The coco palm, however, is now cultivated like any other staple agricultural product. Large plantations are to be found throughout the tropics, for supplying the international trade in copra and coconut oil.

In domestic cultivation, it is customary to set out trees in rows, about 30 feet apart, giving room for about 48 to the acre. Crops of abaca, or Manila hemp, and other quickly growing plants, are usually grown between the rows. During the fifth or sixth year, the trees begin to bear, and after the seventh year the planter can reap an annual harvest of 15 or more nuts from each tree. The trees reach maturity at the age of 10 years, when about 70 nuts per tree are collected annually. In rare instances, as many as 500 nuts have been harvested in a year from a single tree, and trees have been known to continue to produce after reaching an age of 150 years.

IN THE JUNGLE

At the right is a coco palm. In the left background is a primitive cart for hauling nuts

The natives pick or shake the nuts from the trees and crack them open with a machete. The broken nut meats are then placed in the sun to dry. Sometimes the broken pieces are placed on drying racks under which coconut husks are burned to speed the drying process. The resulting smoke-colored copra is called "smoke-dried" to distinguish it from that which has been sun-dried. The fire-drying method is used in regions where excessive rain makes natural drying impossible. Mechanical driers are employed on some of the larger plantations, but the practice has not become prevalent.

MATURE nuts yield copra of the best quality, but it is customary for the natives to harvest the nuts before they are ripe and depend upon a month's curing on the ground. Copra made from immature "meat" has a tendency to re-absorb moisture after drying, as well as to become moldy and sour, but dry-curing before removing the husk that surrounds the shell overcomes this objectionable tendency.

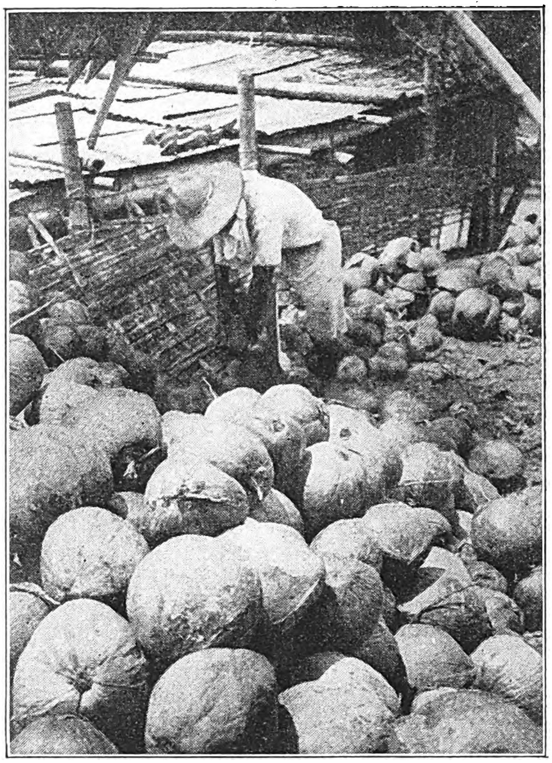
In some parts of the islands, where sunshine during the harvesting season is very uncertain, the copra is dried by the use of a *tapajan*. This device is a bamboo grate, about 20 feet square, under which a rough earthen oven has been prepared. Over the grate, a roof or watershed is erected, composed of coconut fronds. The nuts are husked and the shells split, and the broken coconuts are placed on the bamboo grate. A fire is built under the grate, and the meat shrinks from the shell as it dries. The shells, when removed from the meats, are used as additional fuel for the fire. The total drying time by this method is from five to 12 hours.

THE natives have various ways of disposing of their crop. In some districts, they sell their copra direct to the dealers at trading stations operated by the exporters. Chinese merchants in the small towns also acquire much of the local copra stocks, usually giving merchandise in exchange. The merchant, in turn, settles his accounts in the form of copra shipments. The coconuts are frequently made into "rafts," and are floated down the rivers to market.

Some years ago it was the practice to ship almost all of the copra overseas for crushing and conversion into coconut oil, but a few mills have been established in the Philippines, in India, and in the Dutch East Indies. These local oil mills have become important factors in the copra market, exerting a balancing influence on the market price of copra and oil. However, the proximity of raw material, and the cheap native labor available for operation of the mills is offset by lower power costs, more efficient labor and machinery, and more convenient marketing conditions in the United States.

Copra first became an important item in world commerce in 1886, although a French sailing vessel had carried a load of coconuts to Marseilles as early as 1750. Marseilles soon became a manufacturing center for copra products, and is still one of the most important copra importing ports of the world. It was in France that the first butter substitute, consisting of coconut oil and peanut oil, was produced.

Traders, operating sailing vessels in the South Seas about the year 1890, brought copra and other native products to the United States. Coconut oil mills were established at San Francisco and Berkeley. The phenomenal growth of the copra industry in the United States is shown by the fact that imports in 1920 amounted to 218,521,916 pounds, of which only 7 percent came from the Philippine Islands. By 1927, our copra imports had increased to 450,994,519 pounds, of which 72 percent came from the Philippines. Of the 238,471 tons of copra exported in 1928 from the Philippines, 181,111 tons came to the United States, and 57,360 tons to Europe. About two thirds of the American copra imports were consigned to the major Pacific Coast ports — San Francisco, Los Angeles, Portland, and Seattle.



REMOVING HUSKS

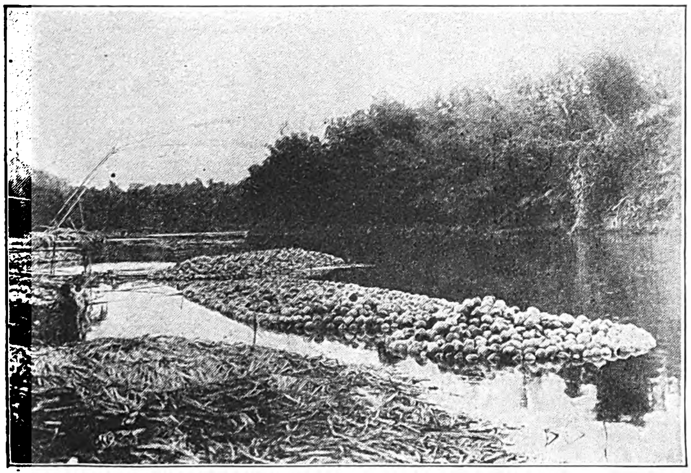
Before the nuts are broken and meats extracted, the thick, fibrous, outside husk must be removed

Originally coconut oil extracted from copra at the source was shipped to San Francisco and other ports in five-gallon cases, barrels, and drums.

THEN a system was perfected whereby the oil was shipped in tank steamers and in deep tanks on passenger and cargo vessels operating between America and the Orient. This practice immediately revolutionized the transportation situation; for years the great ocean steamers had been carrying petroleum from this country to the Orient and returning in ballast, until someone thought out a practical scheme of carrying the coconut oil on the return voyage. A number of tank steamers are now engaged in transporting petroleum from Pacific Coast points to the Orient, returning with a capacity cargo of coconut oil in the same tanks.

Of course it was necessary to devise a very effective system of cleaning the tanks of the ships before filling them with edible oil. After the petroleum cargo has been removed, a charge of live steam is forced into the tanks. This is continued for a period of 12 to 24 hours. After pumping out the bilges, and waiting a sufficient length of time for the interiors to cool, men are sent down into the tanks to clean them as thoroughly as possible. Later, upon arrival at the port where the coconut oil is to be taken on, the tanks are given a final cleaning.

A fleet of specially designed coconut oil barges, with two large pumps, transfer the oil from the copra crushing plants in Manila to the oil tankers or



COCONUT RAFTS

OIL TRANSPORTATION

Above: Specially designed coconut-oil barges are used to transfer the oil from the crushing plants to huge tankers. *Right:* A pump barge alongside a tanker. The machinery pumps the oil from the barges to the tanks on the ocean steamer

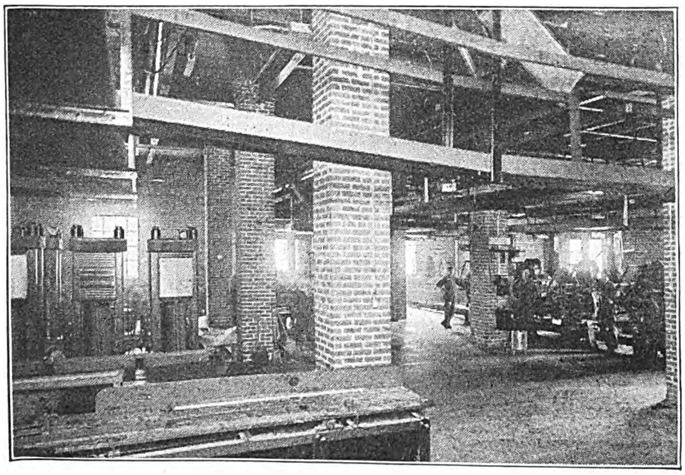
passenger vessels equipped for transporting oil. Each barge has a capacity of 250 tons of coconut oil. Pump barges are equipped with two duplex pumps, each of which can pump 100 tons an hour. There are always a number of loaded barges on hand, so that there will be no delay in transferring the hose when one barge has been emptied. A loaded barge is pushed into place while an empty one is being removed, and the pumps seldom stop running until the tanker has been filled to capacity or the supply of coconut oil available at the time has been exhausted.

The most important factor in handling coconut oil is temperature, for in order to keep the oil in a liquid state, the temperature must be more than 70 degrees, Fahrenheit. Under cooler conditions, it hardens into a dense material resembling butter or lard. Consequently it is necessary to provide heating pipes in the tanks of the steamers, in storage tanks, and in the tank cars used for distributing the oil in the United States. In many cases, the delivery pipes or hoses have a small heating tube running down the center, carrying steam or hot water. Compressed air is sometimes used to force the oil out of tankers and the loading pipe, in order to expedite the transferring operation.

When the copra is not to be pressed at its source, it is transported in much the same way as other bulky materials are handled. One of the most familiar sights in San Francisco Bay is the process of transferring copra from the holds of ocean-going ships to the dock. By means of large metal tubs operated by the ship's tackle, overhead hoppers on the dock are filled. Dump wagons and trucks back up under the hoppers, where they are loaded and then proceed to the warehouse or crushing plant. Copra is also transferred directly from the ship's hold to railway cars. On the Oakland waterfront there are several pneumatic boat unloaders which "suck" the copra from the hold, loading it into a railroad car or warehouse.

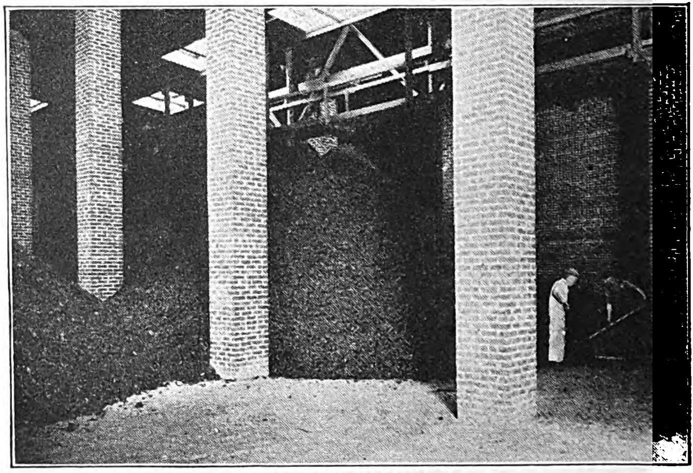
In making coconut oil, the copra is first put through expellers which force out about 25 percent of the oil content. The residue is then ground into meal, and the remaining oil content is squeezed out by hydraulic presses. Most of the oil is then filtered, and used for the manufacture of soap, shaving cream, shampoo solutions, and a long list of cosmetics. Some of the coconut oil is used for edible products, and must be refined several times to remove free fatty acids, color, and odor.

Besides being used in making margarine, the oil is employed in manufacturing thin sugar wafers, cookies, candies, and for shortening in cakes and pies. About 63 percent of the copra is converted into coconut oil, and the remaining 37 percent is used as coconut meal, which has high food value and is used as a feed for stock and poultry. About three fifths of the coconut oil consumed in this country is used in the soap industry; one fifth is used in the production of margarine, and practically all of the remainder is consumed in the manufacture of candy and biscuits.



IN AN EXTRACTION PLANT

This copra crushing plant is located in Berkeley, California. In the left background are three hydraulic presses for pressing oil



COPRA STORAGE

Part of the dried copra is shipped direct to this country, where the extraction of oil takes place. This pile of copra awaits pressing

Birds of a Bleak Arctic Island

A Bit of the Far North Is Borrowed for a Museum Habitat Group

IN Bering Strait, a few miles south of the Arctic Circle, lie two granite islands. The larger, Big Diomede, seven miles long, is Russian; Little Diomede, much smaller, is American. Here where the East and the West are but little over two miles apart, the East is to the West, and the West is to the East! The International Date Line, here a line of convenience, swings east of the 180th meridian and passes between the two islands. The days are born on Big Diomede, follow the sun around the earth and end 48 hours later on Little Diomede.

AT Little Diomede was collected the material for the Bering Strait Bird Group which completes the series of habitat groups of North American Birds at the American Museum of Natural History, under direction of Dr. Frank M. Chapman. Mr. Francis L. Jacques, Assistant in Preparation, says in *Natural History* that his problem was to suggest to the museum visitor, through sight alone, some sense of the flying gray clouds, the wind-whipped sea, the cool salt air, the towering cliffs with their teeming bird life, and the savage loneliness of the scene. The group space is 20 feet in width, 7 feet from front to back, and 12 feet high.

The birds having been collected, and the skins properly prepared, the artist faced the problem of how to use the material obtained. The first step in making a museum group is the construction of a scale model. The model made for this group was about 30 inches long, or one and one half inches to the foot. About 65 mounted birds are used in the group. Each bird is mounted to fill a certain place according to the scale model.

The American Museum has a large staff of preparators and artists under the direction of Mr. James L. Clark, and a number of habitat groups are now being prepared, each with problems of its own as difficult, or more so, than those of the group described. Museum standards are being raised so that we may expect even more perfect groups.

Fragmentary Molecules of the Sun

On the Sun Most of the Elements Are in Isolated Atoms, Because of the Heat. Unfamiliar Compounds Are Being Discovered

By HENRY NORRIS RUSSELL, Ph.D.

Chairman of the Department of Astronomy and Director of the Observatory at Princeton University
Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

NOT long since (February and March) it was told how an analysis had been made of the sun's atmosphere, giving not only a list of the elements present there but the approximate quantities in which they appear. The upshot of this work was that the solar atmosphere consists mainly of hydrogen mixed with a much smaller proportion of the other prominent gases (perhaps one part in 12) and a still smaller quantity of metallic vapors.

The question then arises, are the other bodies known to astronomy of similar composition? How about the stars—and the earth and the other planets?

The answer comes easily for the stars, far off as they are. Thousands of them have spectra almost exactly like the sun's, and therefore must have atmospheres of very similar composition. For the rest, which are hotter or cooler than the sun, the spectra often appear at first sight very different, but when allowance is made for the different manner in which atoms are set up in the business of absorbing light or put out of business at different temperatures it is found that the stars too do not differ greatly in composition. Indeed, Miss Payne, whose work at Harvard has given us most of our information in this matter, concludes that the stars are "remarkably similar in composition."

FOR the earth the resemblance is apparently much less close. We know with certainty only the composition of the outer crust of our planet down to a depth of perhaps a few dozen miles, though the general nature of the denser material in the deeper interior is fairly well assured. This is composed mainly of *rocks*—compounds of the metals with silicon and oxygen. Hydrogen, instead of being predominant, is present only in a small percentage, mainly in the ocean water.

It is important, however, to notice that the relative proportions of the various metals in the terrestrial rocks are not very different from those of the same substances in the sun. Just those metals which are the main constituents of the rocks—aluminum, iron, calcium, sodium, potassium and magnesium—are the most abundant in the solar atmosphere; and silicon and oxygen, still more abundant in the rocks, are also present in great quantities in the sun. The detailed proportions are different; there are more aluminum and silicon on earth and less magnesium. But it is probable that if we could get at the dense deep-lying rocks which form the main bulk of the earth the discrepancy would be smaller.

The earth, then, is very similar in composition to what we would get out of the sun's outer layers if we let a great mass of them cool down and preserved the portion that liquefied or solidified, throwing away about all the excess of uncondensed gases. But this is exactly what might be expected to have happened if the earth was produced by the ejection of incandescent matter from the sun—as all present theories of its origin assume. Hydrogen would escape most easily of all and it is no wonder that there is relatively little of it left on earth.

FOR the other planets we have no chemical data to go on, but only general information about density and the like. The smaller bodies, Venus, Mars, Mercury, and the moon, are probably much like the earth in composition, for similar reasons. The great planets, from Jupiter to Neptune, are so much less dense that it is certain that they contain a much greater proportion of substances of low density than does the earth. Chamberlin and Moulton years ago suggested that this indicated that these larger masses had retained a greater proportion of the light constituents which were originally present in the matter ejected from the sun, and this view is now generally accepted.

In all these respects, then, the composition of the sun, the stars, and the planets appears to be very much the same. But some exceptions are still to be found. There are several important elements and many less familiar ones, the lines of which do not appear at all in the solar spectrum. We know precisely where to look for them, and they are not there. Among the list of missing we find fluorine, phosphorus, and chlorine, which are all present in abundance on the earth; as well as less abundant but familiar ones like neon, argon, bromine, and iodine. Are these substances really absent from the sun?

Modern spectroscopy gives a definite answer. The lines which these substances give in the laboratory (within the range of the spectrum which we can get at in the sun) are all produced and absorbed only by very highly excited atoms heavily loaded with internal energy. Even at the high temperature of the sun only an exceedingly small fraction of all the atoms of fluorine (for example) would be in a state to absorb the lines in question (which in this case lie in the red). Calculation shows that unless fluorine was more abundant than any other metals, or even than oxygen, its lines would not be strong enough to detect. The same is the case for all the other "missing" elements which are at all abundant on earth or even moderately rare there. The more striking cases of apparent absence are thus fully explained.

Some of the heavy metals such as bismuth, have the strongest line in the accessible region and if there was much of them in the sun we would surely detect them. But all the heavy metals, even those whose lines appear, are present in but small proportions and a moderate decrease in abundance would put them beyond detection. So even in this last instance there is no evidence of any real difference of importance between the composition of the earth and sun, beyond those which may be reasonably explained by the circumstances surrounding the origin of our planet.

IN another respect, however, the difference in composition between the earth and the sun is very great. The earth is made up almost entirely of chemical compounds. Metals in the free state are rarely met with, though platinum and a few others are sometimes found "native." Among the non-metals only the oxygen and nitrogen of the air are counted "free" and these are not composed of isolated atoms but of molecules in which a pair of atoms are tied very tightly to one another. Only the inert gases—neon, argon, and the others—which can not enter into combination are found on the earth in the atomic state.

But upon the sun isolated atoms are in the overwhelming majority. All the spectral lines of which we have so far spoken are produced by free atoms and many atoms which have not only been released from combination, but themselves partially decomposed by the loss of an electron.

This, of course, is a result of the sun's high temperature and so obvious a result that it has been understood and generally accepted since Lockyer pointed it out in the very dawn of astrophysics.

It was not until the last 20 years indeed that any definite evidence of the presence of chemical compounds in the sun's atmosphere was forthcoming. About this time it became clear that the molecules of such compounds, if they stood up at all without decomposition under the rough treatment required to get them to emit light, gave spectra of a very complex sort, consisting of thousands of lines closely packed together in certain regions to form conspicuous "bands." A few such bands appear in the solar spectrum, the most prominent being in the violet (Fraunhofer's G group) and in the ultra-violet (the well known "cyanogen" bands).

WITH the rise of spectroscopic theory it was shown that the complexity of these spectra arose from the fact that a molecule can do many things which an atom can not. The separate atoms within it (or at least their heavy nuclei) can oscillate, changing their distance apart, while at the same time the molecule as a whole rotates about an axis. We have now in many cases a good idea just what processes correspond to each of the multitude of lines in the band spectrum. Molecules of three or more atoms are too complicated to tackle as yet, but when there are only two it is possible to find the distance of the two nuclei, and various other things. Spectra due to a number of different molecules have thus been definitely identified in the sun, the list including CN (cyanogen), C_2 giving bands in the yellow and green, CH (the G band), and OH and NH (bands in the ultra-violet).

Very little knowledge of chemistry is required to make the reader exclaim at these formulae. CH_4, H_2O, NH_3—these represent very familiar molecules; but what are these other queer things? Exactly what the formulae indicate. They are not familiar molecules of methane, water vapor or ammonia, but *fragments* of these molecules already partially though not completely decomposed. The CN molecule, too, is recognizable not as that of the well known cyanogen gas, C_2N_2, but as one half of it.

Clearly, then, at the temperature of the sun the dissociation of such molecules as are familiar to us has already advanced far, though it is not complete.

The amounts of these various molecules in the sun's atmosphere can be found by the same methods which are used in the atoms. They come out small. Cyanogen, the most abundant of them, is present in smaller quantities than even the rare element scandium, and for every such molecule there are thousands of atoms of uncombined carbon or nitrogen. This is in harmony with the fact that for stars only a little hotter than the sun the bands disappear, showing that all the molecules are dissociated into atoms. In the sunspots, which are well known to be cooler than the rest of the sun, new kinds of molecules are recognizable but show no bands in the solar spectrum—hydrides of magnesium and calcium, MgH and CaH, and oxides of titanium and boron, TiO and BO. These molecules are evidently decomposed at normal solar temperature. Like the others they are chemically incomplete or "unsaturated"—the familiar stable compounds being MgH_2, CaH_2, TiO_2, and B_2O_3.

It seems curious that only these fragmentary molecules should reveal themselves, but there is a good reason. The spectra of molecules consist partly of bands which are absorbed by the molecule in its normal state, and partly of those which are absorbed only by excited molecules loaded with energy like the excited atoms discussed above. The number of excited molecules, too, would be a very small fraction of the whole, so that only the bands absorbed by molecules in the normal state should be expected to appear unless the compound in question was present in great quantity.

NOW the analysis of laboratory spectra shows that for all the saturated stable gaseous compounds with which the chemist ordinarily works the strong absorption bands due to the unexcited molecules lie far out in the ultra-violet, while for the unsaturated, fragmentary molecules they are usually to be found in the visible spectrum or just outside it. This probably means that ordinary saturated molecules are, so to speak, so well satisfied with themselves that it takes a powerful disturbance such as is given by light of short wavelength to stir them up, while the half molecules are much more easily irritated. Anyway it explains why the latter have been depicted in the solar and sunspot spectra and not the former. There might be, however, a very considerable quantity of molecules of the stable sort in the solar atmosphere without our knowing it, since the lines which would reveal their presence are in the inaccessible part of the ultra-violet. Proof that this is actually true in the case of hydrogen has very recently been given by a brilliant young Italian physycist, Professor Piccardi of the University of Florence.

Besides the familiar line spectrum, which appears so strongly in the stars, hydrogen in the vacuum tube shows a second, and much more complicated, "secondary" spectrum which is now known to arise from the hydrogen molecule H_2. The lines of this spectrum, at least in the visible region, are not visibly grouped into bands but the spectrum has been worked out and found to be similar in nature to other molecular spectra. The bands absorbed by the unexcited molecule lie very far in the ultra-violet and the visible lines are produced only by highly excited molecules.

THE energy which is required to dissociate a hydrogen molecule into its two atoms is not accurately known and Piccardi, calculating from this, showed that at the ordinary temperature of the sun's atmosphere and the pressure prevailing there practically all the molecules should be dissociated, but that at the lower temperature of the spots one percent or even more of the hydrogen atoms might be combined into the molecules.

Working with a copy of the great Mount Wilson map of the sunspot spectrum he found faint lines in the position of most of the strongest lines of the "secondary" hydrogen spectrum—except for some which were obviously "masked" by strong lines of the ordinary solar spectrum that happen to fall close by. These lines appear only in the spots, as they should do if they really belong to H_2. Moreover they show no trace of the Zeeman effect due to the magnetic field in the spots (as lines belonging to atoms practically always do but those of molecular spectra practically never). Some of the strong lines observed in the vacuum tube failed to appear in the spots but this supports rather than weakens the argument.

This mass of cumulative evidence justifies most thoroughly Piccardi's conclusion that hydrogen molecules are present in the sunspots. The number of excited molecules which absorb the observed lines is very small compared with most other constituents of the atmosphere. But the unexcited molecules must be enormously more numerous and they may outnumber even the atoms of abundant metals like iron. Since only a small percentage of all the hydrogen atoms are combined in the molecules we have here another proof, perhaps the most convincing of all, of the overwhelming preponderance of hydrogen at the sun's surface.

It is probable that molecules as well as atoms of some of the other familiar elements such as oxygen and especially nitrogen are to be found in the sun's atmosphere. We may soon be able to calculate what proportion of such molecules there may be, but there is no hope of detecting them spectroscopically.—*On the Nile, Jan. 7, 1930.*

Beautiful Bridges On New Rail Line*

Exceptional Engineering Problems Involved in Construction of European Railway

BRIDGES of remarkable beauty, and several long tunnels, are the outstanding features of a railway extending from Nice, France, to Coni, Italy, with a branch to Ventimiglia, Italy, which was opened a little over a year ago. The new railway is approximately 63 miles in length, of which total about 39 miles are situated on French territory. Its construction presented a large number of serious engineering problems, owing to the fact that the line extends through extremely mountainous territory.

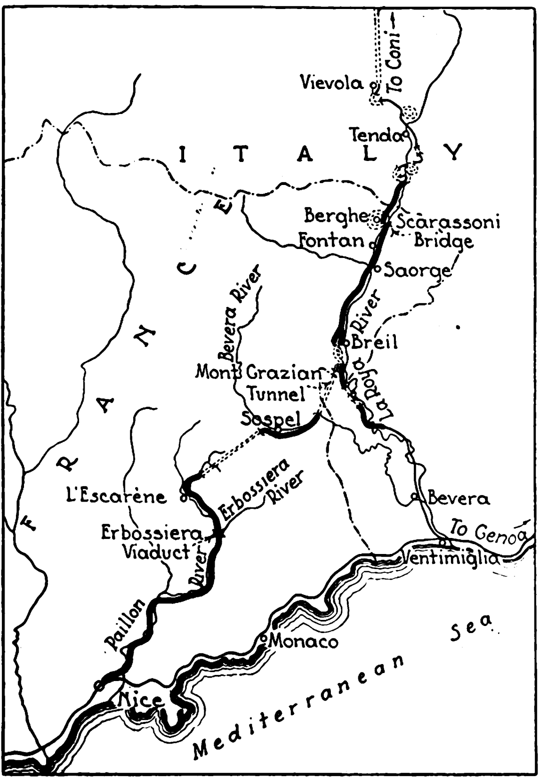
Prior to the construction of the new line there was no direct rail connection between southern France and northern Italy with the exception of the northern line from Lyons to Turin and the coast line from Marseilles to Genoa, via the Mediterranean coast. Neither of these existing lines provides a direct line from Turin, Milan, and the important towns in the plains of Lombardy to the south coast of France and the western section of the Italian Riviera, the only route to these places being a long detour via Savona.

THE need for such a direct link led to an investigation by the Italian government into the possibility of the extension of the existing line from Coni to Col de Tenda, as far as Ventimiglia on the Mediterranean. It was soon discovered that the only feasible and economically practicable route for this extension would be through the communes of Fontan, Saorge, and Breil, in the French Department of the Alpes-Maritimes.

As a result of an international conference, an agreement was signed between France and Italy in 1904, under which both governments agreed to construct, each in its own territory, a railway line linking up Nice and Coni via Sospel, while another line, leaving the main line at Breil, would prolong the railway to Ventimiglia. It is these lines which have now been completed, 24 years after their construction was authorized.

Owing to the rugged character of the mountains in the Alpes-Maritimes, it was necessary to construct no less than 45 tunnels, with a total length of 14¾ miles, nearly a quarter of the whole mileage. Of these, the longest is that under the Col de Braus—3¾ miles. In addition, the numerous ravines and deep valleys which abound throughout the traversed territory called for a large number of bridges and viaducts, many of which are of unusual interest, as they involved exceptional forms of construction.

Among the most remarkable of the bridges is that over the narrow gorge of the Bevera River. Since the location was unfavorable for the construction of a span of 300 feet, an intermediate pier was desirable, but such a pier would have almost completely blocked the waterway. The problem was solved by constructing an arch rib, approximately parabolic, spanning between the walls of the gorge at right angles to the center line of the bridge. The skew arch has a span of 82 feet, a height of 49 feet, and is 10½ feet thick at the base. It is surmounted by a bridge seat which supports two lattice steel trusses 147 feet 8 inches long. (See February, 1929, issue, SCIENTIFIC AMERICAN.) The solution of this problem consists of a variation of that employed in the "hanging bridge" on the Denver & Rio Grande Western.



SERVING A TOURIST SECTION

Map of the Nice-Coni Railway, with its branch line to Ventimiglia, showing bridges and tunnels

Another interesting structure is the Saorge Bridge which spans La Roya River at a height of 197 feet and has an arch with an opening of 131 feet 3 inches, while another remarkable crossing of the same river is the Scarassoni Bridge near the frontier. This consists of a main span comprising an open-spandrel arch of 160-foot span with its crown 148 feet above the stream. It is flanked by approaches embodying arches of 42½-foot span.

Many of the difficulties which confronted the engineers in the construction of the Nice-Coni line must be ascribed to the unstable rock formation of the Alpes-Maritimes. This is largely of a chalky nature in distorted and faulted stratification. In some cases the strata stand almost vertical or lean toward the valley so that loss of support through excavation could easily have resulted in great slides. As a result, large expenditures were made for retaining walls, while on some mountain slopes where ordinary practice would call for side hill cuts, it was deemed unsafe to disturb the slope by excavation and the line was supported on solid or arched masonry viaducts.

IN addition, it was found that the water from many underground water pockets caused the rapid disintegration of the mortar used in the masonry of tunnels and retaining walls, and special steps had to be taken to prevent this water from reaching the mortar. The large amount of special construction which was thus necessary throughout the length of the line naturally had a marked effect on the cost of construction, which amounted to nearly 450,000 dollars per mile.

Apart from the value of the new line from an economic standpoint, it will also tend to foster a very considerable tourist traffic. Hitherto there has been little opportunity for the visitor to the Mediterranean coast to penetrate into the interior of the Alpes-Maritimes and the adjoining provinces of Italy except by the comparatively slow motor coach service. With the coming of the new railway, however, a more rapid route has been opened, which abounds in picturesque scenery and new playgrounds.

Sinanthropus, the Peking Man

As Evidence Accumulates, the Million-Year-Old Fossils Found in China Are Assuming Increasing Importance

ANTHROPOLOGISTS are attaching vast significance to the fossil finds that have been reported from time to time from the vicinity of Peking, or Peiping. As the possible significance of these fossils gradually emerges, men of science are filled with eagerness to see the excavations completed; likewise to know the full evolutionary meaning of the finds already made. It is manifestly impossible to make more than a preliminary determination short of painstaking, detailed study at present. No discovery of fossil man since that of *Eoanthropus*, the "Dawn Man" of Piltdown, England, has aroused interest to such a fever pitch among anthropologists.

Owing to the accident of geographical location the belief appears to have become widespread that the fossils of *Sinanthropus* were those of an ancestral Chinese. No such asumption is justified by the facts, for the antiquity of *Sinanthropus* is doubtless a million years. The existence, even 10,000 years ago, of a race in a part of the world which the original owner of the bones in question inhabited 100 times as far back in the remote past is doubtless little if any more than a coincidence.

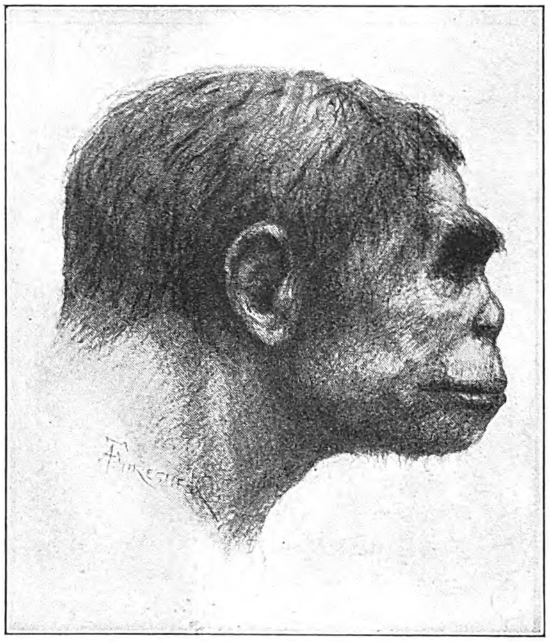
SCIENCE has but small knowledge of the origin of the human races, with regard to time, place, cause, or manner. In 1,000,000 years, or even 100,000 years, a race would have ample time to have passed through many vicissitudes, wandering far afield from its point of origin. Therefore the search for the "cradle of the human species" is likely to prove elusive. The human species evolved from some earlier animal, and this process doubtless took place gradually, covering a vast period of time. When, then, and where in its possible wanderings, can the human species be said to have been cradled? Had we a perfect rather than a fragmentary collection of ancestral fossils the impossibility of attempting to choose the "beginning" of humanness in what would then be seen to be a long, gradual transition doubtless would become more patent.

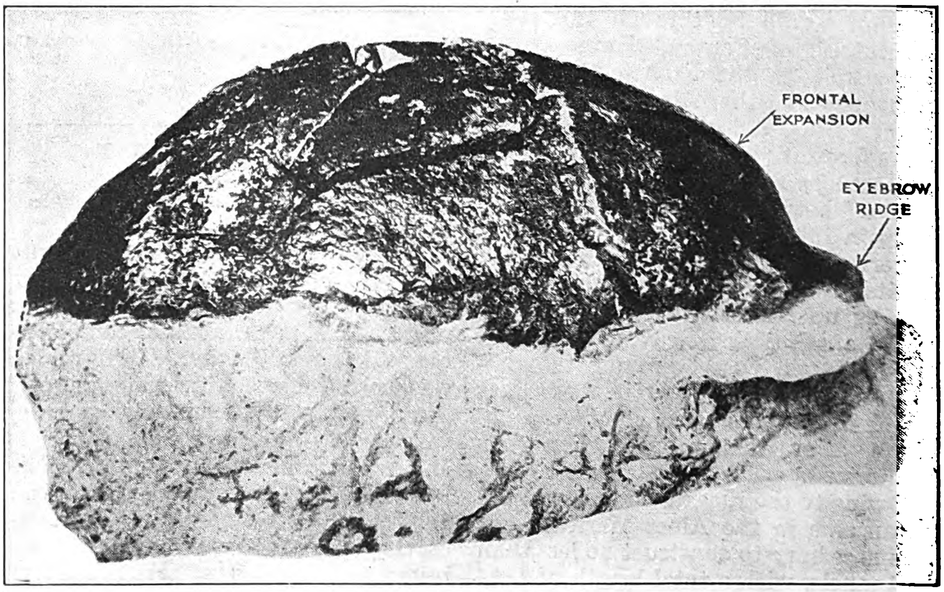
From our contemporary, the *Illustrated London News*, we reproduce the accompanying illustrations and quote the following comment on the Peking Man (by the way, the single skull found has turned out to be that of a woman), written by Professor G. Elliot Smith, Professor of Anatomy in the University of London, author of "The Evolution of Man" and other books, also of several articles previously published in the SCIENTIFIC AMERICAN, and one of a dozen leading authorities on human evolution. Professor Davidson Black, to whom Dr. Elliot Smith refers in his opening paragraph, is a Canadian anatomist attached to the Peking Union Medical College, and has had more to do with the discoveries of *Sinanthropus* than any other man of science.

"The discovery of the first complete brain-case of one of the three earliest and most primitive members of the human family is obviously an event of exceptional interest and importance. Most people are sceptical of reconstructions of ancient skulls built up from fragments. Hence the finding of a specimen which is intact provides a more convincing demonstration. Professor Davidson Black's courtesy in permitting the reproduction of the photograph, which reveals part of the wonderful fossil, makes it possible for us to appreciate something of the significance of what is probably the most illuminating discovery of early human remains ever made.

"Until November, 1928, nothing was known of the existence of the early Pleistocene Man in China, beyond some teeth, on the basis of which Professor Davidson Black, with great daring, created the new genus and species of the human family, *Sinanthropus pekinensis*, to which he assigned approximately the same antiquity as the famous apeman of Java, *Pithecanthropus*, found by Dr. Eugene Dubois in 1891. On the last day of the excavations in 1928, however, Dr. Black's boldness was completely justified by the discovery of fragments of two jaws, those of an adult and a child, in association with the fragments of two brain-cases of corresponding ages.

"History repeated itself last winter: again on the closing





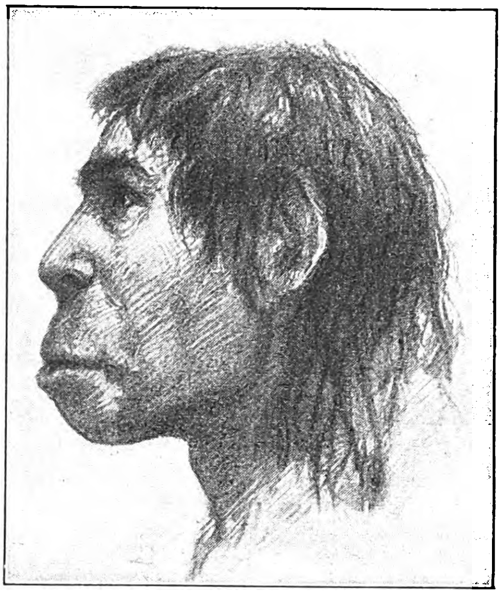
SINANTHROPUS PEKINENSIS

Above: Restoration drawing from *Illustrated London News*, by A. Forestier, from scientific data by Prof. G. Elliot Smith. *Below:* The Peking skull mounted on a plaster of Paris base day of the season's excavations (Dec. 2, 1929), the young Chinese paleontologist, Mr. W. C. Pei, of the staff of the Geological Survey of China, while excavating the sheltered recess of the main deposit at Chou Kou Tien, discovered the greater part of an uncrushed adult skull of *Sinanthropus pekinensis*. Mr. Pei at once recognized the importance of the specimen, and personally carried out the difficult work of excavation and preparation of the block of matrix in which it lay. It is entirely due to his skill and devotion that this bulky mass, with its unique and fragile contents, reached the Peking Laboratory quite undamaged.

"CONTRARY to the reports which have been circulated, no skeletal parts other than the skull and numerous isolated teeth have been recovered during this year's excavations. The different sites where *Sinanthropus* has been discovered in the Chou Kou Tien deposit are all clearly contemporaneous with one another, being Lower Quaternary in age. The evidence collected in a preliminary report on the geology and paleontology of the site by Père Teilhard de Chardin and Dr. C. C. Yong definitely establishes this fact. Though hundreds of cubic meters of material have been examined, no implements or artifacts of any kind have been found, nor has any trace of the use of fire been observed.

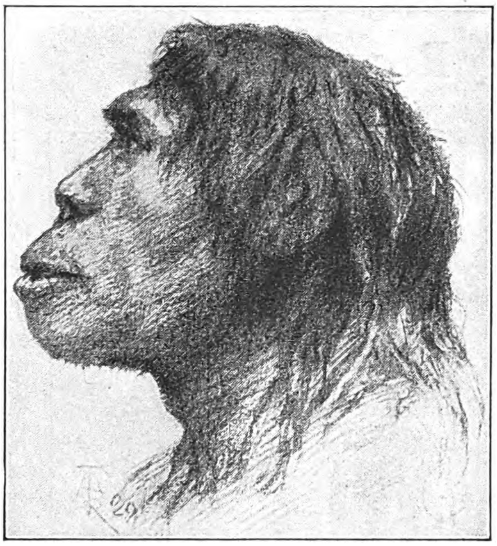
"The photograph of this skull enables us to get a much more exact idea of the nature and affinities of this early inhabitant of eastern Asia than earlier descriptions conveyed, and we are able to correct misunderstandings arising out of the telegraphed reports. The greater part of the left side and the forepart of the base of this unique skull is still embedded in a block of very hard travertine. The vault, from its massive brow-ridges in front to the back of the skull, and the whole right side seen in the photograph, were embedded in a relatively soft matrix, which has now been removed. The brain-case has been almost completely preserved, while most of the facial region would seem to be lacking.

"The skull of *Sinanthropus* is of approximately the same length as that of *Pithecanthropus*, and, like the latter, is provided with massive brow-ridges. However, *Sinanthropus* differs from the Java ape-man in the following important features: there is a slight filling out of the forehead; expansion of the localized parietal eminences on the sides of the head above the ears; and a greater height of the vault. All these differences point to a relatively greater brain capacity in *Sinanthropus*. The mastoid processes (not seen in the photograph) are small and rugged. The sockets in which the lower jaw articulated are well preserved on both sides, a circumstance which will be of great value in the restoration of the lower jaw from the fossils recovered in 1928. While the new specimen bears out what little was already known from the fragments found in the previous year, the perfection of its preservation will enable much to be learned that is now obscure concerning the evolution of the head in early man.



EOANTHROPUS, PILTDOWN MAN

Like the drawing below, this was made by A. Forestier from Prof. G. Elliot Smith's data

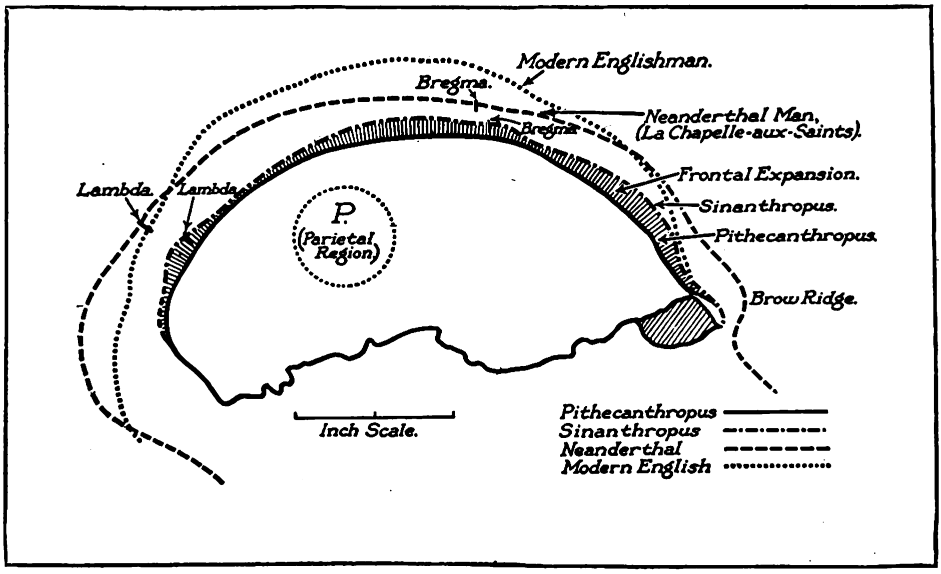


PITHECANTHROPUS, OF JAVA

The Java ape-man was a more primitive being than the Peking man, who was human

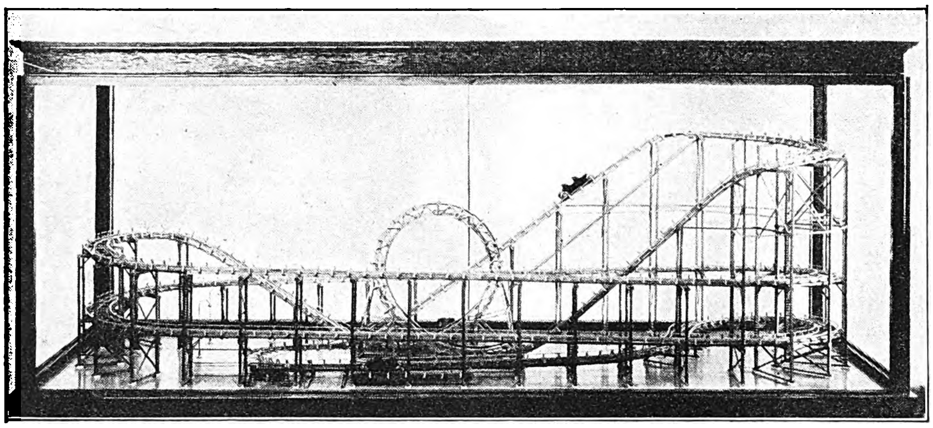
"TO show the distinctive characters of this newly found specimen, its outline, as seen from the right side, has been superimposed (in adjoining diagram) on similar projections of the cranial fragment of *Pithecanthropus*, the La Chapelle skull (Neandertal species), and a random sample of a modern Englishman's skull. Neandertal man and *Pithecanthropus* have been chosen for comparison because the new skull presents a much closer analogy to these two types than it does to the Piltdown man. There is a similar flattening of the skull, and all three have very pronounced eyebrow ridges. It will be seen, however, that in the frontal region there is a distinct fullness of the skull of *Sinathropus* in comparison with that of *Pithecanthropus* in the region marked 'frontal' in the drawing; and that the skull is slightly loftier. According to the report (quoted from Professor Davidson Black), there is a greater fullness in the parietal region marked 'P' in the diagram, which is one of the significant areas in which the human brain differs from that of the apes, and modern man from primitive man.

"The skull is, therefore, one of particular interest."



THREE FAMOUS FOSSILS COMPARED

A drawing by Professor G. Elliot Smith. Skull of Peking man compared with the Java ape man, Neandertal man, and modern man. Shape, not size, is the principal criterion



"LOOP THE LOOP"

This daring amusement device of 1901 consisted of a roller coaster with a loop in the center. The car is raised to the highest point. The centrifugal force prevents falling out

Coney Island's Museum

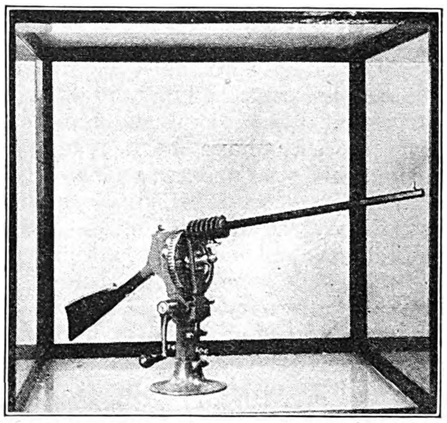
The First Institution Designed to Show Human Play-Reaction

IN a small building not far from the Coney Island boardwalk, where pleasure-seeking crowds pass up and down, is a museum which epitomizes the whole idea of the amusement center. This summer resort furnishes facilities for enjoyment which are fully equal to its more aristocratic New Jersey neighbors. Once you are on the wide boardwalk you have the sand, the same sun, and the same ocean. In no other country can such a fine sea resort be reached from a center of population, for only five cents. You can go from Queens Borough through Manhattan and Brooklyn to the "Island" for a nickel.

This summer will probably see plans mature for a larger museum building located on Ocean Parkway and accessible from all quarters. The City of New York will give a plot of ground of sufficient size to build a museum which will be adequate to the subject and which will be a fitting monument to the period of the Elegant Eighties and the Golden Nineties when the amusement enterprises of Coney Island were raised to a high, clean level. This was done with the aid of a band of inventors who are to be commended for their efforts to promote a good time for many who live a rather drab life and whose occasional outing by the sea gives healthful relaxation.

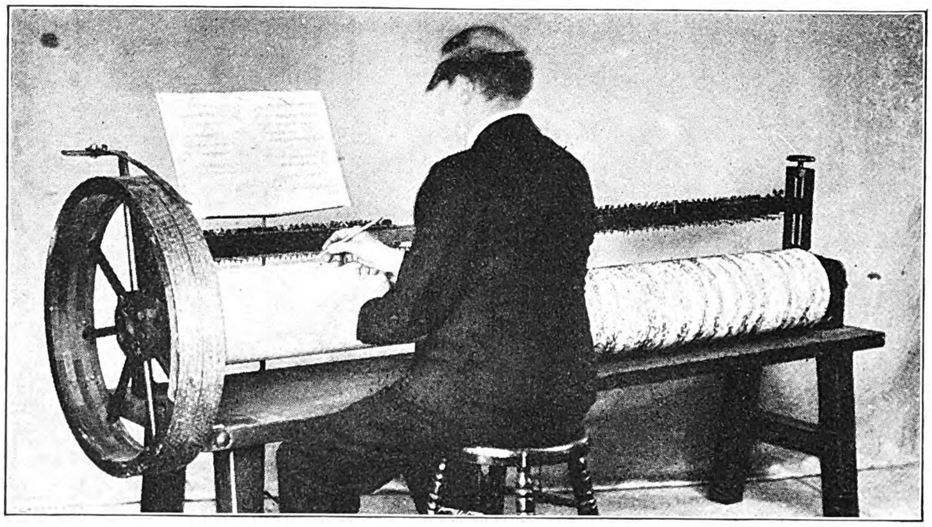
THROUGH the courtesy of Mr. William F. Mangels, himself a well-known inventor of amusement devices and one of the moving spirits in the enterprise, we are enabled to give our readers the first description and illustrations of the "American Museum of Public Recreation."

At present the Museum is housed in a temporary laboratory and storehouse on West Eighth Street, on the corner of Sheepshead Bay Road. The underlying plan is to resurrect the Coney Island of other days from authentic sources. This is the first institution ever devoted to the showing of the human play-reaction as expressed through facilities which man has created and developed. Recreation has become a scientific study in recent years. The establishment of a museum which will show the genius and development of outdoor amusements, the change in public taste and demand from year to year, and the psychology on which the success of recreations depends, fills a well defined need. The functions of such a museum are defined in the Charter which states that the institution acts "as an historical museum of public recreation exhibits, with power to collect and publicly exhibit amusement and recreational devices, novelties, inventions, mechanical and decorative amusement conceptions, and to accumulate and maintain a library and records pertaining to the history and progressive development thereof." The wealth of material



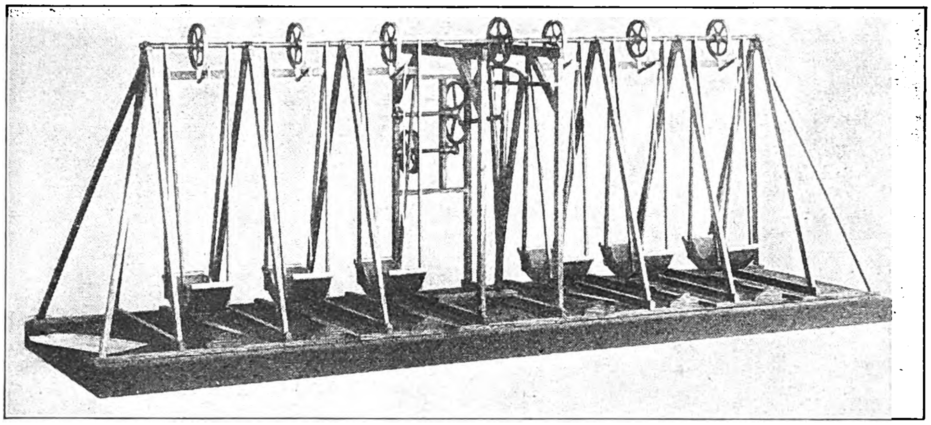
MACHINE GUN FOR GALLERIES

The gun fires by turning a crank. It can be pointed to all parts of the gallery



ORCHESTRIAN

The "orchestrian" was a forerunner of the unit orchestra of today. It was operated by weights and was coin controlled. Instead of a perforated roll it had pins driven in a barrel available for this institution is apparent. America leads the world in the production of novel recreational devices and the development of municipal playgrounds. The National Association of Amusement Parks is sponsoring the Museum.

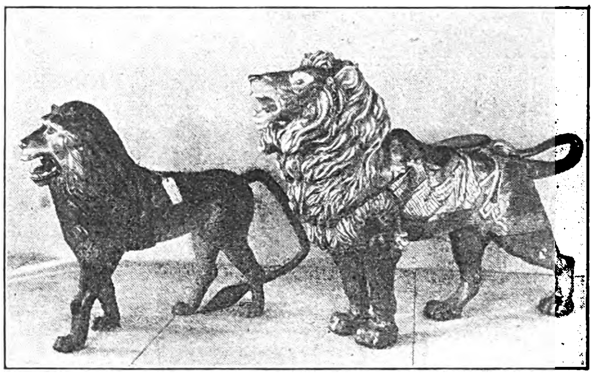


STEAM OPERATED SWINGS

Here operation by the exertions of the persons occupying the seats was replaced by steam power. The occupants started swinging by pulling the cord which operated a band brake

HERE we find examples of the work of Frederick Thompson, who was the creator of "Luna Park," "A Trip to the Moon," and "Toyland," and who built the New York Hippodrome that is so soon to succumb to the crowbar and torch of the house-wrecker. In the Museum will also be found a unique set of carving tools, benches, hand screws, et cetera, used in carving some of the original lions for carousels by the American founder of this industry, G. A. Dentzel. The collection of musical instruments is highly interesting and includes some of the early "orchestrions" operated with pin cylinders and weights. There is also a monkey organ 150 years old and a street piano of 1862 which inspired the ever-popular "Sidewalks of New York." Most of us have forgotten the "melodian" but an example is here. Some time the phonograph of 1885 will be a great rarity, but one will be found in this collection.

Some of the framed photographs and posters are priceless to the collector and student. Many of the devices can only be shown by models, their bulk is so great. A model of a roller coaster may cost several thousand dollars. Such models are being built at Mr. Mangels' amusement device factory a short distance away, where expert model makers are engaged in their fabrication. It is fascinating to watch these clever mechanics work to the minute scale which the model demands.



A PAIR OF LIONS

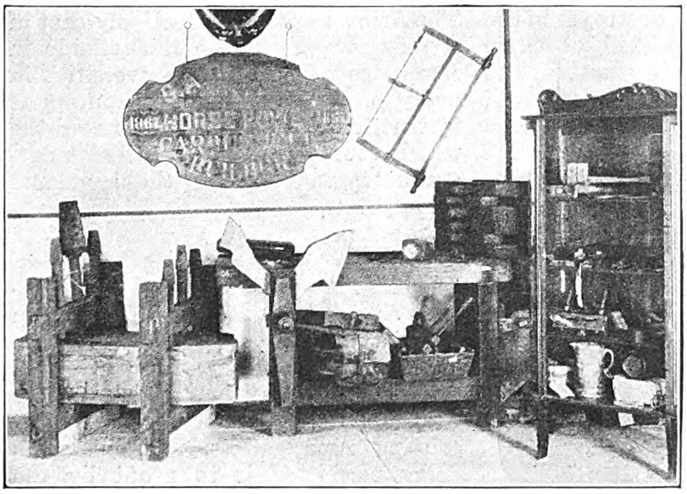
Here we have a pair of carousel lions. There is approximately one hundred years difference in their ages

THE MODEL MAKER

The clever little models are made to scale. The "loop the loop" model shown on opposite page cost 3200 dollars to build

Perhaps the most amusing exhibit in the entire Museum is a pair of carved lions. The smaller lion is of the vintage of 1831. It was carved by Michael Dentzel and was brought to this country on a sailing ship. The other lion was carved by his grandson, William A. Dentzel in 1926. This exhibit shows a real development in the art. We are now going to give away a secret of the business—most of the "merry-go-round" horses, lions, and other animals are now not carved at all but are cast of aluminum and are made of two pieces joined together.

The Museum is one which does not rule out modern devices. For example, Mr. Mangels exhibits one of his machine guns for shooting galleries. The revolving disk holds 60 .22 caliber cartridges. The gun is operated by turning the crank. It can be pointed to all parts of the gallery but stops prevent its being turned in other directions. The empty disk may be quickly replaced by a loaded one. The barrel is easily replaced by another if overheated.

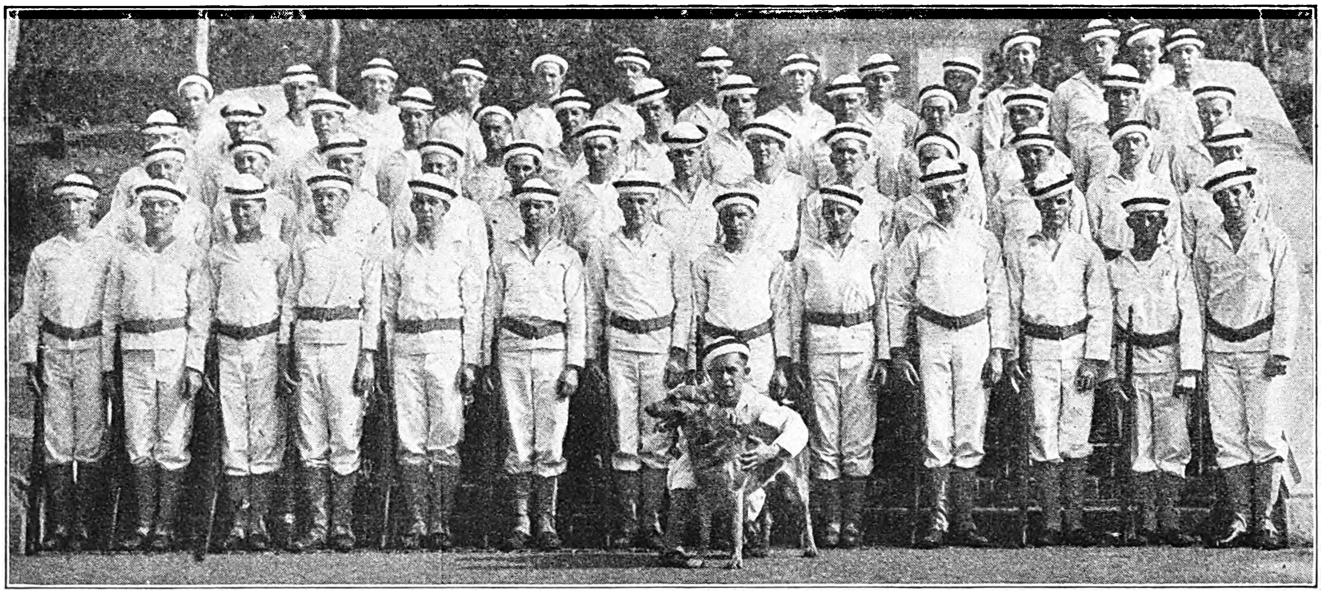


OLD TOOLS

These old tools are priceless. Here we have benches, vises, saws, clamps, and everything the old carver needed; a unique collection

PART OF THE MENAGERIE

No, this is not the "zoo," but a collection of the playmates of children during the last century. Some of them were worn out



PIONEERS OF THE CALIFORNIA UNIT

The 1930 class at the University of California, soon after their enrollment in 1926. The successful ones will receive with their diplomas this June commissions as Ensigns in the United States Naval Reserve. Much of their training has been aboard ship

Midshipmen at 'Landlubber' Colleges

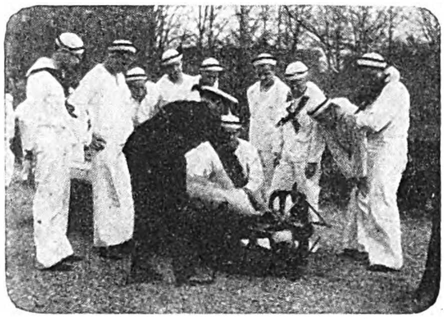
Six Great Institutions Co-operate With the Navy in Preparing Naval Reserve Officers for Sea Duty

By CAPTAIN W. D. PULESTON, U. S. N.

THE senior classes at Harvard, Yale, Georgia Institute of Technology, Northwestern University, University of Washington, and the University of California, now include for the first time a group of Reserve Midshipmen, who have completed their naval course. The successful ones will be tendered with their diplomas commissions as Ensigns in the United States Naval Reserve. In the event of war, these specially trained graduates will be qualified to take their places aboard ship as junior line officers of the Navy, carefully prepared for their specific duties aboard ship. Behind this pioneer class of 1930, there are already entered Reserve Midshipmen in the classes of 1931, 1932, and 1933, and it can now be safely stated that the Naval Reserve Officer Training Corps is fairly launched, and that each succeeding class in the years to come will graduate its quota of Ensigns of the Naval Reserve.

DURING the World War the commissioned line officers on the active list of our Navy were increased from about 2100 to about 21,000 — roughly ten-fold. The additional officers came from various sources. Many were former warrant officers and enlisted men of the regular service; others came from the Naval Militia and merchant marine; and still others came into the Navy directly from civil life. Some of those from civil life, who were recent graduates or under-graduates of colleges or universities, were sent, soon after their enrollment in the service, to the United States Naval Academy at Annapolis where they were given an intensive course, lasting three to six months, in seamanship, naval ordnance, and navigation.

Graduates of this intensive course made unusually good junior officers, readily adapting themselves to life aboard ship, and quickly grasping the essentials of their various tasks. To indicate the Navy's dependence on its reserve officers, it is only necessary to recall that during 1918 the commissioned complement of a destroyer in the war zone usually consisted of three regular naval officers, the Captain, the Executive (who also navigated) and the Chief Engineer, while the Ordnance Officer, the Signal Officer, and all the watch officers were volunteers, most of whom were college men who had successfully taken the intensive course given at Annapolis. The Atlantic Fleet, based in home waters and engaged on a huge training program, carried an even larger proportion of volunteer officers.



PRACTICAL INSTRUCTION

Students at the Georgia Institute of Technology study torpedo mechanism

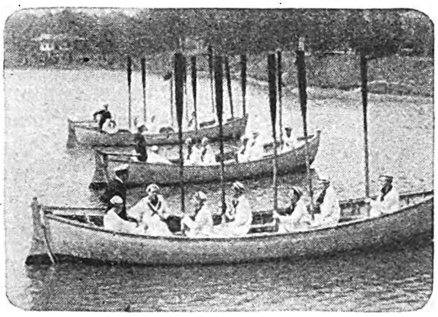
The United States Army during the World War was obliged to train and commission many more reserve officers than the Navy, and immediately after the war very wisely determined to establish a permanent system that would produce in time of peace an ample supply of trained reserve officers. The Army worked so effectively that in a very few years it had available in numerous colleges and universities in every part of our country, courses of instruction that, in addition to the usual courses taken by the undergraduates, would qualify these students for appointment as Second Lieutenants in the Army.

THE Navy, also, realized the necessity of training reserve officers in peace time, but it was 1925 before authority was obtained from Congress to establish Naval Reserve Officer Training Corps units similar to the existing Army units. The Navy's delay permitted it to profit by the Army's experiences, and much of the success of the Navy's effort is due to the cordial co-operation and assistance it has received from its sister service.

The Navy's need for officers in the event of a major war, will never be as great as the Army's, so, at the start, naval units were established in only six institutions, with the intention that, as experience was gained in the operation of these units, a few additional units would be established in other institutions. In order that these courses might be readily available to American students in all parts of the United States, it was necessary to distribute them in educational institutions regionally; it was also necessary to establish them in institutions with a sufficiently large student body to insure obtaining enough students to justify the maintenance of a naval unit; and most important of all, it was essential that the standards of scholarship at the selected institutions be so high that the Navy could be sure that the students would be well grounded in all the regular university courses. Another important factor in the selection of the six institutions was the attitude of the president, faculty, and student body towards the naval unit, and it is a pleasure to record that, in all of those chosen, a warm welcome has been given naval units by the entire personnel.

HARVARD has always been conspicuous for its willingness to cooperate with the government in any endeavor, and from the beginning, President Lowell gave the new naval unit his powerful assistance. The headquarters of the First Naval District and one of our largest navy yards are in Charlestown; and their proximity to Cambridge also facilitates the administration of the naval unit, and enables the students to familiarize themselves with the operation of a navy yard and to inspect visiting ships. Much of the Navy's early history centers around Boston and vicinity, Harvard treasures many traditions of our early days, and an intangible but powerful bond between Harvard and the Navy results.

Yale, located on Long Island Sound, is no less favorably situated for a naval unit. During the World War it almost converted itself into a naval academy, and President Hadley in one of his annual reports calls attention to the ease with which Yale could be made into an emergency naval academy. Finally, the famous Yale spirit assures a fine morale among the members of the naval unit.



STUDENTS AFLOAT

Part of the unit at Georgia Tech takes a turn at the oars on Lake Piedmont

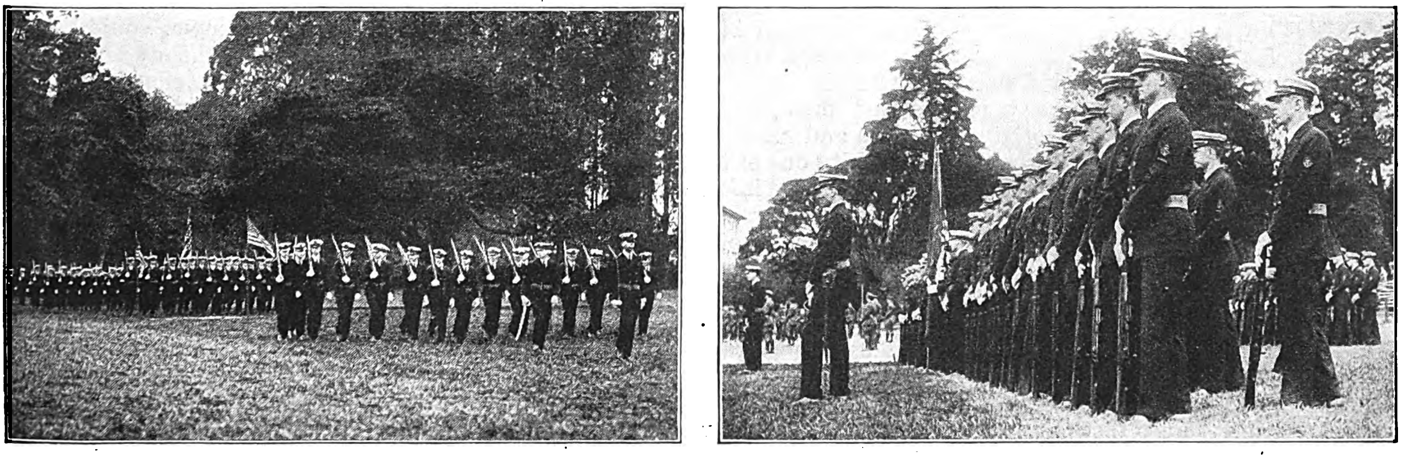
Situated inland at Atlanta, the Georgia Institute of Technology may not, at first thought, seem adapted for a naval unit, but the enthusiasm of President Brittain and the loyal support of the faculty and students have overcome the geographical difficulties. On Lake Piedmont, in the heart of Atlanta, the naval students are trained in navy cutters, to pull an oar and to handle boats under sail; while on the campus an ingeniously designed bridge, fitted with a standard compass and wheel, permits instruction in compass correction and steering. The Tech unit is very enthusiastic and always sends a large contingent on the summer cruise. The standard of scholarship at Tech is very high, and athletics and physical training are encouraged, so the student body furnishes plenty of excellent officer material.

Northwestern University, at Evanston, on the shores of Lake Michigan, lies about half way between Chicago and the Great Lakes Training Station. Like Yale, in an emergency, it could readily be converted into a naval academy. President Scott served in the Army during the World War and is still in the Reserve Officer Corps. Through his interest, a handsome boat house has been built on the campus for the use of the naval unit. Northwestern offers the young men of the middle west an opportunity to fit themselves to serve their country in the Naval Reserve.

The Ninth Naval District includes the heart of the country and embraces the populous states that border the Great Lakes, the navigable portion of the Missouri, and the Mississippi north of Cairo. It will surprise many readers to hear that this inland naval district contains more Naval Reserve officers than any other. It is expected that the graduates of the unit at Northwestern will be the future source of supply of junior officers to these mariners of our inland seas and waterways.

WASHINGTON University, on Lake Washington, on the outskirts of Seattle, is perhaps best known in the east for the superb crews it sends each year to Poughkeepsie. Dr. Suzzalo was President when the Navy Department asked if the University would be interested in a naval unit. In reply he telegraphed that the University of Washington wanted a unit and would comply with all conditions prescribed by the Navy. His fine enthusiasm evoked a similar spirit on the part of the Navy, which accepted his offer by despatch, so that Washington has the honor of being the first institution formally selected by the Navy for an R. O. T. C.

Dr. Suzzalo's patriotic interest in the Navy is a natural consequence of his enthusiasm for sea-going and the American merchant marine. During his presidency he was fond of calling the University of Washington a "sea-going university," and among its many courses is one devoted to the merchant marine and cognate subjects. Shortly after the naval unit was established at Washington, Dr. Suzzalo was succeeded as President by Dr. Spencer,



FOURTH YEAR EFFICIENCY ON PARADE

The two photographs above show the California unit in 1929 after three years of training. Comparison with the photograph at the top of the opposite page will indicate the progress in numbers and efficiency. Other institutions show a corresponding improvement who has continued his loyal support of the naval unit.

The University of California, located on San Francisco Bay, with one of the largest student bodies in the United States and a varied curriculum that could easily furnish a course practically identical with the one given at the United States Naval Academy, was an inevitable choice for a unit. President Campbell, a firm believer in national defense, from the beginning has been stalwart in the support of the naval unit. Among California's faculty are several reserve officers, all of whom have helped in the establishment of the unit.

NAVIGATION AT YALE

Above: a group of students of the Yale naval unit receiving instruction in compass correction. *At right:* members of the Yale unit are shown plotting ship's position

Vessels of the Battle Fleet frequently visit San Francisco harbor, and the Naval Reserve Midshipmen are cordially welcomed aboard and are thus afforded ample opportunity to combine practical work with their naval studies. The proximity of the Navy Yard at Mare Island and the dry dock at Hunter's Point permit the students to see the material side of the Navy.

There is a zestful spirit on California's campus which its students bring with them to their practical work on board ship.

THE purpose of the Naval Course offered to students at these six institutions, as stated in the original regulations prescribed by the Bureau of Navigation, is to supplement the regular courses taken by the naval students so that successful graduates of both courses will possess:

(a) A good general education.

(b) Sufficient knowledge of such subjects as seamanship, navigation, ordnance, military and international law, naval engineering, naval strategy and tactics, and naval communications, to fit them to perform their duties as Junior Officers of the Naval Reserve.

(c) A well disciplined mind and body.

(d) The quality of self-reliant leadership.

The naval courses are conducted by regular naval officers, who are chosen with care for this particular and exacting duty. They come to the campus directly from sea duty or from some important shore duty, and bring to the classroom the prestige of a successful career in the profession they are detailed to teach. The Navy Department is careful to send only successful officers to represent the Navy in the life of these populous educational centers, and to personify the naval service to the numerous undergraduates.

In some of the institutions, the regular professors assist in the instruction of the Reserve Midshipmen and, in return, naval officers are sometimes permitted to assist in other departments. Thus at Harvard, which for years has maintained an excellent Department of Navigation, the regular and naval classes in this subject are combined, and the instruction is carried out jointly by civilian professors and naval officers. At another university one of the naval officers was unusually well informed on combustion engines so his services were utilized in the regular aeronautical engineering course at the university. This cooperation directly adds to the effectiveness of the naval course and promotes a friendly understanding between the regular faculty and their naval colleagues.

Some difficulties were encountered in establishing these units, and while they have been overcome, it is well to note them. At every educational institution there is a positive lack of space because the demand for higher education in our country is actually much greater than our higher institutions of learning can supply; practically every department could advantageously use larger offices, more class rooms, and more extensive laboratories; so when the Navy appeared asking for its share of space it was crowding into an already over-populated region. Similarly the advent of a new course added somewhat to the complications already existing in the various schedules of study, but these difficulties were faced and gradually surmounted. The question of credits towards the regular degree for the successful completion of the naval course was one that required careful handling: the Navy Department required sufficient hours in the classroom and of outside preparation to enable naval students to master its course properly; the students could not give this time to the naval course unless they obtained sufficient credit towards their regular degree; the deans could not give the credit until they were satisfied of the intellectual content of the naval course and its cultural value to the student.

THE situation created a neat triangular problem between the Navy Department, the institutions, and the students, but it was solved when the deans realized that there was nothing easy about the naval course, and that the naval instructors would insist upon high standards of scholarship and in many cases would bring to their tasks the experience of an instructor or even of a head of a department at the Naval Academy.

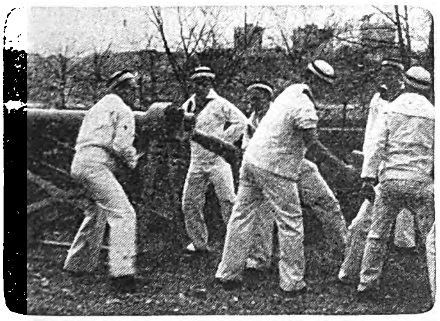
But it should be added further that there are compensating factors. Responsible university authorities realized that the presence of a well-conducted naval unit on the campus would have a stabilizing effect on the student body, that a group of naval students who had learned from practical experience aboard ship the absolute necessity of discipline and who had unconsciously imbibed a respect for constituted authority would have a steadying effect on the other students that would be helpful to the university. And it was generally acknowledged that the quality of self-reliant leadership resulting from naval training would be of great value to the students after graduation.

Even the best universities can not produce junior naval officers without giving them actual sea duty, so the Navy Department provides that no student will be commissioned as an Ensign unless he has successfully completed one practice cruise on a battleship and all are encouraged to take practice cruises every summer during their school vacation. Students from California and Washington cruise in the Pacific and usually visit Victoria and Vancouver in addition to their home ports on the coast; students from Harvard, Yale, Northwestern, and Georgia Tech cruise in the Atlantic and usually call at Halifax, Bermuda, or Havana in addition to some of our east coast ports.

On these cruises, which last about two weeks, the Reserve Midshipmen obtain a practical knowledge of their duties at sea; they work navigation, carry out gun drills and target practice, stand junior officer watch, familiarize themselves with the routine of a man-of-war, and at a receptive age unconsciously absorb our naval traditions and habituate themselves to the customs of the sea.

In addition to becoming acquainted with Navy personnel on these practice cruises, members of reserve units get well acquainted with each other, and while they are encouraged to retain the spirit of their own institution, their surroundings influence them to join together in one body, to develop a Naval Reserve spirit, and, finally, to merge themselves entirely with the naval service.

Besides the regular summer cruises, the Navy Department has authorized these students to embark on the regular week-end cruises given reserve officers and crews, to take passage on vessels of the fleet whenever convenient for them, provided their presence aboard does not interfere with the ship's schedule of work, and on special occasions students have been allowed to take passage on a man-of-war going from one coast to the other.



IN WORKING CLOTHES

Gun practice at Georgia Tech. Such work reflects the completeness of the course

Aboard ship, the Reserve Midshipmen are treated exactly as regular Midshipmen. Their service uniforms are identically like those worn by the regular Midshipmen except for a device on the sleeve; they mess together in junior officers' quarters usually referred to as the "steerage"; and are furnished white working clothes in which they can pull an oar, load a turret gun, crawl through a boiler, or inspect a double bottom. From the moment they are accepted as Reserve Midshipmen they are treated as junior officers and in return are expected to bear themselves at all times in an officer-like manner.

A requisite for enrollment in the naval unit is a deep interest in the Navy, which the Department hopes to make abiding, and a sincere determination to enroll in the Naval Reserve after graduation. Obviously, the government can not afford to give this training to students who at the end of four years will turn their backs on the service. There has been no difficulty in securing sufficient students who are fond of the sea and interested in naval affairs to enroll.

Wherever these young reserve officers go in the United States after graduation they will find fairly close to them some Naval Reserve unit or some regular naval activity to keep them in touch with the service. Generally speaking, it is probable that a majority of the graduates will eventually settle in or near the region of their alma mater. Consequently it is a reasonable hope that in time the Naval Reserve of the various naval districts will come to regard the institution within their district as their Naval Academy from whence they can annually expect their quota of reserve ensigns to replace those who for any reason have disenrolled or have retired.

Fortunately for the success of this new Navy undertaking, Secretary Wilbur realized its importance from its inception and never failed to give it his strong support; amid the press of other duties he would find time on his inspection tours to visit units adjacent to his route and took pains to inspect the units embarked on board ship for the summer cruise.

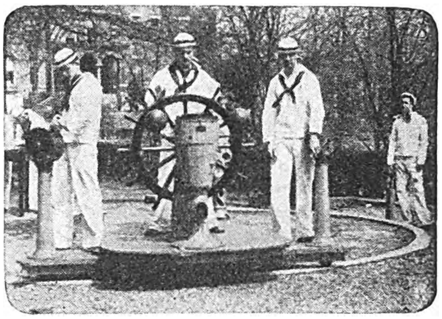
Secretary Adams, whose long association with Harvard has familiarized him with modern university life, also takes a keen interest in these naval units, as is indicated by the following extract from his letter to Mr. Richard Chamberlin, Commander American Post Number 42, American Legion, Evanston, Illinois, expressing the Department's appreciation of a medal awarded annually to the honor student of the naval unit at Northwestern University:

"The course in Naval Science and Tactics is intended to fit students to perform duties as junior officers in the Naval Reserve. But it does more than that. It brings out and ripens the qualities of self-reliance and leadership which are not only required in young officers but are essential in promoting the highest type of American citizenship. It is fitting, therefore, that recognition of merit among students of the unit at Northwestern should have been given by the American Legion.

Very truly yours,

(Signed) C. F. Adams."

In the spring of 1917 after the United States had severed diplomatic relations with Germany, and when it became increasingly evident that hostilities could not be avoided, the Navy began to enroll for active duty some volunteer reserve officers. The first enrolled were some young yachtsmen in the Second Naval District who, on their own initiative in the summer of 1915, had organized a volunteer patrol squadron of their own yachts and trained themselves under the direction of regular officers to operate against submarines. From this very small beginning, the Navy continued throughout the war to carry on simultaneously its training program and its operations against Germany.



SHIP'S BRIDGE ON LAND

Compass correction and a trick at the wheel on the campus of Georgia Tech

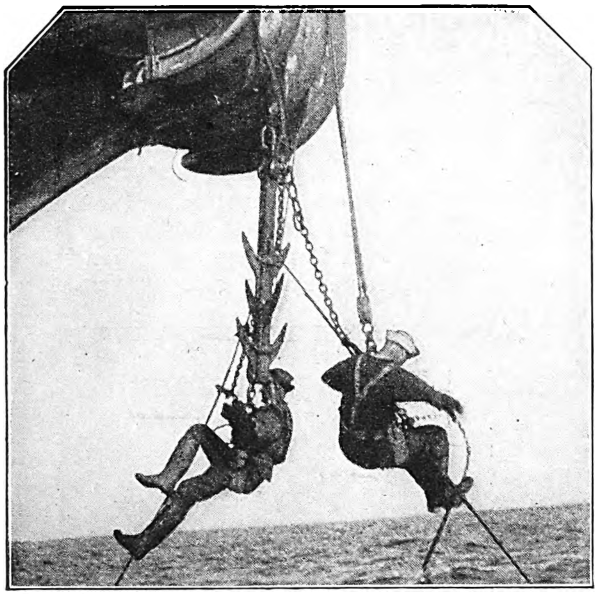
But our just pride in their abilities and the Navy's war achievements should not blind us to the fact that even such fine raw material required at least a year, with all the stimulus of a war atmosphere, to become useful naval officers. Manifestly, in future wars we should not depend upon the enemy giving us a year after hostilities begin to prepare our commissioned personnel.

Reserve officers who served in the Navy during the World War should regard members of these Naval Reserve Officers Training Corps units as their natural professional descendants, and aid and encourage them in every way; and the members of these units should familiarize themselves with the achievements of the reserve officers in the last war so they will realize fully their future duties and responsibilities. As these reserve officers grow in numbers and efficiency, it is not too much to hope that their existence only may prevent a possible enemy from attacking us as did Germany on the assumption, happily erroneous, that the United States could be defeated before it could develop its latent military power.

Linemen of the Sea

When Transatlantic Cables Are Broken, Men Must Be Sent to Splice Them

By JOSEF W. VON STEIN



Courtesy Commercial Cable Company

THE CABLE IS UP

Workmen lowered in bosun's chairs attaching stoppers to cable. After cutting, both ends are hoisted on board

An epic of the sea was enacted during the past winter in the icy, gale-torn reaches of the cold North Atlantic. A continuous struggle was staged by storm and elemental forces pitted against Man and his aides: highly developed scientific equipment and organized industry. Little did many of us realize at the time, that resolute "linemen of the sea" were fighting against overwhelming odds—midwinter cold and terrific storms—to maintain electrical communication service between two continents.

The earthquake* which upheaved the bed of the Atlantic and which seismographs registered November 18 and 19, caused havoc among the spider-like webs comprising the transatlantic cables. "About half past three on the afternoon of November 18," we were informed by Mr. A. E. Powell, Vice President and Chief Plant Engineer of the Commercial Cable Company, "we had the first intimation of the tasks confronting us, when a 'phone message from the main operating room in New York informed us that they had 'lost London' on all circuits.

"A few minutes later other messages began to come in from relay stations that their circuits were upset. The Canso, Nova Scotia, station reported a severe earthquake. Their instruments were badly shaken, and they believed that breaks in the cables had occurred. Routine repair work was begun, and three circuits were patched up to get the most important messages across. Within 15 minutes after the earthquake disturbance, reports came through from the Far Rockaway, Long Island, station to the effect that their tests showed that both cables from New York to St. Johns had been broken at approximately the same geographical position.

"Communicating with Mr. G. H. Ridge, Chief Cable Engineer, Western Union Telegraph Company, we learned that their tests showed breaks in both of their New York to Bay Roberts cables running through the same geographically situated sector. Meanwhile, Canso had effected temporary repair of their shaken instruments; but their tests showed the loss of the two Canso to Fayal cables which also passed through this apparently disturbed center."

The final tabulation showed that a total of 12 of the 21 cables connecting North America with Europe had been silenced. The powerful machinery of the highly organized cable industry began to function. The Commercial Cable Company's repair ship, *John W. Mackay*, was off Cape Cod repairing a feeder cable. Orders were issued to stop these repairs and rush to Halifax. Two days later this ship was well under way on its trying task in the earthquake zone.

The *All America* was in the Canal Zone. Word was flashed to this vessel and it raced northward. The *Faraday* was dispatched on November 24 from England. Meanwhile, the Western Union Telegraph Company's cable ships were also put to work. The *Cyrus Field* was dispatched to work on the 1926 fast, loaded cable, which was broken in two places. The *Lord Kelvin*, working at the time with the *Dominia* to repair the 1924 New York to Azores cable, which was broken in two places, later went to complete the work begun by the *Cyrus Field*.

The first indication that a cable is broken or faulty is the failure of the receiving instruments in the cable stations to record incoming signals properly. When a conductor is completely broken, there is an absolute loss of electrical continuity; but in the case of a leakage in the insulation, there is an escape of current without complete loss of continuity. These leakage faults are the most difficult to localize for repair.

When the receiving instruments indicate something wrong in the line, a test is immediately made from each end of the line by means of extremely sensitive apparatus using a mirror galvanometer. Several methods of testing are used, the most general being the Wheatstone bridge balance. In this, the galvanometer, or a similar sensitive instrument, is joined up between the arms of the bridge. Since the resistance of each mile of cable was tested and charted as it was laid, accurate location of the breaks is determined by altering the resistance of the resistance box that is used, until the beam of light in the mirror galvanometer remains stationary at the neutral point. Assuming, therefore, that the known resistance per mile of cable is two ohms, and the measuring apparatus indicates a total resistance in the cable of 800 ohms, the break would be ascertained by dividing the 800 ohms by

2, which would place the rupture 400 miles from the shore.

With such information, the captains of the cable-ships were able to determine, on charts showing the positions of the cables, the latitude and longitude of their projected activities.

The ship is aided in locating the supposed position of the cable by electrically driven deep-sea sounding machines which indicate the depth, nature of bottom, and temperature at the ocean bed. Knowledge of the depth aids in finding the location by comparison with known, charted soundings; the character of the bottom determines the type of grapnel to be used; and the temperature indicates what allowances should be made for this factor in repairing the cable. The sonic depth finder is also generally employed.

HAVING arrived at the apparent location, a marking buoy is moored by mushroom anchor and line. If weather conditions are satisfactory, the actual work of grappling for the cable, reposing in the soft ooze below, can begin. Inasmuch as it may take fully an hour before the heavy grapnel reaches the ocean bottom, the ship steams to a suitable distance from the line of the cable. Should there be a strong current, the grappling is done against the current. There are different kinds of grapnels, but all have similar general features. The ordinary kind for general use has a shank about four feet long with five prongs and weighs about 250 pounds. For very deep water work, a special type of grapnel is employed, which cuts one side of the cable and clutches and holds the other. This is done to avoid excessive strain on the cable, and this type was often used during the repair work of the past winter.

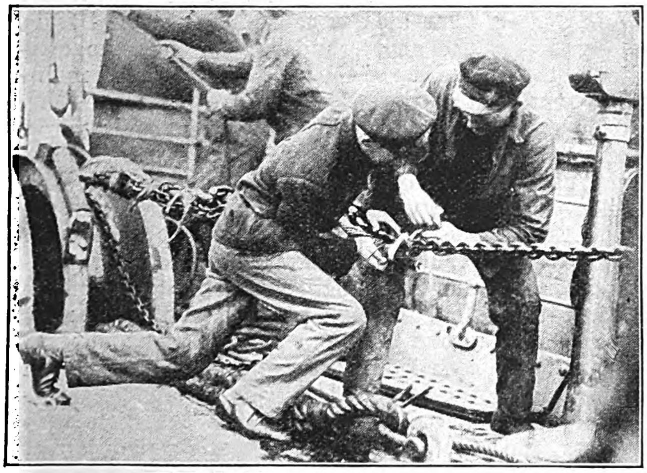
▲ THE INSTRUMENT ROOM

Some of the delicate instruments aboard the *John W. Mackay*. When the cables are brought up from below, they are tested to determine the location of the fault. Cable is also tested mile by mile as it is being laid



◄ HARD WORK

Fastening cable to grapnel chains after pulling on board, to facilitate the testing and splicing operations

As the ship proceeds across the line of the cable at a speed of one knot per hour, the iron fingers of the grapnel rake the bed. The hooking of the cable is indicated on deck by a dynamometer, which registers a steadily increasing strain on the grapnel rope, or one of the crew "sits on the cable." If rocks or other obstructions are encountered by the grapnel, the fact is shown by the irregularity of the strain on the dynamometer. In grappling for a cable only an inch in diameter far below, the cable ship must be maneuvered and handled with the greatest delicacy. It is no simple problem to move a 4000-ton ship just a few yards one way or another, especially when there is a current or heavy, wintry seas. Frequently ships had to grapple for days this past winter before the telltale strain began to register on the dynamometer.

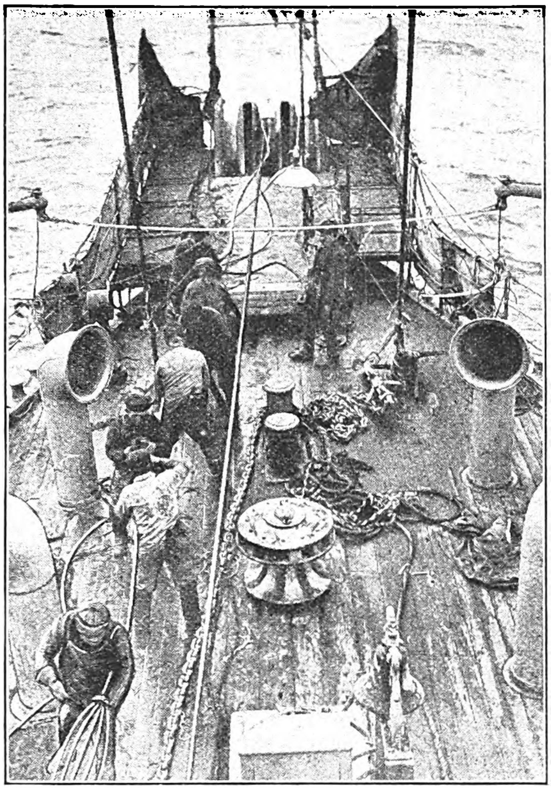
"When, at last, it appears that the grapnel has hooked the cable," related Mr. Higginson, who saw service as Chief Electrician on the *John W. Mackay*, "the engines are momentarily stopped to ease the strain on the cable, and orders are issued for 'full speed astern,' to keep the ship in this position. The dynamometer is carefully watched. Practical experience has taught us to know if the cable is hooked. If this is the case, word is passed to 'stand by to pick up.' There is a tense expectancy all over the ship.

"If the visibility is low, 'lights on' are ordered. The boatswain calls the watch. The ship is brought up to keep the long, heavy grapnel line leading away now from the bow sheaves. The captain stands on the foc'sle head, alternately watching the line coming slowly aboard and turning around to watch the strain registering on the dynamometer. Between times he shouts orders to the crew or to the quartermaster nearby, who stands by a duplicate engine-room telegraph. There is great danger of stretching the cable too tightly or allowing too much slack. The rise and fall of the vessel may snap the cable. The ship, barely making headway, is steered by her engines. At her slow speed, she will not answer the helm satisfactorily.

"THE 'skipper' tries to get his ship directly above the cable at the moment the cable begins to get free of the bottom. In this way, the cable will have the shortest distance to travel to the ship. The long line continues to come slowly in. It passes along the big bow sheave and over another wheel and in turn over and under the various other wheels and braking gears. At last! The beginning of the 15 fathoms of grapnel chain, polished to a bright silver by the chalky sea bottom, breaks water!"

Men are then lowered over the bow, strapped in "bosun's chairs," and "stoppers" are placed on the picked-up cable. This means that the cable is secured by chains passing over sheaves on each side of the sheave holding the grapnel line. The cable is then cut and both ends hauled on board and connected with the ship's electrical testing room. Tests similar to those described in the land terminus are applied. The end of the cable which is found intact to the shore, is then chained to a mooring anchor with a massive seven-ton buoy attached and dropped overboard temporarily. The short end to the point of fracture is either abandoned or picked up and stowed away. When the cutting type of grapnel is used, there is, of course, no short end.

The ship then proceeds on her way to grapple for the other end. The above grappling process is then repeated. This end is then spliced onto a length of spare cable on board. A skilled jointer and his assistants clean and solder together the ends of the



Courtesy Commercial Cable Company

THE FINAL SPLICE

Scene aboard a cable ship while the splice is being made between grappled cable and the new section

central copper wire or conductor. In the newest types of cables the copper wire is wound around with flexible copper tapes. Thus, should the central wire break, these flexible copper conductors will carry the current around the gap. Around this conductor is wound a single continuous strip of Numetal one eighth of an inch wide and six thousandths of an inch thick.

The total diameter of the conductor and its Numetal wrapping is just a fraction short of a fifth of an inch. Over this central core, the jointer then draws the gutta-percha covering from each side and applies two or three more coats of the same material.

Oddly enough, at this point the health of the men who work the hot gutta percha is important. If the jointer's perspiration is acid, this would cause the gutta percha to harden soon and develop a fault. Also, an imprisoned air bubble will later cause trouble since the pressure at a depth of 18,000 feet is 8000 pounds per square inch.

WHEN the jointer has finally completed his task, the joint is placed in cold water for about 20 minutes to harden. The splicer then places a serving of jute yarn around the core as a cushion for the armor wires. These wires are put back as nearly as possible in their original lay, and a heavily tarred jute yarn is put on tightly over a distance of 15 to 20 feet. The splice is complete and the cable is dropped overboard.

The ship then begins to pay out toward the end which was originally left buoyed. This is again located and taken on board. The two ends are tested in the electrical testing room by the chief electrician. If the results are satisfactory, the ends are then spliced, dropped overboard, and another cable has been put back in service.

It is interesting to note that this laying of a new length of cable is not an easy matter even in calm seas. It is of utmost importance to know the topography of the ocean bed before the cable is laid, to avoid suspending the cable between submarine hills. Unless it rests on the bottom all the way across, it would be only a matter of time before it would break under the strain. Since it was feared that the earthquake had changed the contour of the ocean bottom, new surveys were necessitated. These surveys, as mentioned before, consist of deep-sea soundings which determine the depth of water, produce specimens of the bottom, and give the temperature of the water. If, by chemical analysis, it is learned that there is any mineral deposit on the bottom which would seriously affect the cable, or if the temperature should show that there is volcanic action at certain places, these places have to be avoided.

THE sounder invented by Rear Admiral Sigsbee, United States Navy, probably possesses the essential features of the others and may be taken as a typical one. It consists of a central tube fitted with valves at top and bottom, and three smaller tubes fixed beneath the central one. As the sounder descends, the valves open upward and the water rushes through. When the bottom is reached, the valves close, and a sample of the bottom water is retained. The three smaller tubes sink into the ooze, and bring specimens of it to the surface for analysis.

A low temperature increases the conductivity of the copper wire and the insulating qualities of the gutta percha covering, and is therefore desirable for cables. It is known that a conductor when normal gives a certain resistance per nautical mile at a given temperature. Thus a knowledge of the temperature of the bottom is indispensable for accurate results should the cable require testing for some future break, and in taking soundings a thermometer is always attached to the wire a short distance above the sounder. As we know, an ordinary thermometer cannot be used in great depths as the pressure causes an error of 8 to 10 degrees, Fahrenheit, and has been known to cause implosion of the bulb. Thus, for deep sounding, a special thermometer, the Miller-Casella, is used. The bulb of this instrument is enclosed in an outer bulb three-quarters full of alcohol. Before this outer bulb was sealed, the alcohol was warmed to expel some of the air. Between the two bulbs there is formed a cushion which takes up the pressure, and the inner bulb remains unaffected.

ONE of the most interesting spots on board a cable ship during the laying of new lengths of cable is the testing room. In front of a table covered with various testing devices, sits an electrician, watching a spot of light as it sways to and fro on a graduated scale. This spot is the reflection from the galvanometer mirror, and the swaying movement is caused by the induced currents set up in the coiled cable by the rolling of the ship. At the end of every fifth minute the spot gives a kick sideways on the scale, and the electrician duly notes its magnitude. This kick is caused by a signal from the shore, and proves that the continuity of the conductor is being maintained.

During this phase of repair work, careful nautical records are kept. When the length of cable has been laid, a copy of these records and charts are filed for future reference, together with results of tests and electrical measurements by engineers at both ends of the line. These records and data may prove useful at some distant date in case trouble is again experienced with the cable. It is safe to assume, however, that not one of the men who took part in the gigantic repair job of the past winter, is anxious for this time to come; for the work is infinitely hazardous and difficult.

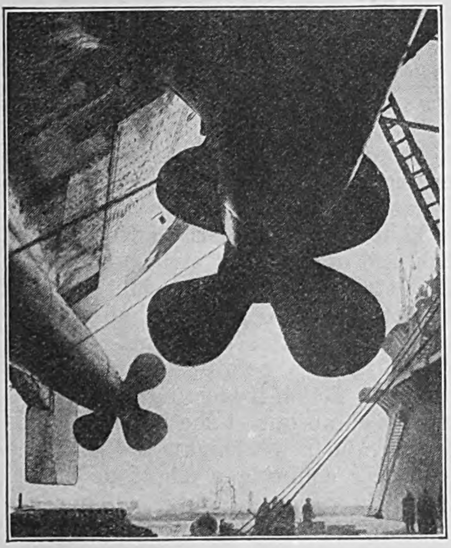
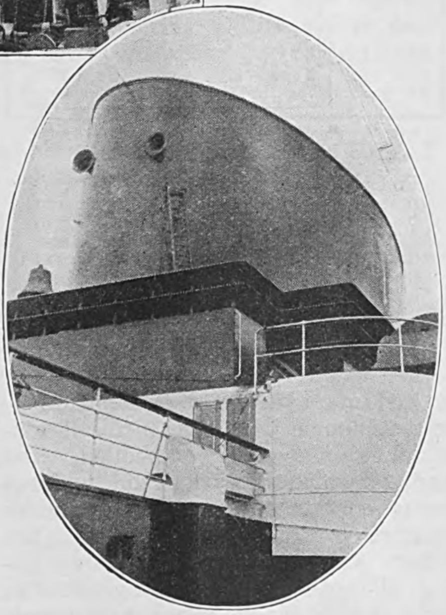
"SLIGHTLY BULBOUS"

The rounded bow was forecast after the World War, when sharp-bowed liners held the record. It creates dead water for the propellers, as against the outward push from a sharp bow

FOURTEEN-TON PROPELLERS ▼

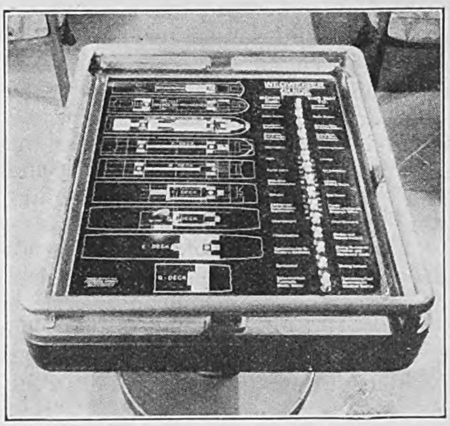
The *Europa's* propellers are smaller than those of the *Bremen* and make more revolutions per minute. Two of them churn the water outward, and two inward. The huge turbines are of 138,000 horsepower





SIRENS

The funnels, instead of being pear-shaped, as in the case of the *Bremen*, are of elliptical shape, measuring 50 feet long diameter, and 21 short diameter. The products of combustion of the oil fuel are thrown upward by a blower system. Note the semi-concealed sirens forward



THE "WEGWEISER"

These indicators, to direct passengers, are in many locations on the boat. If you want to go to the shooting gallery or the swimming pool, just press the button opposite the name and an electric light flashes up under the part of the proper deck plan and directs you understandingly

Is There An Ether?*

Aid for the Layman Who Attempts to Keep Abreast of the Changing Concepts of the Modern Physicist

By PAUL R. HEYL, Ph.D.†

Physicist, United States Bureau of Standards

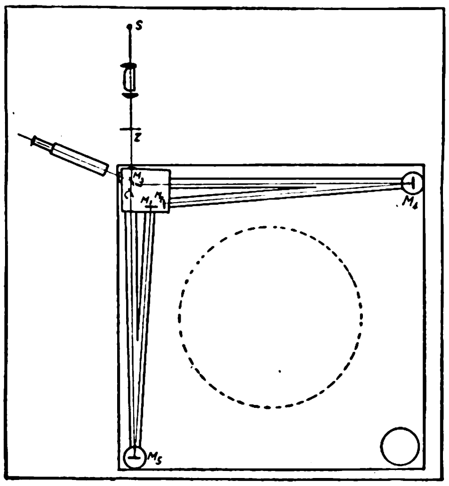
THE ether had its origin in human need and will last as long as human thinking requires it. Not always in the same form, perhaps, but unchanged in function.

The word "ether" comes down to us from the Greeks, but with their concept we have little interest. The "divine ether" to which Prometheus made his impassioned appeal was merely the rarefied upper air. The ether of physics dates from the time of Newton, who, like all the natural philosophers of his day, was greatly puzzled by the fact of apparent action at a distance. The full force of this was first felt when Newton showed that the earth's gravitative action extended to the distance of the moon. The question then presented itself: "Can a body act where it is not?" And the universal answer was: "No; it is unthinkable. There must be some connecting medium."

THUS arose the concept of the ether, at first a substance of rather vague physical properties. This hypothetical substance, while it did not succeed in explaining gravitation, at least furnished a medium by means of which it might be shown some day that gravitation could act.

In Newton's day the ether was not generally regarded as a carrier of light, for the corpuscular theory of light was then in favor. The early part of the 19th Century saw the establishment of the undulatory theory for which a medium of some kind was a necessity, and the luminiferous ether, as it then came to be called, was soon considered an indispensable part of physical theory. Later in the century Maxwell added to the duties of the ether the explanation of electro-magnetism, and with this additional responsibility came an increased measure of authority. In the eighties and early nineties the ether was everything in physical theory, and while it had not yet been shown capable of explaining gravitation it was confidently expected that this would also come to pass, perhaps in the near future.

The 19th Century felt very well acquainted with the ether, almost as well as with matter. Said the physicists of that time: "We know the ether just as well as we know iron or coal, and by the same evidence—its properties. True, it is transparent and invisible, but so is air. The ear can perceive air vibrations, and the eye those of the ether. Though it is not so simple a matter to weigh air as water, yet it can be done indirectly; likewise we can determine indirectly that the ether has a density of 10^{-18}. Moreover it must possess the properties of a solid rather than of a liquid or a gas, else it could not transmit the transverse waves which constitute light. The ether may be thought of as a vast mass of transparent, frictionless, tenuous jelly in which all material things are embedded, and through which we slip and slide without being conscious of it. Nay, matter itself may be only a kink or twist in the ether. One continuous substance filling all space, which can vibrate as light, which can be sheared into positive and negative electricity, which in whirls constitutes matter, and which transmits by continuity and not by impact every action and reaction of which matter is capable. This is the modern view of the ether and its functions."[1]



From Proceedings National Academy of Sciences. Vol. 12. p. 622

THE KENNEDY EXPERIMENT

Professor Kennedy stated that air currents and temperature effects sufficient to change the optical path one part in 1,000,000,000 would produce the ether-drift effect Miller obtained, so he sealed up his apparatus in a closed atmosphere of helium. Otherwise the set-up was the same in principle as that of the Michelson-Morley and Miller experiments. It was compact—about one yard square

But with the 20th Century there came the new physics with its revolutionary concepts. How does the picture of Nature look at present?

The jelly-filling of space is gone; matter can no longer be distinguished from electricity; the atom is a little bunch of waves traveling like a moving corpuscle; space is curved, and this causes gravitation; energy is atomized into quanta—

But stop! Let us catch our breath! Where is the ether? Is there anything left of it? And how are we ever going to get along without it?

These are very human questions. They suggest the alarm with which inherited tradition has ever viewed the iconoclast. It is easy enough to break down, but what have you to put in its place?

I think that a little study of the subject will show that the 20th Century has changed the form rather than the function of the ether; that action at a distance is as great a challenge as ever, and that modern physics binds every particle of matter to every other no less closely than did the older theory.

IN common opinion Einstein perhaps bears the blame for doing away with the ether. It is true that he asserts that there is no force of gravitation between the earth and the sun, and therefore it would seem that there need be no medium to serve as the physical basis for such an attraction; but the circular orbit of the earth must be accounted for, and this is how he does it.

Gravitation is not a pull, but a push. The earth is not drawn toward the sun by some mysterious force, but pushed out of what would otherwise be a straight course by—space itself!

Sink a large shallow bowl into smooth ice with the upper edge flush with the frozen surface. Stand off a little distance and send a golf ball rolling over the ice toward the bowl. What will happen?

That depends on the speed of the ball and on where it strikes the bowl. If it strikes well to one side and if it be not going too fast the ball may be captured by the bowl and describe several circles before settling to the bottom. But if it is going fast enough it may climb out of the bowl and proceed again in a straight line over the ice, after suffering a slight deflection from its original course. This deflection, or circular motion, as the case may be, does not mean that there is any force of attraction originating at the center of the bowl; the curved path is caused not by a pull but by a push of the curved surface of the bowl against the moving ball.

---

[1] Composite of Kelvin and Lodge (1882)

In a similar manner Einstein says that the motion of the earth in a circular orbit is due to a push from curved space, and that this curvature of space is caused by the mass of the sun. According to Einstein, space is not mere emptiness, but a sufficiently robust entity to be curved and to deflect the earth. It is this very resistent space itself that forms the bond of union between the sun and the earth and relieves us of the necessity of assuming action at a distance.

RATHER a neat substitute for the ether, is it not? We need no medium filling all space if space itself is capable of doing the trick. And after all, whether we spell the connecting medium E-T-H-E-R or S-P-A-C-E—what does it matter?

Let us now look at the latest concept of the atom. I do not mean the Bohr atom, though to many this attractive planetary concept still represents the 20th Century idea. The readers of the SCIENTIFIC AMERICAN know that the Bohr atom has for some time been superseded by a more powerful and plastic form—the wave atom of Schrödinger. According to this concept an atom is a little bunch of vibrant energy, spreading out in all directions and thinning as it goes, so that all atoms are connected, though rather tenuously, into one great vibrating system. And what is it that vibrates? Electricity.

Schrödinger assumes a filling material in space, a universal electric plenum which in vibration constitutes matter. Here we see again our old friend the ether in a new disguise. There is no escaping it. Scientific thought demands it and inventiveness supplies the demand under a different form suitable to the changed times. The ether is indeed protean in its properties, all things to all men. From the vague, imponderable medium of Newton's day we have come by way of the tenuous jelly of the 19th Century to the curved space of Einstein and the universal electric plenum of Schrödinger. In one form or another the ether will last as long as human thinking requires it.

But, then, is the ether nothing more than a logical proposition? What does experiment say? Can it give us no evidence of the ether as a physical reality?

Apart from the ever present evidence of our sense of sight and the stars of heaven there is no evidence available. Many times has the attempt been made to detect the ether by our motion through it, but to no avail. Not one but several independent lines of evidence concur in this negative answer.

But, you may say, is there not at least one positive result—that of Miller? And does not the evidence of one skilled observer who has seen an elusive phenomenon count for more than the negative testimony of the many who have failed to notice it? This is often true, but it happens that in this case the presumption is exactly the other way. The well known Michelson-Morley experiment is carried out by means of interfering light waves. The adjustment is one of extreme delicacy, difficult to obtain and to maintain. It is a very easy thing to get an apparent positive result and a very difficult thing to avoid it. It is a matter of wonder and admiration on the part of those who know the ropes that Michelson and others should have been able to reach their negative conclusions.

REPETITION OF THE MICHELSON-MORLEY EXPERIMENT

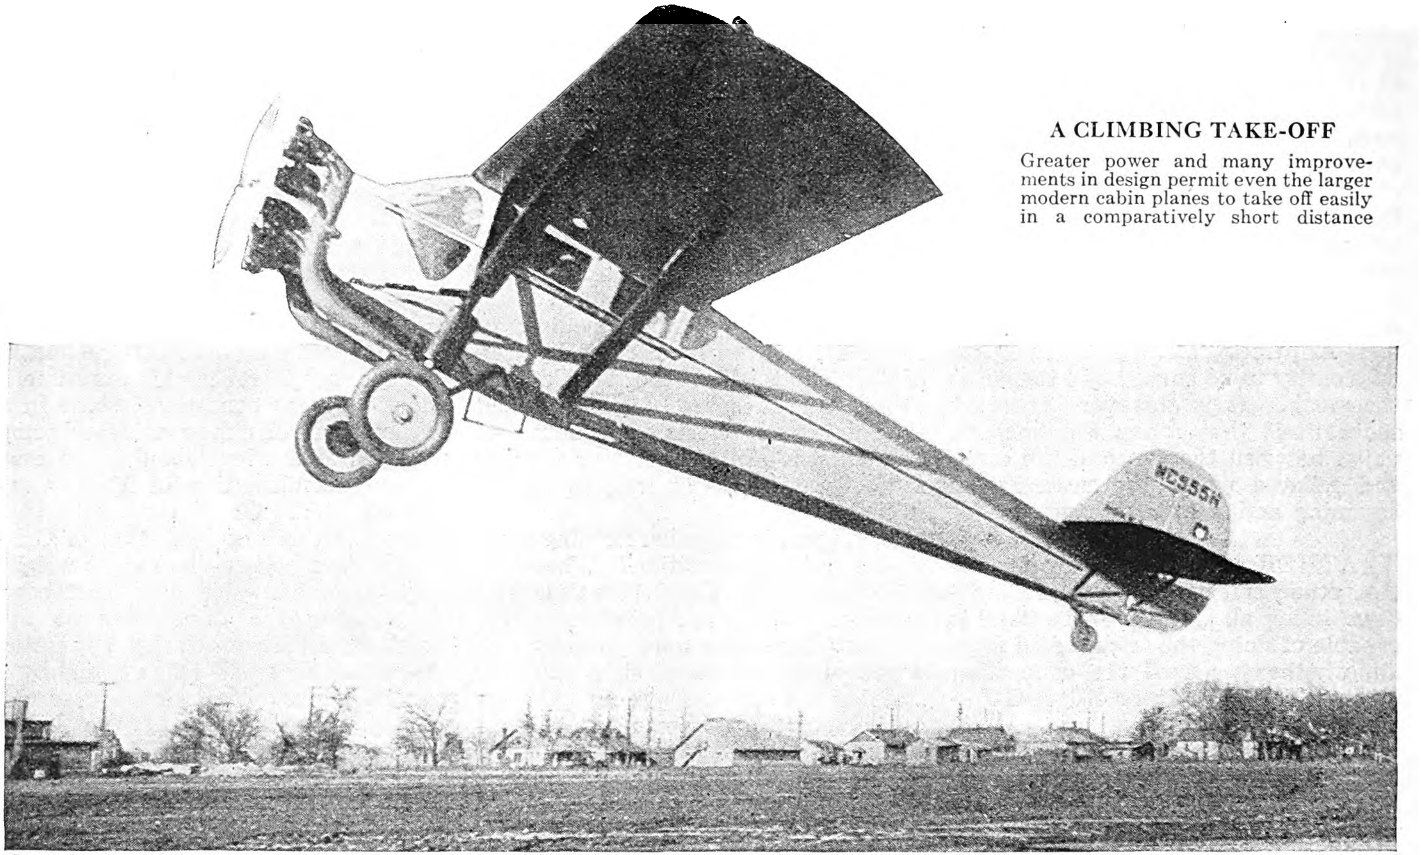
In 1926-'28 Michelson, Pease, and Pearson re-performed at Mount Wilson Laboratory the original Michelson-Morley experiment on the basis of which Einstein dispensed with the ether, in order to check Miller's findings—i.e., of an ether drift, hence the existence of an ether. Their results did not support Miller's findings, which connote the existence of an ether

For there have been others. Miller's first announcement stimulated a number of experimenters in Europe and in this country to repeat his experiment under different conditions, some in a balloon, some on a mountain, and some on earth at sea level, and in no case was any confirmation of Miller's result reported. Of all these other experiments those of Kennedy, of California, have perhaps had most weight with physicists. Kennedy succeeded in reducing the dimensions of the classical Michelson-Morley apparatus to a relatively small volume, and by a very ingenious optical device preserved all the sensitiveness of the larger form. He was therefore able to enclose his apparatus in a case filled with helium, thus obtaining unquestioned control of pressure and temperature. And his result was negative.

EXPERIMENTERS of the first rank have more than once been self deceived. There will be recalled the case of Ramsay, one of the best chemists of England, and a co-discoverer of argon. Soon after the discovery of radium it was found that radium emanation gradually turned into helium. This was the first recognized case of transmutation among the elements, and aroused great interest. Ramsay, as a result of some very carefully conducted experiments, came to the conclusion that not only helium but neon could thus be produced, and that even copper could be changed into lithium. Other experimenters failed to confirm Ramsay's results, and it took five years to settle the question. Finally J. J. Thomson developed the unexpected fact that certain gases were retained by glass under the most severe treatment, such as heating to the softening point. Ramsay's alleged results are now of historical interest only.

And so it is with the supposed "anti-Einstein" evidence today. Miller's results stand alone. Without independent confirmation they can not gain acceptance. Half a dozen attempts at confirmation have failed, and their very failure is the best proof of their claim to recognition.

¶ *"Waves and Particles" is the title of a thought-provoking article written by Professor G. P. Thomson of Scotland, and soon to be published. Professor Thomson helped prove the new wave-atom theory.*



A CLIMBING TAKE-OFF

Greater power and many improvements in design permit even the larger modern cabin planes to take off easily in a comparatively short distance

Better Days for Aviation

Present Safe, Dependable Airplanes Will Be Further Improved and the Industry Placed on a Sound Business Basis

By EDWARD S. EVANS*

President, Detroit Aircraft Corporation

AT a Chamber of Commerce dinner which I attended recently, two men were talking about the future of the aviation industry.

"Five years from now we shall all have our air flivvers parked in our garages, and regulating traffic in the skies will be as much of a problem as street traffic is now in downtown business sections," one of them said to me. "I have half of my investments in aviation securities, and I expect to see these make a small fortune for me in the next five years."

"You are wrong," said my neighbor on the left. "Air transportation offers few practical advantages over other means of travel. It has yet to be developed to a safe practical basis. Aviation offers a thrill to the young man and woman, and airplanes are useful for carrying mail, but they cannot compete with other means of transportation. One hundred years from now our successors in business may travel by airplane regularly, but our generation will never see aviation developed so that it is of much value to the public."

Both of these men had entirely the wrong picture of aviation, but their opinions are held by many business executives, so that it may be of interest to consider some of the questions that are confronting the industry, as well as some of the past and probable future developments. In the next few years, every executive of a large corporation, who has not already done so, will have to give consideration to the place of air travel in his organization.

IN order that present conditions may be understood, it is necessary that we review briefly the development of popular interest in aviation. Colonel Lindbergh's historic flight may be said to have marked the beginning of commercial aviation in this country. Immediately after this flight, every airplane manufacturing company was flooded with orders for new planes.

In 1925 the writer made a record-breaking trip around the world in 28 days, using airplanes for a large part of the trip. Many of my friends at this time thought I was writing my death warrant every time I stepped into a plane. And yet these same men and women and millions of others all seemed to want to get into the air in 1927, and there were not planes enough to accommodate them. Commercial operators were making small fortunes from taxi hops and cross-country flights; and scores of planes were purchased for various advertising and other commercial services.

At the old San Diego plant of the Ryan Aircraft Corporation which built the *Spirit of St. Louis*, it was not unusual for purchasers to offer from 1000 to 3000 dollars over the advertised price of a ship for immediate delivery. Not one of the companies then in business was equipped for anything like quantity production, and by the fall of 1927, the company that could make delivery within two months after receipt of an order was unusual. Many purchasers were willing to buy anything that would fly, regardless of the plane's reputation or design. This surplus of orders caused the formation of a large number of new manufacturing concerns, many of which were not making planes based on sound engineering design. The crashes in which such planes figured did much to shake the public's confidence in flying. Fortunately this situation has now been corrected by the strict Department of Commerce regulations requiring engineering approval and flight inspection of every new plane, and periodic inspections of all planes used in inter-state travel.

---

*See "Among Our Contributors," page 421.

Although there was undoubtedly far more business than the existing plants could take care of, the fact that many purchasers tried to obtain planes from two or three companies before finally placing their orders gave rise to the belief that there were more purchasers than was actually the case. Many plants were doubled and tripled in size; scores of new ones were built; and everything possible was done to speed up production.

LINDBERGH'S plane was one of the few cabin ships on the market, and the demand for that type was so great that many companies were forced to design entirely new ships. All materials entering into aircraft construction were difficult to obtain, competent men in all departments were scarce, and the industry was suddenly confronted with the new problem of quantity production. Selling planes was the least of the worries of aircraft company executives.

In view of these conditions, it is little wonder that the industry has made many mistakes. It was to be expected that certain promoters would seize upon the public's desire to invest in aviation enterprises as an opportunity to organize companies having no economic reason for existence. The history of the aviation industry has been no different from that of other new industries in this respect.

It has been only recently that aviation companies could offer high enough remuneration to attract men of broad and successful business experience. Originally, the pioneer work was done either by engineers or pilots. The country owes a debt of gratitude to these men who carried on through nine years of almost insurmountable obstacles, bringing the airplane to its present stage of reliability. It was only after this tedious pioneer work had been accomplished that the country's purse strings were opened and the necessary money provided for establishment of air transport lines and aviation schools, and for the development of improved airplane designs and manufacturing facilities.

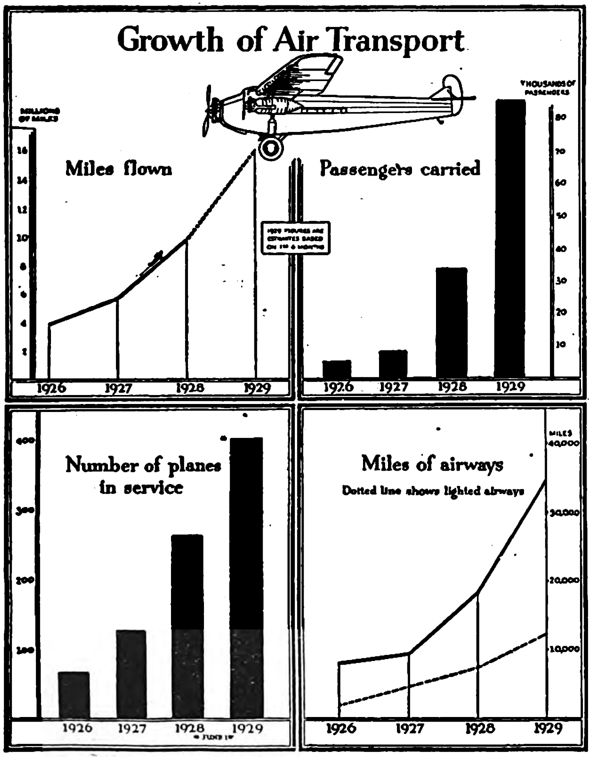
THE AIRPLANE IN CHINA

The awakening interest in aviation of oriental and South American businesses and governments is expected to open a rapidly increasing foreign market for American-made aircraft

We have heard much in recent months about overproduction in the aircraft industry, and many unfounded rumors as to the general condition of the industry have given rise to opinions in some quarters that the aviation industry is in anything but a strong position. Despite the fact that aviation has just had the most successful year in its history, production did fail to come up to certain over-optimistic predictions made early in 1929. In 1928, approximately 5000 planes of all types were built in this country. Some aviation enthusiasts predicted that the 1929 production would be over 10,000. Figures for 1929 recently released by the Aeronautical Chamber of Commerce give the airplane production at 6034 planes and the value of motors and planes manufactured at 98,000,000 dollars.



PROGRESS TO DATE, FROM 1926

A self-explanatory series of graphs which strikingly show the increasing use of airplanes in this country

In 1929 the production of planes for commercial use increased 51 percent by number and 93 percent over the preceding year in value. There is nothing phenomenal in this increase, but it is a record which few industries could point to last year, and one of the best indications of the increasing air-mindedness of the American public and business man.

The Army and Navy are taking a rapidly decreasing proportion of the total production. Seven years ago, all airplanes produced were intended for military purposes, while last year this market absorbed less than 25 percent of the production.

The greatest problem now confronting the industry is that of educating business executives to the practical value of air transportation. It is true that the industry has been somewhat backward in adopting a sound merchandising policy. From 1918 up to the present time aviation has been presented the greatest amount of publicity ever given a new industry. In some ways this has hurt rather than helped in educating potential users as to the value of this modern mode of transportation. Far too much emphasis has been placed on the romantic appeal of flying, the danger of traveling by plane, and the thrilling experiences encountered by pilots and passengers.

THE whole American business structure is based upon speed. Small inventories require fast deliveries, the many recent mergers have placed a great premium on the time of business executives, the necessity for frequent changes in the design of products requires many consultations with high salaried consulting specialists, and present conditions require frequent personal contacts between salesmen and the home office.

A survey recently conducted by the Detroit Aircraft Corporation showed that approximately 180 companies now own one or more planes. At least 20 of these own two or more ships, and it is believed that this list will be increased to many hundred by the end of 1930.

During the recent scramble to increase production in an attempt to meet the sudden demand for planes, many plants were expanded more rapidly than future economic conditions warranted. Certain companies now find themselves with uneconomical manufacturing facilities on their hands, and this will result in a certain amount of new plant construction in the near future.

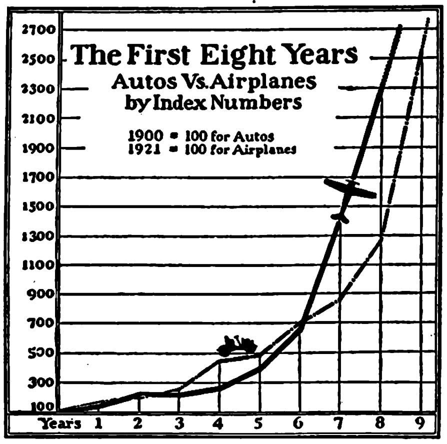
Airplane buyers today are most discriminating, and usually carefully compare the performance, reputation, and price of all ships that might fulfill their requirements. This has placed certain of the smaller companies, whose planes are not soundly engineered, in a serious position, and will undoubtedly result in a great reduction in the number of aircraft manufacturing companies. The Department of Commerce recently listed 240 companies that claimed to manufacture airplanes. The great majority of these were not equipped for anything like production, and many were founded purely as a basis for stock promotion. The production of 20 of these companies accounted for 85 percent of the 1929 production. By the end of 1930, it is probable that the number of companies engaged in all phases of aviation will be greatly reduced.

The prospective investor will do well to limit his investments in aviation enterprises to those companies which have a long record of achievement behind them, or holding companies controlling a well rounded group of organizations the permanency of which is assured by past accomplishments.

THE most significant factor of the industry for 1929 was the vast amount of new money that was poured into aviation, and the many mergers which were consummated. In the last 18 months, some 60 formerly independent companies have been merged into the "Big Four," composed of the Curtiss-Wright Corporation, the Aviation Corporation of America, the United Aircraft and Transport Company, and the Detroit Aircraft Corporation. Each of these companies controls a well rounded group of from 10 to 20 organizations specializing in various lines of manufacture and operation. There are still some 20 strong independent companies that have enough reputation and financial backing to meet the larger groups in any period of competition. In view of the stock market situation, it is not probable that there will be much further consolidation during the present year except possibly in the accessory or raw material fields.

The industry is now going through the third stage of its development. From the time of the Wright brothers' first flight until Colonel Lindbergh's flight in 1927, aviation was going through an engineering development. During this period, the basic aerodynamic problems were solved; and the next 18 months were devoted to meeting problems of efficient production. The latter half of 1928 and 1929 saw nearly 500,000,000 dollars of new financing poured into various aviation enterprises, the merger of many companies, and the introduction of more highly efficient business management.

We now approach 1930, when the main emphasis will be laid on efficient merchandising and selling the public and the business man on the practical time and money-saving value of flying. Until the last six months, airplane sales took care of themselves, but now with more discriminating buyers and the ready market from commercial operators and transport lines well covered, the industry has had to branch out and seek new purchasers. Up to the last year, not more than five companies had developed anything like a nation-wide distributing organization. Now every company is making efforts to establish dealers and distributors in all parts of the country. Most of the companies are requiring that these distributors make arrangements for servicing and storing planes, and some are requiring that they carry a stock of replacement parts.



LAND VERSUS AIR

Progress of aviation compared with that of the automobile: first eight years of each

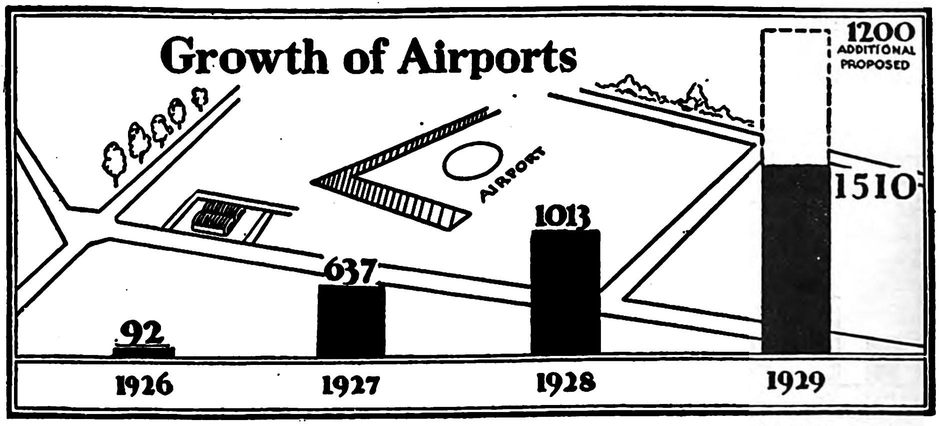
Showrooms have already been established in some of the larger cities, and the next few years will probably see even cabin planes on permanent exhibition in the business sections of every large community.

Financing plans have recently been put into effect by the better established companies, and it is now as easy to finance the purchase of an airplane as it is to buy an automobile out of income instead of capital.

Every few months we see some statement predicting that in the future we will all have "flivver" planes parked alongside our automobiles in our garages, that soon we will be flying directly to the roofs of our office buildings, and other startling developments. Such things may come in the next generation, but it is doubtful if the readers of this article will ever witness much change in design.

IT is a brave man indeed who is willing to make any predictions as to what the future holds in store for aviation, but there are some things that stand out as fairly certain. In spite of all the many new developments in the field of aeronautics, it is doubtful if we will see much basic change in airplane design in the next few years. Improvements and refinements, of course, will be made. These will increase the speed and carrying capacity, reduce the length of run required to land and take-off, give more comfort and even greater reliability. We will see many spectacular experiments in the next few years, but our present modern planes incorporate the features that make for safe, dependable operation. The engineering departments of several of the larger airplane manufacturing companies are working on radically different designs, but it will be many years before any of them will have gone through the engineering development necessary to bring them to the point of safe, practical application to air travel.

The present year will see the aviation industry settled on a definite stable business basis, with healthy increases in the value of products, and popular confidence in flying. Spectacular achievements will be less frequent, for there will be less need of them. The problem which is rapidly being solved will be to place dependable, economical aviation equipment at the convenient disposal of every individual and corporation in need of fast transportation.

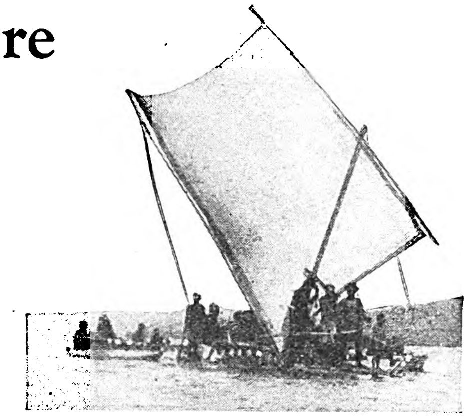


EVERY SIZABLE TOWN BOASTS ONE OR MORE AIRPORTS

In 1926 there were very few well-equipped airports but at the end of 1929 their number had multiplied over 15 times. Now many communities have several and others are being added

Tangled Commerce Abides Where Children Smoke and Swim

The Antipodean Manus Are the Pack Peddlers of the Pacific

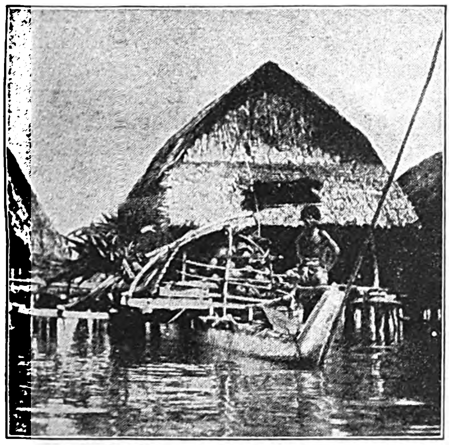


A CANOE FUNERAL

The Manus of the Admiralty Islands have curious death customs. It is necessary to bury the deceased on the land

DR. MARGARET MEAD, Assistant Curator of Ethnology in the American Museum of Natural History, recently returned from the Pacific where she had been investigating Melanesian tribes on the islands off the coast of New Guinea. Dr. Mead's presence in the Admiralty Islands was prompted by a desire to see how children and adolescents of a primitive people compare with children and adolescents in civilized society. The Admiralty Islands formed a part of what was German New Guinea, but they are now governed by Australia under a League of Nations mandate.

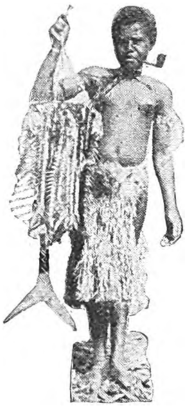
These islands were selected because they have been little studied. The Manus, while a primitive people, are highly developed commercially. The Manus number about 2000 and they live in several thatched Venices on stilts like Swiss lake villages. Why these people should have left the mainland for the reefs and tiny volcanic peaks where there is standing room only, is a mystery of the South Seas.



BUILT ON PILES

A South Sea Venice. Visiting and trading is done by water with the aid of canoes

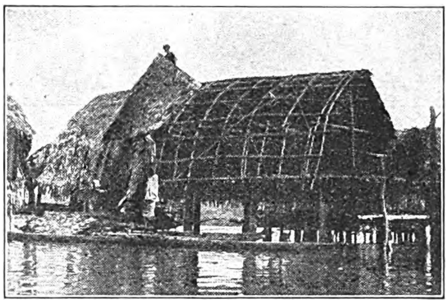
Dr. Mead learned the language of the Manus and made an excellent collection to illustrate their manners and customs. The Manus are born traders and they exchange anything at a profit. They bring sea water to the mainland and exchange it for fresh water with those who live on the mainland. The fresh water is transported to their island home. The legal tender is dog's teeth, but the currency was becoming debased because wily traders had been importing the teeth from China and Turkey. In trading with the whites, Louisiana tobacco twist is the standard of barter and as it passes from dirty hand to dirty hand it becomes mouldy and it has to be consumed in a pipe or rolled into cigarettes with the aid of old newspapers. Children of both sexes begin to smoke at the age of three and it apparently does them no harm, nor does it stunt their growth—but it surely looks extraordinary.



GIRLS MAY SMOKE

An adolescent girl holding up the skeletons of fish she has eaten. It looks like a perpetual Lent. Below is a war charm, one of the interesting specimens collected

The Manus developed the character of traders because they have a virtual monopoly on fish, while the mainlanders had virtual monopolies of everything else. The Manus catch fish, trade them to one mainland tribe for carved wood, trade the wood to another tribe for pigs, and trade the pigs to another tribe for dog's teeth, making a profit on each transaction.

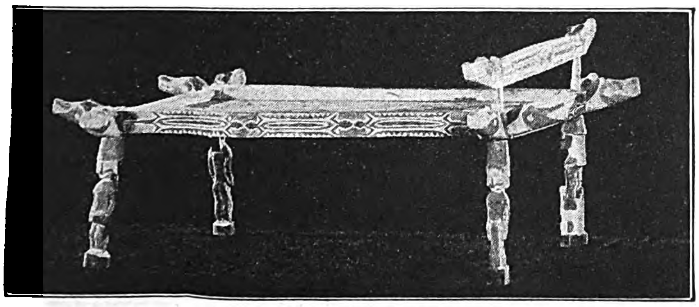


POST MORTEM HOUSE MOVING

After a death it is customary to remove a house to a new location, as is being done

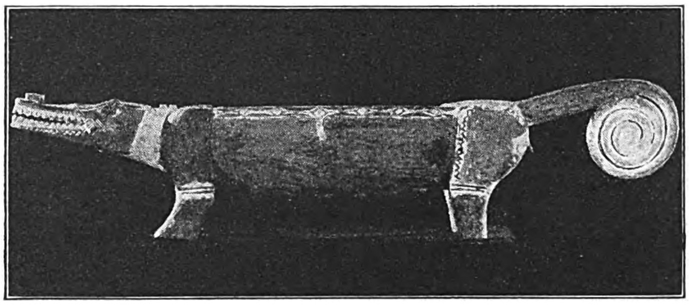
The Manus are so isolated that they must use canoes or swim. Even children three years old swim and are able to handle canoes. The oldest member of the tribe can remember only one case of drowning. Two children were out in a canoe which capsized and the younger, aged three, was drowned. The father wanted the other child, aged five, punished for murder, as any five-year-old child should be able to swim half a mile and tow another one. There is eternal wrangling about nothing among the tribesmen, and they like nothing so well as to foregather at the sound of a native drum.

Their religion is based on worship of the spirits of ancestors and the community laws are maintained by religion and shame rather than by civil punishments.



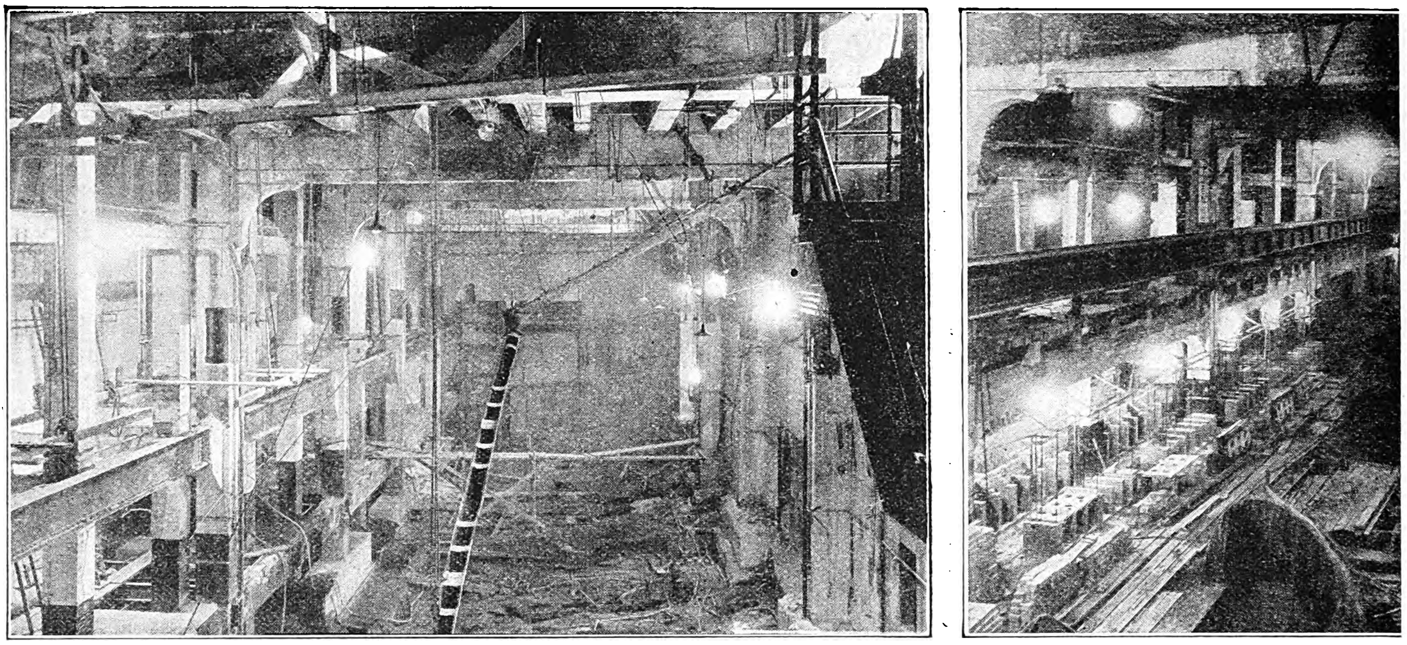
BED MODEL

The Manus are the only South Sea people that sleep in regular beds. This bed certainly looks hard, especially the pillow



NATIVE ART

Here we have a wooden bowl with a crocodile's head and a pig's tail. This is probably the South Sea Islander's conception of art



THREE VIEWS OF PROGRESS IN THE DYNAMO ROOM OF GRAND CENTRAL

Moving a Substation Underground

Without Interruption of Service, Substation Is Moved Seven City Blocks to New Underground Location

By F. B. FREEMAN
Chief Engineer, New York Central Railroad

WITH the co-operation of the General Electric Company and the Thompson-Starrett Company, the New York Central Railroad Company recently completed the unique engineering feat of dismantling and transposing the Grand Central Terminal power plant—a city block in area—from its former location on the surface at Lexington Avenue and 50th Street, New York City, to a site about 100 feet underground and seven blocks distant. The present installation constitutes the world's largest power substation.

Light, heat, and power is distributed by this plant to more than 60,000 persons occupying floor space exceeding 256 acres. This plant provides the electricity which illuminates 100,000 or more electric lights, moves more than 650 trains daily, operates 325 elevators in 28 buildings, and supplies these buildings—among the largest in the world—with the hot water which heats some, the steam that heats others, and hot water for general purposes. It also distributes steam to warm innumerable railroad cars, and it compresses air, not only for railroad purposes, but to open and close hundreds of elevator doors in the buildings, to assist in cleaning, and for other uses.

The magnitude of this moving job becomes apparent when one considers that the engineers were compelled to dismantle the plant, move much of it the distance of seven blocks, and add new apparatus, without interfering with the operation of the terminal or of the trains entering it, without hampering street traffic, which is quite heavy, and finish the job on a scheduled date which necessitated the work being placed on an emergency basis, all due to the former site being required for the construction of the new Waldorf-Astoria Hotel.

The economic necessity for a change in the location of the old plant was foreseen, due to the ever-rising midtown real estate values, some years ago, and careful studies showed the advisability of moving the power plant facilities underground. It was presupposed in all plans, however, that the major apparatus would remain at 50th Street.

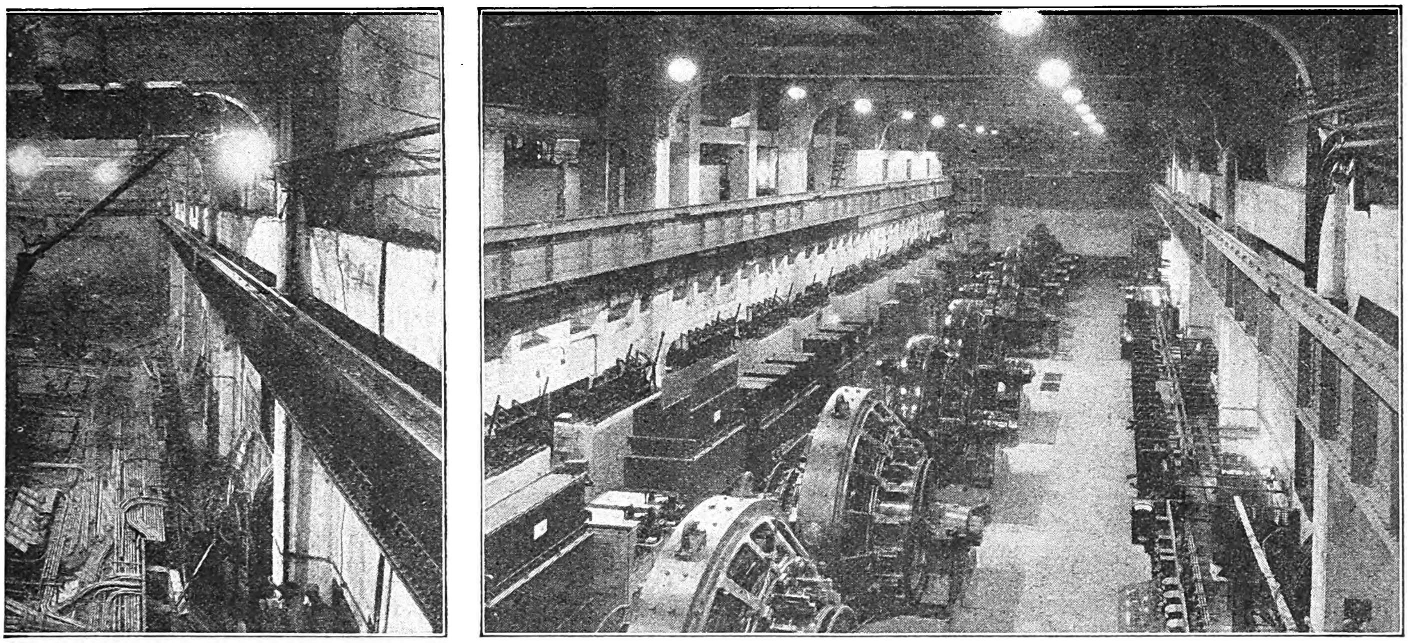
IN line with the company's general expansion program, the present site of the substation—an excavation about 90 feet deep and 225 feet long by 60 feet wide—had previously been made in the solid rock under 43rd Street, to accommodate a boiler plant. Two boilers were installed, with room for four more. This plant consisted of four floors: a basement, a boiler room, a meter room, and the coal bunkers. The stack extended to the top of the Commodore Hotel and was concealed in that structure.

Another vast cellar was also dug out under the southern end of the Graybar Building, adjoining this boiler plant excavation, for the accommodation of the mechanical facilities which, under the early plans alluded to, were not to be included among those to be placed underground at 50th Street at some future date. Calculations then established the fact that it would be possible to utilize the great stone vault, intended for the boiler plant, as the new site of the substation.

Ordinarily, six months would be required to draft the plans, and at least a year for the construction and removal. The lease was signed March 4, 1929, and dates set for the clearing of the various buildings for demolition. Although no drawings had been prepared, other than preliminary sketches, work was begun at once under verbal direction, followed by drawings as soon as possible. Despite these trying conditions, no change in any major plan was necessary during the course of this work.

Briefly, the following broad plans were carried out:

The steam generating plant was abolished and steam was purchased from the New York Steam Company system; and the space under the Graybar Building was turned into



TERMINAL'S NEW HEAT, LIGHT, AND POWER PLANT, 100 FEET UNDERGROUND

a heater and pump room to utilize this steam to heat the immense quantities of hot water needed, utilizing tanks of 20,000- and 50,000-gallon capacity. In this space were also placed the fire pumps, hot and cold water pumps, air compressors, and other auxiliary apparatus.

The two boilers were removed from the "boiler plant" excavation, the basement was enlarged, concrete foundations constructed for the 10 rotaries, an operating floor provided for conduits and with spaces for transformers, switchboards, oil switches, and other apparatus. Also, crane girders and a 30-ton electric crane were provided.

The meter room was made into an exhaust fan room, taking air from the top of the substation and exhausting it into the boiler breeching of the old arrangement and thence up the stack. The bunker space was converted into a stand-by battery room. Here was installed an 8000-ampere battery consisting of 150 cells, each weighing 4550 pounds.

The transfer of this battery was a major problem. A city ordinance prohibits the transportation of acid in open tanks through the streets, and use was made of an underground trucking passage. Time being at a premium, the battery could not be dismantled. Part of the acid was removed, the plates were clamped in place, and each cell was placed on wheels and lowered by tackle a distance of about 55 feet. They were hauled underground by an electric truck to 43rd Street, and raised by an elevator to their present site. During the moving not a drop of acid was spilled and not a cell was injured. The care that had to be exercised may be judged by the fact that the weight of each was sustained on glass plates.

Reliability of service was assured by connecting the lighting substation at 50th Street to the New York Central high-tension system and the lighting substation at 43rd Street to the New York Edison system. This stand-by battery was removed and re-assembled and placed in service in 53 days.

The total weight of the 10 rotaries installed, their transformers and other major electrical apparatus, was 850 tons. Much of this had to be lowered piece by piece a vertical distance of 50 feet from the unloading platform to the substation main floor. All materials were moved by flat cars from 50th Street on tracks which could be kept out of service only a few hours at a time. To remove 30-ton armatures in a limited number of minutes required exceptional skill.

THE traction system of third-rail feeders, 36 in number, extended through a complicated system of ducts from the substation at 50th Street to various third-rail sections on both levels of the terminal. To lead them all to the new substation would require an expensive duct system and miles of cable. Therefore, a circuit-breaker house was constructed at 49th Street and all these cables connected to switchboard panels therein, but under distant control from 43rd Street. Twelve cables were connected between the 43rd Street substation and this circuit-breaker house.

These cables carry the average current to this 49th Street house, where it is subdivided among the various third-rail feeders. The electrical effect is the same as though the 50th Street substation had not been moved; but the relaying by miles of wires was eliminated.

Since the piping system of the terminal was laid out in a square with one corner near 50th Street, where steam, water, and air were introduced, and another corner near 43rd Street, it was decided to open these pipes at 43rd Street as a new feeding point and to close them at 50th Street, thus using the same pipes.

Existing masonry conduits were used, as far as possible, to contain the electric cables and supplement these by an overhead metal conduit system in existing trucking subways. It was necessary to install and support in an elevated position throughout the terminal, approximately 20 miles of 3½-inch steel conduits. Into these conduits and the existing masonry conduits, 35 miles of cables of large size were drawn. These are the lighting and traction feeders. In addition, several miles of high tension and control cables were installed. The conduits concealed in the floor of the substation have a total length of 25,000 feet. In each conduit, from one to 16 wires are installed.

The high-tension masonry bus is 175 feet long and is divided into five sections. Connecting to it are 36 high-tension oil switches. More than 70 tons of bar copper was used in the buses. This all had to be drilled, bent, insulated, and supported.

All this work was accomplished without any interruption to, or interference with, the normal operation of buildings, in the lighting or signal power supply, or in the traction current for the movement of trains. No traffic delay occurred in connection with the loading or unloading of apparatus, although such work took place on tracks in daily rush-hour service. Each unit of the new plant started operation on or ahead of schedule. No damage was done to any piece of apparatus during transfer. And during the entire intricate operation, which was completed at a cost of more than 3,000,000 dollars, not a single man was injured.

Warmed By Satan

An Engineer's Discussion of the Familiar Proposal to Derive Power from the Earth's Hot Interior

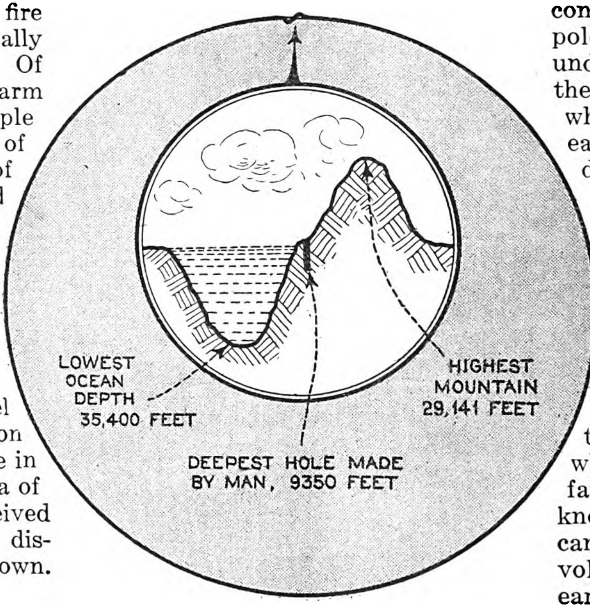
By THOMAS T. READ, E.M., Ph.D.*
Vinton Professor of Mining, Columbia University

THAT the interior of the earth is very hot is one of the things that people generally believe, without knowing anything about it. Primitive men needed no evidence other than volcanic outbreaks to convince them of it, but then the number of people who have ever seen a volcano at any time, much less one in eruption, must be very small indeed, and it is probable that the idea is one of those that the superstitious mind (and most of us are superstitious) has a natural tendency to believe. Millions of people believe that there is somewhere a place of everlasting fire where the wicked will be eternally punished for their sins on earth. Of course, such an idea originated in warm countries, where heat makes people uncomfortable. The primitives of the northland believed the place of eternal punishment was a cold place. The inside of the earth was a conveniently inaccessible place to assign as the locus of Sheol, Gehenna, Hades, or whatever the hot place was called.

Interest in Hell as a place of eternal punishment has generally waned and many people now feel that they catch enough Hell on earth, without expecting any more in the hereafter. Meanwhile the idea of a hot interior of the earth has received some scientific support from the discovery that the earth is cooling down.

OF recent years public attention has been stirred, every now and then, by someone's suggestion that since the interior of the earth is very hot, all we have to do is to find a way of bringing the heat to the surface and we will thereafter have a perpetual source of heat, without having to dig and burn coal. There is something peculiarly comforting in the thought that the presiding genius of the hot place, instead of being an evil spirit who will torture us forever, may really be a beneficient individual who will bless our descendants by freeing them from coal strikes and furnace tending, and it seems worth while to consider whether there is any more inherent probability in the new view than there was in the old one.

Why do we believe the interior of the earth is very hot? The distance from the outside of the earth to the center is about 21,000,000 feet and the deepest hole men have made into it is about 9350 feet or about 0.045 percent of the whole distance. But hold up, where is that measured from? From the top of the hole, of course. It does not require a very alert mind to see that a man who dug a hole in the bottom of a valley would be starting nearer the center of the earth than a man who dug a hole, starting on top of a hill. The deepest hole is Oscar Howard's No. 7 Hathaway well in the Sante Fe Spring Field in California, and it does not get as near the center of the earth as many "deeps" in the Pacific Ocean, for its reported depth in January was 9350 feet. The highest mountains stick up nearly six miles above mean sea level, and the deepest holes in the ocean bed are even deeper, so that the holes that men have been able to make are only about one quarter as deep as the holes Nature has made.



LOWEST OCEAN DEPTH 35,400 FEET
HIGHEST MOUNTAIN 29,141 FEET
DEEPEST HOLE MADE BY MAN, 9350 FEET

JUST A SCRATCH

The deepest place in the sea, exaggerated six times, is shown at the top of the outer circle representing the earth. In actual distance this place reaches only 1/620 of the distance to the earth's center

But men have made lots of holes several thousand feet deep; the total number of oil-wells in the world is somewhere near a half million, not to mention water wells and mines. I have myself been 6700 feet below the surface of the earth in the St. John del Rey mine in Brazil, which has since been deepened to over 7200 feet. Workings in South Africa are 7600 feet deep. As you go down in these holes you find the temperature rises as you descend. To make matters more difficult for us, the rate of increase is different in different places. In some it is as much as one degree Fahrenheit for every 60 feet in depth. In South Africa where there are many deep mines, the rate is only one degree for every 250 feet.

It is all very puzzling, for if the earth was uniformly hot all over hundreds of millions of years ago and has been cooling down ever since, it is evident that it ought to have cooled down faster near the poles, and the rate of increase as you go down there ought to be slower. No one has yet found it convenient to dig deep holes near the poles, so we do not know what it is like underground, but we do know that there are active volcanoes in Iceland where there ought not to be any if the earth has been cooling off for hundreds of millions of years. The only way to get around that is to suppose that relatively recent cracks in the earth's crust have let hot material come up from below, just as hot lava comes up in a volcanic outburst.

Explaining the mechanism of a volcano is much more difficult than explaining that of a radio set, for there are at least a thousand people who are interested in and somewhat familiar with radio, to every one who knows or cares anything about a volcano. The simplest way is to say that volcanoes are local hot spots on the earth's surface, much as a steam radiator is a local hot spot in a room. We know very well where the steam in a radiator comes from, but there are at least seven different hypotheses as to what makes lava melt. The one which nobody believes any longer is that the interior of the earth is molten, and that the lava comes up from below as steam does from the boiler in the cellar.

ALTOGETHER, figuring out that the interior of the earth is at a temperature of 7000 degrees, or 27,000 degrees, as various people have done, seems to me to be a good deal like the well known process by which a city dweller figures out, with pencil and paper, how he can get rich by raising chickens. The scientist calls the process extrapolation; you know the course of the line from A to B, and you simply prolong it to C. It is perfectly easy to prolong a straight line, but when the known points make a line that looks like the track made by a two-day old calf trying to get to the other side of the pasture, prolonging it is anybody's guess. Anyway, you always can say, if anybody denies your conclusions, that he can not prove it is not the way you say it is.

---

*See "Among Our Contributors," page 421

After all, it doesn't matter just how hot the interior of the earth is, as long as it is a good deal hotter than the outside, and everybody who knows the evidence of observations made can at least agree on that much.

The next question is, what of it? Everybody knows that Palm Beach is considerably warmer than Kennebunkport in January, but the only practicable way for a Kennebunkporter to benefit by it is to buy a ticket to Florida. The people who dream of having Satan for a janitor are pleasantly vague about it. They propose to dig holes anywhere from five to 25 times as deep as the deepest artificial holes yet made and somehow bring the heat up the hole.

Maybe the digging of the hole can be done. It costs from 75,000 to 150,000 dollars to dig a deep oil well and the deeper you go the more expensive it gets. A hole five miles deep probably could not be made at all with present methods and equipment, and even if it could no one could guess whether it would cost 5,000,000 or 50,000,000 dollars. Obviously we would have to have two holes, for if the water to make the steam went down an inner or outer tube in the same hole that the steam was coming up, the heat in the steam would go into the water. In fact, it is a very puzzling problem how, starting with steam at the bottom of a hole five miles deep, you could get it to the top without having it cool down and condense to water again. But maybe it could be done if the steam passed through the hole fast enough, for the rate at which the heat would leak away is so many heat units per minute and if the quantity of steam passing through is multiplied by ten the percentage of heat lost is reduced to one tenth. So let's say it can perhaps be done, and that we will trust inventive genius to find the way.

ONE OF THE EARTH'S "HOT SPOTS," THE GEYSERS, CALIFORNIA

Wells drilled into the warm ground at The Geysers, 60 miles north of San Francisco, give steam at high pressure. This thermal region has been studied scientifically by Dr. Arthur L. Day, Director of the Geophysical Laboratory of the Carnegie Institution of Washington and Dr. E. T. Allen of that Laboratory. This photograph, showing escaping steam, was taken by Dr. Day, as was the one on the cover of our number for November. Through an inadvertence having to do with editorial routine that fact was not then mentioned

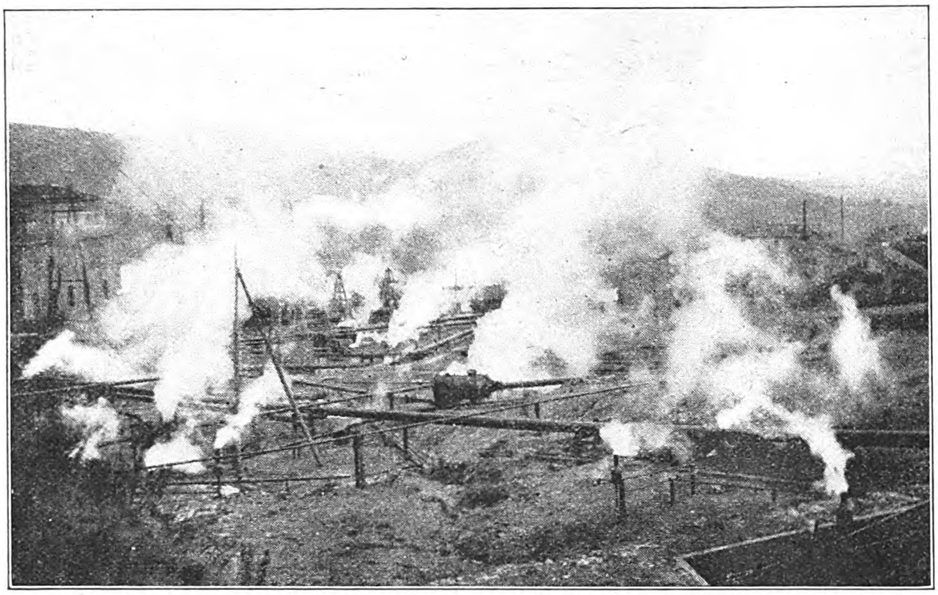
ASSUMING that we can make a hole for the water to go down and another for the water to come up, the next question is, how to connect them at the bottom. The only reasonable answer is, I do not know. The boring of oil wells is done from the surface, but to make a hole five times as deep as the present deepest would probably involve getting down inside it, and since we are being so generous let us concede that perhaps people could somehow get to the bottom of the hole and make a cross passage. It is only a few years since nearly everybody was quite sure that men could never fly through the air, and it is decidedly risky to say anything cannot be done, merely because no one now knows how to do it.

But here another question troubles us. How would we keep the hole open, even if we could make it? Everybody knows that in making the tunnels under the North and East Rivers, in New York, much engineering skill is required to guard against the pressure forcing the soft materials of the river bottom into the hole that is being made. At these shallow depths the pressures are such that compressed air, cast iron rings, and concrete are able to cope with them, but when we talk about depths of five miles, or 25 miles, we are in a region of immensely greater pressures. From laboratory experiments Professor Adams, of McGill University, concluded that holes could exist in solid granite at a depth of 11 miles. Whether they could exist at twice that depth is extremely doubtful; where the rock is not solid much difficulty is experienced in keeping the holes open in ordinary mines.

Finally, there are those inexorable things, the laws of thermodynamics. Lest the reader hastily turn over the page, let me say at once that I am not going to tell what they are. Everyone knows that you can not cook eggs on top of mountains, because the water boils at too low a temperature to cook the eggs. The reason is, that the lowered pressure lowers the boiling point. So it is easy to understand that raising the pressure raises the boiling point, but the interesting thing is that it finally gets to the point where you can not boil it at all. Perhaps it would be better to say that at such high pressures and temperatures no one can say whether you would have water or steam. If a hole five miles deep were filled with water flowing down it, to come up the other hole as steam, the pressure at the bottom would be about 11,500 pounds per square inch and the temperature, on the basis of one degree for every 200 feet, would be 130 degrees above what it started down at, or say 200 degrees. This is below the boiling point at surface pressure. The critical pressure of water is about 3000 pounds per square inch; at that pressure it boils at 690° Fahrenheit, and above that pressure no increase in temperature would make it boil. Since the pressure at the bottom of the hole would be nearly four times the critical pressure, even the heat of an oxy-acetylene blowpipe would not suffice to make it boil there. But this difficulty could be met by letting the water, after it had descended a limited distance, discharge into an open catch basin, and so go on down, arriving at the bottom at a pressure corresponding to the last drop, or 433 pounds to the square inch for a drop of 1000 feet. At this pressure a temperature of 450° Fahrenheit would suffice to make it boil.

Of course it is not necessary that the

water should boil at the bottom of the hole, but what we are after is heat, and a pound of water raised 130° Fahrenheit in temperature has taken on 130 heat units, while a pound of water that has been converted into steam 130° Fahrenheit above its initial temperature (whatever that was), has taken on 1102 units. Because of the greater heat-transporting power, therefore, we should much prefer to bring the heat up in steam. Let us see whether there is any chance that we could do this.



ANOTHER WELL KNOWN HOT SPOT—IN ITALY

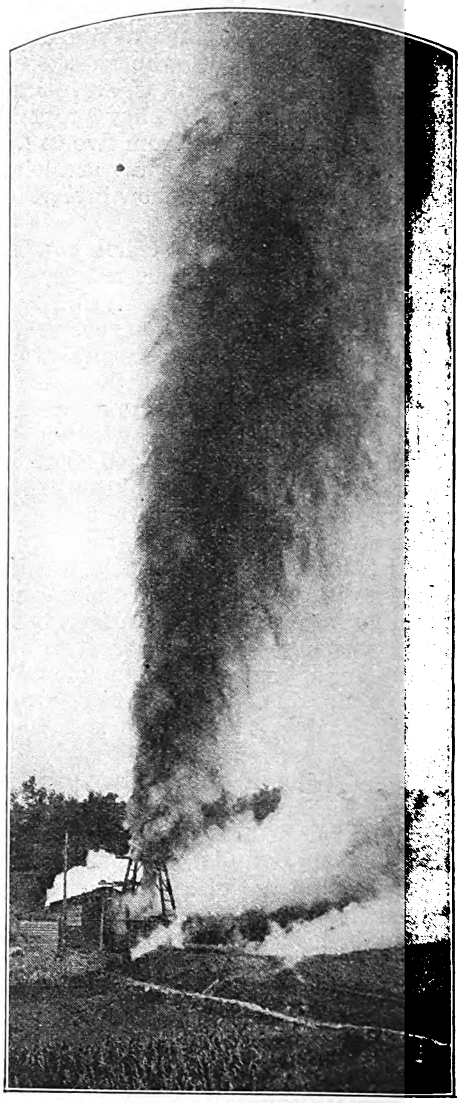
Steam escaping from thermal region at Lardarello in Tuscany. Here several thousand horsepower of energy have actually been developed but, as the author states, these thermal areas are not a promising source of vast energy such as the world needs to keep the wheels moving

Suppose that at the place where we are trying to get heat from the depths the rate of temperature is 1° Fahrenheit for every 100 feet; which certainly is the upper limit, according to the bore-hole records. At this rate the temperature at 26,000 feet would be 320° Fahrenheit, or that inside an ordinary steam boiler which is working at 75 pounds pressure per square inch. By cutting our last drop down to a little less than 200 feet we could reduce the water pressure to 75 pounds and, after all this trouble and expense, we would have——a set-up as practicable as an ordinary cheap coal-fired boiler; with the sole advantage that we would not use any coal in it, if—and there is a big "if"—we could get the heat out of the rock into the water.

The cause of that "if" is that rock is, as geologists know, not much better as a conductor of heat than the protective coverings that are put on steam pipes to keep them from losing their heat. The first few pounds of water would cool the surface of the rock, and the heat would have to pass through the rock by conduction and this rate is exceedingly slow even where considerable differences of temperature exist between T_1 and T_2—the respective temperatures of the two working substances. Perhaps a Jules Verne could imagine some way in which the water could be made to pass out through channels to great distances from the bottom of the hole, finally returning to the bottom of the other hole to emerge as steam, but my own fancy is unequal to the task. Engineers naturally hesitate to say that anything can not be done, but they may say they can not imagine any way of doing it, with present knowledge.

Someone will here say that there must be something wrong somewhere, because he has seen natural steam coming out of the ground in Yellowstone Park and has read that there are numerous other places where steam escapes, while hot springs are even more common. There are many of these local hot spots on the earth's surface and the scientists do not know how they get that way. Many explanations have been offered; such as that by earth movement molten rock has been brought up from below to near the surface and that the steam represents either surface water that has been heated by coming into contact with the hot mass, or else that it is water vapor that was in the molten material and is now escaping from it. There are difficulties in all these explanations, and we may here accept the two facts that over most of the earth's surface the rate of increase of temperature as we go down is too slow to offer hope of practically drawing heat from the interior of the earth, and that at some places there are local hot spots at which steam issues at the surface.

Suppose, then, that we forget about the rest of the earth and concentrate on the hot spots. There we have what Kipling would call "another story," one that I shall not attempt to outline here![1] Suffice it to say that the "steam" is not just steam, but contains a good deal of uncondensible gas and also, usually, chemicals that make it impracticable to use it directly in a steam engine, so some of the attempts that have been made to utilize it depend on using the "steam" to heat water and make ordinary steam that can be used in an engine. Add to this the fact that these hot spots are usually at places where there is nobody nearby who is a consumer of power and you arrive at something like the familiar water-power problem of having a source of power but the cost of harnessing it for utilization makes it cost more than power from coal.[2]



NOT AN OIL GUSHER

The eruption of a large steam well drilled in the thermal soil of a small area in Italy.

THE conclusion therefore is that coal producers need not lie awake nights worrying over the possibility of having their markets invaded by heat drawn from the interior of the earth.

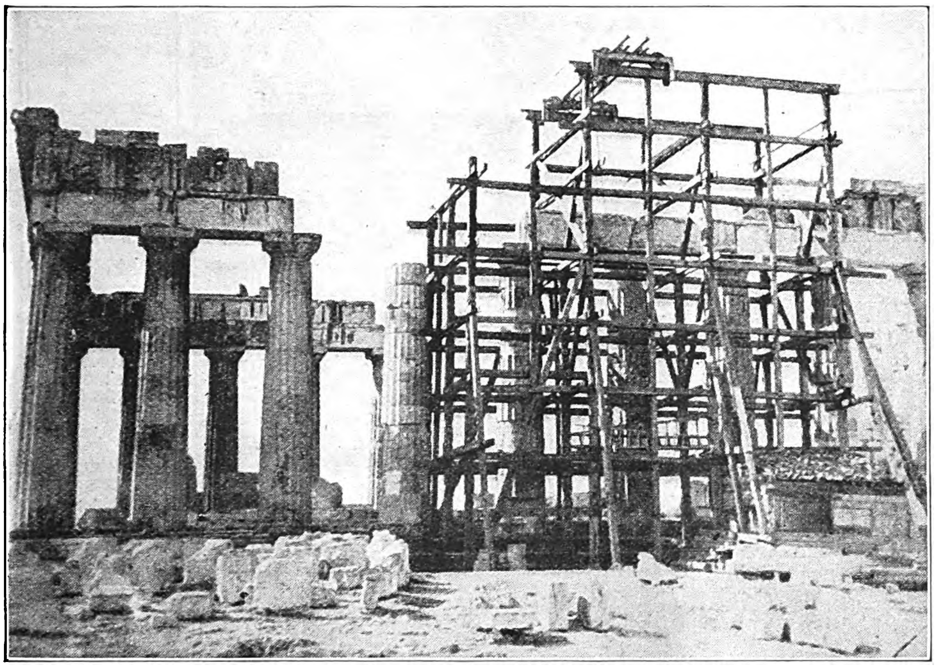
From the Archeologists' Note Book



REPAIRING THE PARTHENON

The drums of the columns of the 5th Century B.C. Parthenon at Athens are being placed in their original position, having been thrown down in 1687 during the siege of that city

Digging up Athens' Broadway

AMERICAN scholarships and American dollars have combined to excavate the *Agora* or market-place and forum of ancient Athens. This might be likened to the Broadway or Fifth Avenue of the antique city of culture. The cost will run into millions and it will require ten years to make the excavation in an orderly manner. Prof. J. Leslie Shear of Princeton University will direct the work. The Greek Parliament has passed a special law by which the American archeologists may condemn the houses by properly compensating the owners. The scientific enterprise is backed by over 40 universities and colleges of the United States. The buildings which now occupy the site are squalid and unimportant.

The *Agora* was the heart of Athens—commercially and socially. Here we had shops, markets, studios, and forums for discussions of all kinds. Here Apelles exhibited his paintings and here occurred the memorable meeting of Diogenes and Alexander the Great. Trading was carried on to a considerable extent, for Athens was a great center for luxurious merchandise. Trial by jury was also inaugurated here and we can almost see the reluctant potential jurors of yore trying to get excused from duty.

There are so many references to the *Agora* in classical literature that the task of the archeologists is much simplified. The excavated regions will be transformed into a park, as far as the maintenance of the antiquities permits. The site is the most promising in all Greece and the finds will probably be very important. When the excavations shall have been completed we can visualize the Athens of Socrates and Plato, as well as that of the dandies and revelers, for all sorts and conditions of men foregathered here.

Our illustration shows the repair rather than restoration of the Parthenon. This is not a part of the *Agora* plan but is a necessary although belated attempt to salvage one of the world's most precious structures.

An Ancient Bakery

THE remains of what is believed to have been the earliest bakery established by any civilized people were found recently by the Field Museum-Oxford University Joint Expedition to Mesopotamia on the site of the ancient city of Jemdet Nasr. The bakery consists of a group of clay ovens, estimated to have been built about 4000 B.C., according to Mr. Henry Field, assistant curator of physical anthropology at the Field Museum of Natural History. The ovens consist of large clay mounds, hollowed out inside, and with holes through the top to permit the passage of heat. At their bases are fire holes large enough for a man to crawl into. Huge piles of cinders of ancient fires were found inside. Pots and pans containing the bread to be baked were placed on the tops of the ovens, where the heat reached them through the holes.

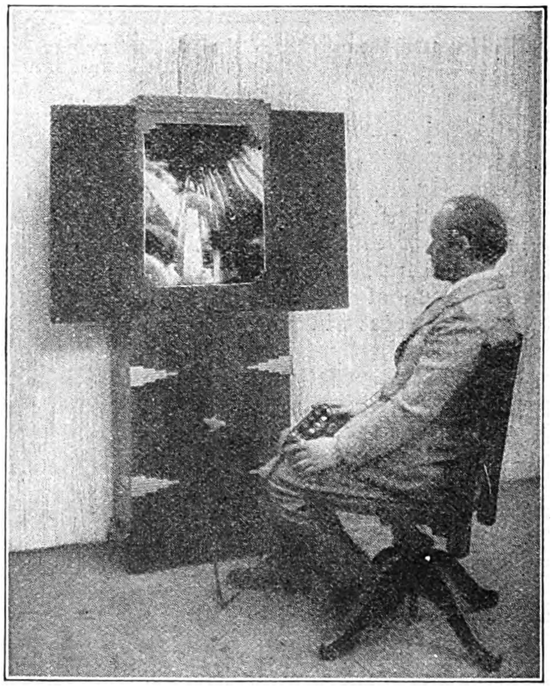
A HUNDRED HALLS IN ONE

In the ballroom of the Hotel Sherman at Chicago the new art of light has found one of its practical applications. Here all the decorations are projected from a suspended chamber



SUPERSEDING THE FIRE-PLACE

An instrument which plays form and color as a phonograph plays music. Colored disks are used

Light Furnishes Ballroom Decorations

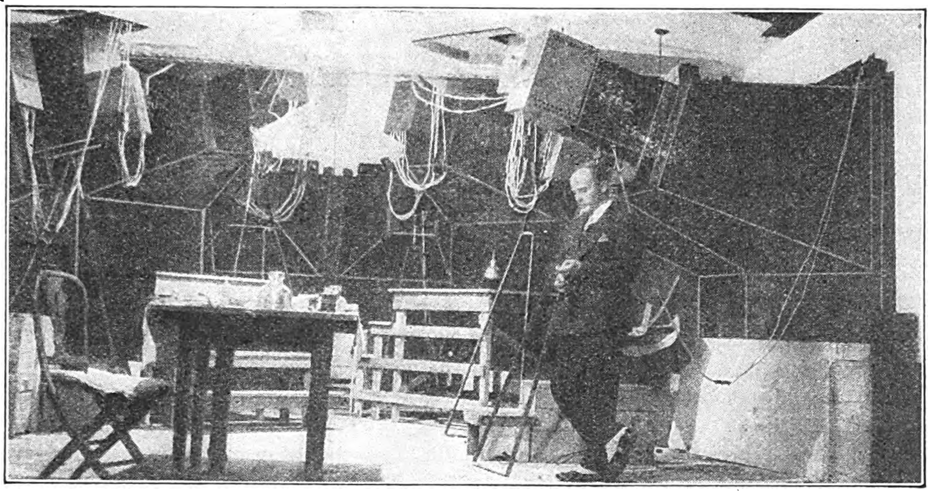
Color-Harmony Introduces a New Mode of Expression

SINCE Bainbridge Bishop patented his "color organ" in 1877, many artists and inventors have been at work on the creation of an art form of light somewhat similar to the age-old art form of sound-music. In its early stages this pioneer work was greatly hampered by the unfortunate and totally unfounded belief that each color corresponded definitely to a musical note. Now, however, the light artists of later years have come to look at light as an independent medium for esthetic expression no more related to music than to painting or sculpture. Form, color, and motion are the basic factors, according to the theory of Mr. Thomas Wilfred, an artist in light who has developed his dreams into the practical applications which we illustrate in this article. He has designed a clever keyboard from which lighting of any kind can be controlled with such delicacy as to enable an artist to express himself in form, color, and motion.

The Hotel Sherman in Chicago, wanted a mobile decoration for their ballroom—one that would be flexible enough to allow rapid changes to be made for varied functions. The hall may thus be used for a piano recital in the setting of a Grecian Court: For the Rotary Club luncheon the turning wheels, their well-known emblem, would be appropriate: For a woman's club tea in the afternoon, it can be decorated by diaphanous moving forms of a purely abstract nature: At night it can be turned into a Persian garden, slowly changing and opening vistas of enchanting beauty.

Our first illustration shows the means by which this is accomplished. The ballroom is finished in plain white plaster without a trace of decoration, which is all to be provided solely by means of light projection. The decorations are filed like phonograph records and are instantly available. The suspended projection chamber takes the place of a portion of the ceiling proper and carries its own ceiling below. This ceiling in turn is also decorated by projected mobile forms which issue from concealed wall instruments. Huge projection instruments in a semicircle are directed toward every point of the white walls. Below in a small chamber is the keyboard from which the operator commands a view of the entire hall. No operators are required in the projection chamber as the keyboard controls the light effects. The projection chamber is surrounded by a runway from which dancers can produce moving shadows of themselves on the walls.

To enhance further the projector images, a flood-lighting system is installed in the edge of the runway and an indirect neon-tube system furnishes



PROJECTORS

Twenty-three projectors in the suspended chamber cover the walls with unbroken images which are changeable at will

light on the suspended ceiling. The true ceiling is not seen, as it is painted black and no light is projected on it, which would differentiate it from the false or suspended ceiling. The effect is that of a vast cyclorama, but the true surface is entirely obliterated by means of the three-dimensional projecting system used. The illusion of three dimensions is achieved by utilizing a new principle of optics. One of the effects which can be obtained, for example, is a tropical forest. Through the spaces between huge tree trunks can be seen vistas of tropical undergrowth, flowers, sky, and water, constantly moving and changing in form and color. A cathedral with sunlight streaming in through a number of stained glass windows is another possibility. Using pure decoration, the entire hall may be covered with abstract forms apparently in three dimensions, rhythmically advancing and receding. Or there may be a modern city with a semi-abstract treatment of towers, cranes, girders, and bridges, swinging and moving. Or, at the operator's fancy, there can be an oriental fantasy suggesting the "thousand and one nights" with movements of festoons of large jewels among minarets and crystal towers.

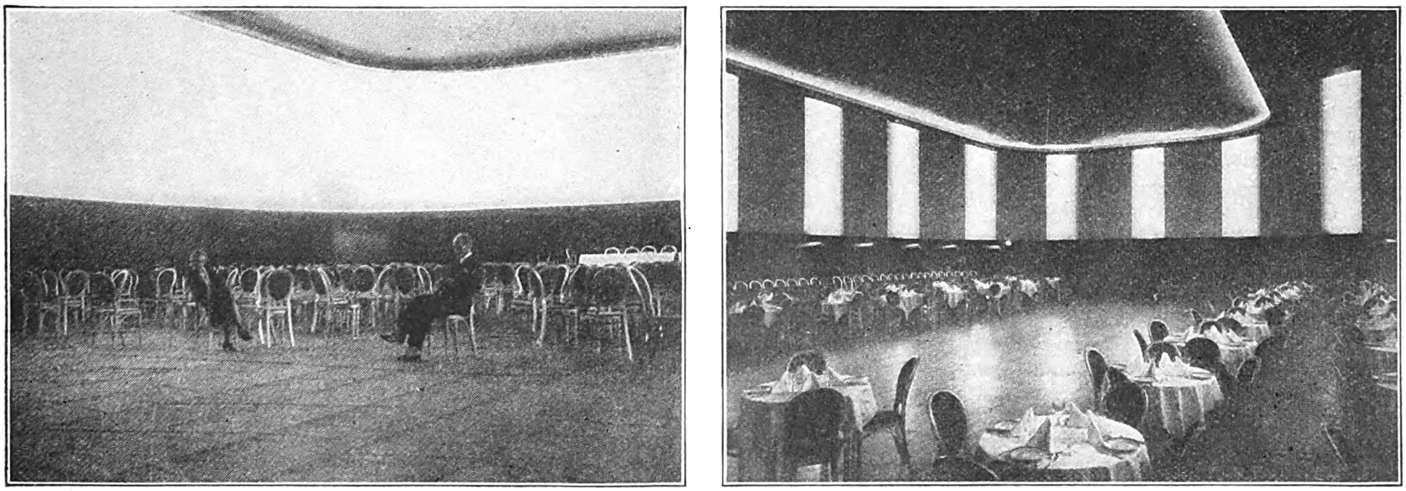
MUCH poetry has been inspired by the fire-place of yore, which has now been largely replaced by the uninspiring steam radiator or the unconvincing gas-log. The charms of story telling around the fire is as extinct as the dodo and the electric bulb has inspired no poetic muse. However, we may now take the very bulb and make it speak eloquently of the "stuff that dreams are made of" by a new instrument for home use. All one does is to open the doors which mask a curved screen, select a record from the drawer, take the tiny keyboard in his lap and the world of make-believe is his. Colored glass records rotating at different speeds are used to allow the lights to be projected onto a screen background lighted from above with the three primary colors from minature floodlights controlled by the player. Eleven buttons enable the player to modify the forms and colors projected through the slowly moving record to increase or decrease the tempo at will, or "freeze" any transitory form which appeals to the fancy, as long as desired.

THE LIGHT KEYBOARD

All projected images, colors, and movements are controlled by means of tiny keys sliding in grooves. This enables a recital to be given by a color artist

These cabinets can be designed to fit the architectural or decorative scheme of the room. They take up no more space than the modern phonograph or radio set. They are self-contained and all you need is to connect to an outlet, as with any other electrical device. The effect when seen for the first time is remarkable. You can give a home "color recital" with it.

With our noise-racked nerves, it would seem logical to seek recreation through silent beauty. We might even visualize, with Mr. Wilfred, large temples of light where people can find a place of silence with light as the only language of beauty.



"BEFORE AND AFTER"

At the left is seen the ballroom with light decoration omitted and all control keys at zero. Only a blank wall is seen. At the right the projectors are functioning and we have a Grecian court with three-dimensional fluted columns with night sky between

The Scientific American Digest

Newest Developments in Science, Industry, and Engineering

Individual Hothouses for Plants

A NEWLY developed paper cover for plants, in effect a miniature hothouse for each plant, is coming into widespread use in some parts of the country. These paper covers, called "Hotkaps," are in the form of cones made of specially prepared waxed paper about 11 inches in diameter at the base. When placed over the plants, it is claimed that they protect fully against late frosts, wind, insects, and heavy rains.

Individual "hothouses" for plants being placed by means of the metal setter. The pre-formed paper caps fit snugly into this special device

The paper cones are inserted in a setter made of metal in the exact shape of the Hotkaps and the setter then placed on the ground over the seed or plant which is to be protected. Slight pressure on the handle of the setter forces the Hotkap into the ground a distance of ¼ to ½ inch. The edge of the paper cone which protrudes from under the edge of the setter is then heaped with soil, the setter is removed, and the paper is permanently in place. After the seeds have germinated and obtained a good start, a slit is cut in the side for ventilation; and later the top is cut out for the plant to grow through.

It is claimed that Hotkaps force a much earlier growth than would be possible under ordinary circumstances.

General Electric's Foreign Interests Gain

THAT the General Electric Company in the future will derive a greater proportion of its income from sources other than operations is evident from the substantial increase in its investments in associated companies, both in this country and abroad.

The greatest gain in such investments last year was in leading European companies, in some of which the General Electric Company, through International General Electric Company, previously had stock interests.

As a result of these acquisitions, investments of International General Electric Company at 74,665,063 dollars December 31, last, showed an increase of more than 100 percent over the total a year previously —35,418,307 dollars—funds for such investments being advanced by the General Electric Company.

General Electric retains intact its holdings of 1,240,530 shares of common of Radio Corporation of America, and these, too, are included, at conservative values, in the investments in associated companies, as well as additional capital supplied in 1929 to Electrical Securities Corporation and United Electric Securities Company to finance normal expansion of the latter's operations.

Income from investments in associated companies and miscellaneous securities, the latter being comparatively small, has been increasing each year for the General Electric Company and in 1929 represented 45 percent of all "other income." Against a total net of 67,289,880 dollars; including that from operations and other income, in 1929, total "other income" represented 31.8 percent.

The 9,681,387 dollars interest and dividends received from associated companies and miscellaneous securities in 1929 represented 6.6 percent of average value at which these investments were carried on the books of General Electric at the beginning and end of the year. It compares with a 7.6 percent return in 1928.

If the General Electric's proportion of undistributed earnings available for dividends of associated companies had been taken into income, the increase in total net would have been approximately $1.74 a share on the 7,211,482 no-par common shares outstanding at the close of 1929, bringing the per-share figure to $10.71, against the $8.97 that was reported.

Considering undistributed equities and various other items, the nearest calculation of share earnings would be around 13 dollars on the common, or an increase of more than 40 percent above reported figure. Total net, on this basis, would be in excess of 90,000,000 dollars, whereas actual reported income was 67,289,880 dollars.—*Barron's.*

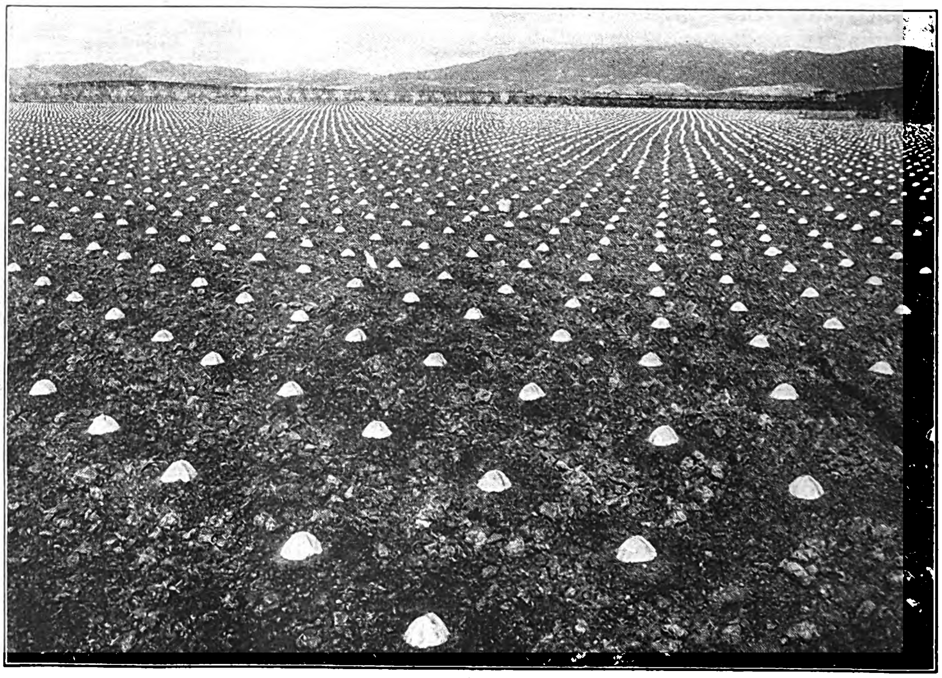
New Rubber Plants in the United States

RUBBER plants, of a species so productive that it has been exploited almost to the point of extinction in its native home in Madagascar, are now growing in southern California and Florida and have withstood the climate during the past winter with no apparent damage. So far only a few plants have been established but this number will be increased as rapidly as possible.

These rubber plants belong to the species *Euphorbia intisy*, and were brought to the United States more than a year ago by Dr. Charles F. Swingle, botanist of the United States Department of Agriculture, who spent several months on a plant exploration trip in Madagascar with Professor Henri Humbert of the University of Algiers.

Intisy is a shrub or small tree reported to reach a height of approximately 20 feet, although no specimens of this height are known to exist at this time. The trees are leafless, and present a scraggly appearance. Their ability to grow in the very dry regions of southern Madagascar is accounted for by an unusual root structure. The roots resemble links of sausage, and act as reservoirs for water.

With the discovery of this plant in



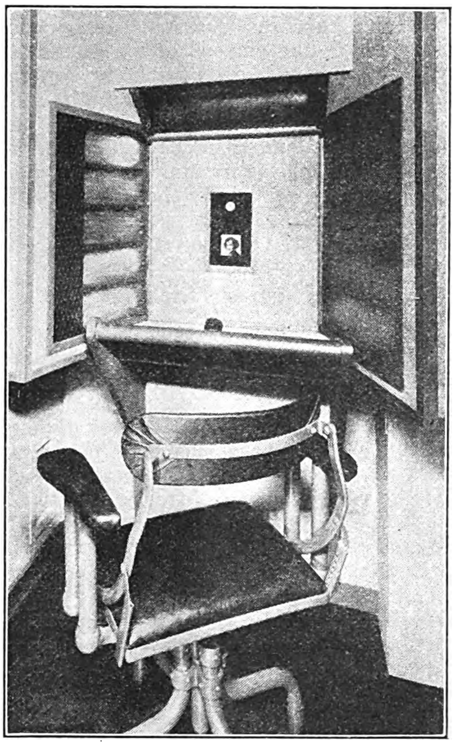
"Hotkaps" in place in a large field. They speed germination of the seeds beneath. The paper is stiff enough to resist the force of wind and rain

Madagascar in 1891, commercial exploitation followed at once, and annual rubber exportation jumped from less than 50,000 pounds to almost a million pounds. The ruthless exploitation soon showed its effect, reports Doctor Swingle, in an article in the *Journal of Agricultural Research,* and within a few years *intisy* had become so rare that observers reported it was very difficult to find specimens.

In some of the regions where Doctor Swingle found *intisy* growing there are periods of six years at a time when there is no rain.

"The manner of obtaining *intisy* rubber," Doctor Swingle says, "is very simple and is one of the factors that led to the commercial disappearance of this plant. The latex, which flows from any cut, coagulates in the air without further treatment. All that the native has to do is to make cuts in the stem, return in a few days and pull off bands of rubber of very high quality, especially desirable for the manufacture of automobile tires.

"The yield of rubber from stems less than one inch in diameter is so slight that it does not pay to tap them. However, during the time of commercial exploitation, spiral cuts were made all the way up the tree, and yields of 15 pounds or more of rubber would be obtained from a single tree. In many cases the first tapping was so severe that the tree died outright."



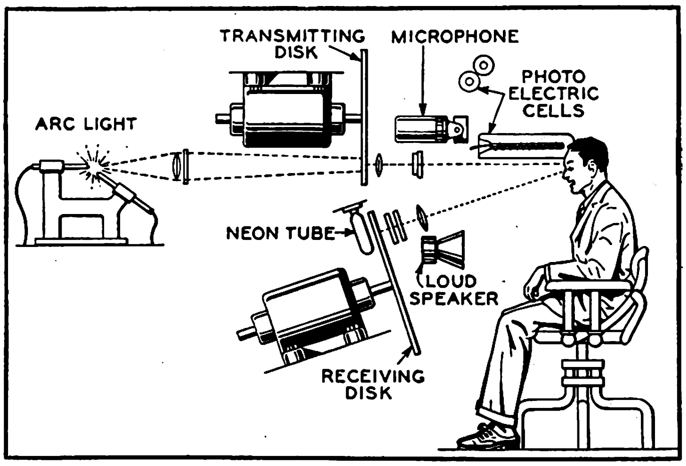
One of the two-way television cabinets. On the small "screen" in the center, one sees the person at the distant end; and above this is the scanning-beam hole

Two-Way Television Demonstrated

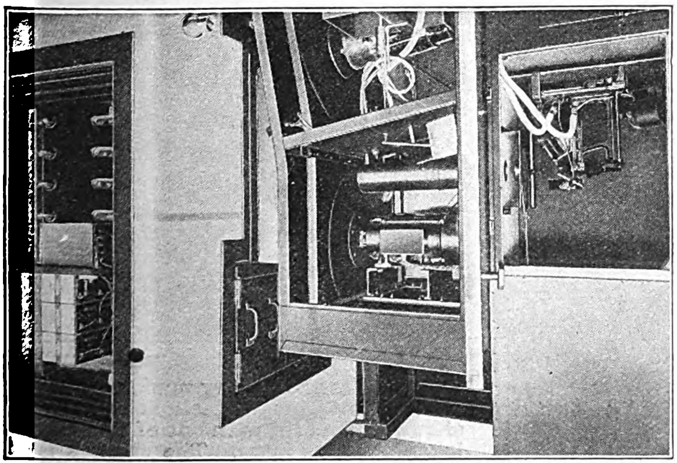
TELEVISION has taken another step in its development, with the production of an experimental system of two-way television supplemented by the usual two-way telephone, permitting the parties to a conversation to see as well as to hear each other.

An experimental service between the American Telephone and Telegraph Company's building at 195 Broadway and Bell Telephone Laboratories at 463 West Street, which has been in operation for some time, was disclosed recently to the editors of this magazine. Special telephone-television booths were installed at these two buildings.

In one of these booths a person seats himself before a frame in which he will see the face of the person with whom he is talking. His own face is rapidly scanned by a mild beam of blue light which reflects from his face to the photoelectric cells and gives rise to the current which transmits his image to the distant booth. There is no fierce glare to the scanning beam; and one is not annoyed by its presence and may even gaze directly at it without inconvenience.



At right: **Arrangement of apparatus in two-way television. As the incoming image is viewed through the lower scanning disk, the speaker's face is scanned by the upper disk. A microphone and loudspeaker complete the layout**



At left: **Opened doors of the three major cabinets of the television-telephone apparatus show photo-electric cells at right, scanning disks for receiving and sending in the center and the arc-light for sending at left**

The first thing which strikes the observer when he steps into the booth—which is lighted with a dim orange light to which the photo-electric cells are insensitive—is the absence of the usual telephone. Special telephone transmitters and receivers are concealed in the booths. One talks face to face to the distant person and a hidden receiver speaks the words which seem to issue from his mouth. The other party to the television-telephone conversation appears with sufficient detail for recognition of facial expression.

The television image is greatly improved over that originally demonstrated by Bell Telephone Laboratories in 1927, and is about twice as large with a corresponding increase in detail. The image, which has the detail of about five thousand discrete points of light, is formed 18 times a second. The photo-electric cells, used in picking up the face which is to be transmitted, have been much improved in sensitiveness and give rise to about 10 times the current for the same amount of light as did those developed for the earlier demonstration. This increased sensitivity and the use of the blue scanning beam have made possible the reduction of the dazzle and glare which occurred to a certain extent in the earlier forms of apparatus. The increased area and detail of the image necessitate the use of a transmitting band of 40 kilocycles.

New Inexpensive Eight-inch Fan

THE Westinghouse Electric and Manufacturing Company has recently announced a new eight-inch fan of the non-oscillating type in the price-range of five-inch fans now on the market. It is a portable type, the body being made of cast iron in an attractive black finish, the fan blades are heavy gage sheet steel, and the guard is of heavy steel wire. It is single speed and is controlled by an on-and-off switch in the base.

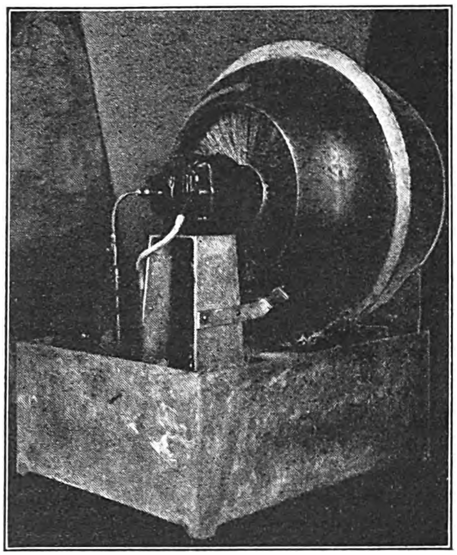
Wasteful America Saves Billion in Scrap Annually

EVEN if Americans are wasteful, as is often claimed, they salvage nearly a billion dollars' worth of their waste every year. This is according to figures of the United States Bureau of Mines on the amount of scrap and secondary metal recovered, which is increasing every year.

The waste trade industry is concentrating in large units. Even gold and silver is recovered in quantity from jewelry and dental waste. Photographic solutions contain half an ounce of silver to the gallon and 1,000,000 feet of waste movie film yield 800 ounces.

Of the 500,000 tons of secondary copper recovered annually, part comes from 300,000 burned out electric lamps collected by one company. About 40 percent of the annual supply of tin and lead has been used before.

The iron and steel saved in a year is worth 500,000,000 dollars. Other metals



Rear view of the small air conditioner showing all of its parts

salvaged in quantity from scrap, sweepings, skimmings, and dross are mercury, zinc, antimony, aluminum, and nickel.—*Science Service.*

A Home-Size Air Conditioner

FOR reasons of health and personal comfort, stress has recently been placed upon the necessity for purifying and cooling the air in which we live and work, in home, office, and factory, but most attempts to solve the problem have resulted in the production of the elaborate air washing and refrigerating equipment now commonly used in theaters and, in a few cases, in office buildings. Recently, however, a compact air washer-cooler-ventilator which can be used for small offices or even in the home was developed by John H. Fedeler, Building Superintendent of the New York Public Library.

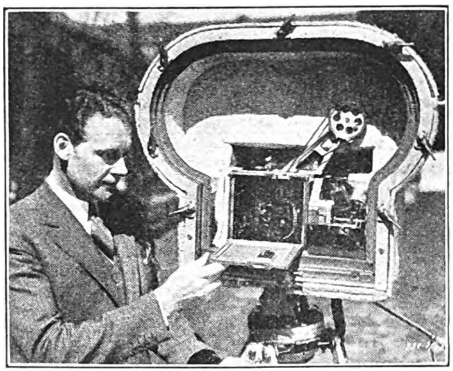
Mr. Fedeler first realized the necessity for such a device when he worked, in 1895, as a draftsman for Mr. Edison at the ore mines in Edison, New Jersey. When the crushing plants at the mines were in operation, he noticed that the whole countryside was enveloped with a dense dust cloud. He later conceived the idea for the unit which he finally developed, but many experiments lasting over a period of 30 years, and the expenditure of thousands of dollars were necessary before he attained his goal.

The complete machine is shown on this page. Its parts are: a circular brush, the "bristles" of which are of crimped Monel metal wire; a scientifically shaped casing of light-weight metal; an electric motor; a small water pump together with necessary tubing of metal and rubber; and a water box or tank on which the other equipment is mounted. As the motor rotates the brush at a speed of 1500 or 2000 revolutions per minute, the pump, which is also run by the motor, draws water from the tank and throws it into the brush. Due to the shape of the casing, air is drawn in and as it comes in contact with the wet brush, dust and dirt in the air are captured by the water and thrown by centrifugal force to the casing. The constant flow of water carries the dirt down into the tank where it settles out and may be removed periodically. The air also is thrown by centrifugal force to the casing and, because of the shape of the latter, is deflected through the unit into the room beyond. The rapid evaporation of water in the current of air causes the temperature to be appreciably lowered and a partial adjustment of humidity.

When desirable, a small amount of perfume may be added to the water used, so that the air will be perfumed. Also, when the air of any locality has been found to be acid, a neutralizing alkali such as ammonia may be dissolved in the water.

Feeding Helps Sick Trees

A RECENT development in the care of shade trees is the importance now given to "feeding" a sick tree before a lot of tree surgery work is attempted. Workers in the United States Department of Agriculture explain that this does not mean that pruning and other surgical work is not necessary, but if a tree is not vigorous, an application of plant food is likely to prove very helpful in restoring the tree to a healthy condition. Fertilizers which give immediate effect include nitrate of soda and sulfate of ammonia, applied broadcast in the spring or early summer at the rate of two to five pounds for a medium-sized tree.



Lane Chandler, movie operator, is shown with the "blimp" camera cell he has devised. By enclosing the camera in this padded cell, all clicking is kept from the microphones while making "talkies"

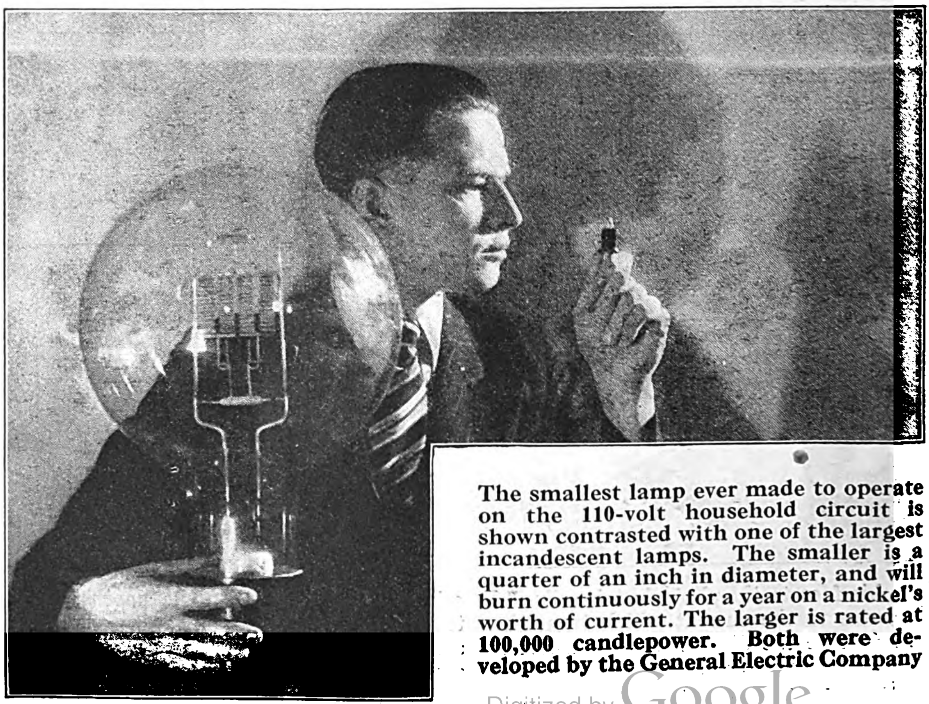
The direct effect of such an application usually lasts for only a year, but the indirect effect may be apparent the following year, as it usually stimulates the healing of wounds made by pruning or cavity work. An excess amount of fertilizer or an application late in the season may cause injury by stimulating excessive development of foliage and failure to mature the new wood properly before winter sets in.

Centennial of the Modern Scale

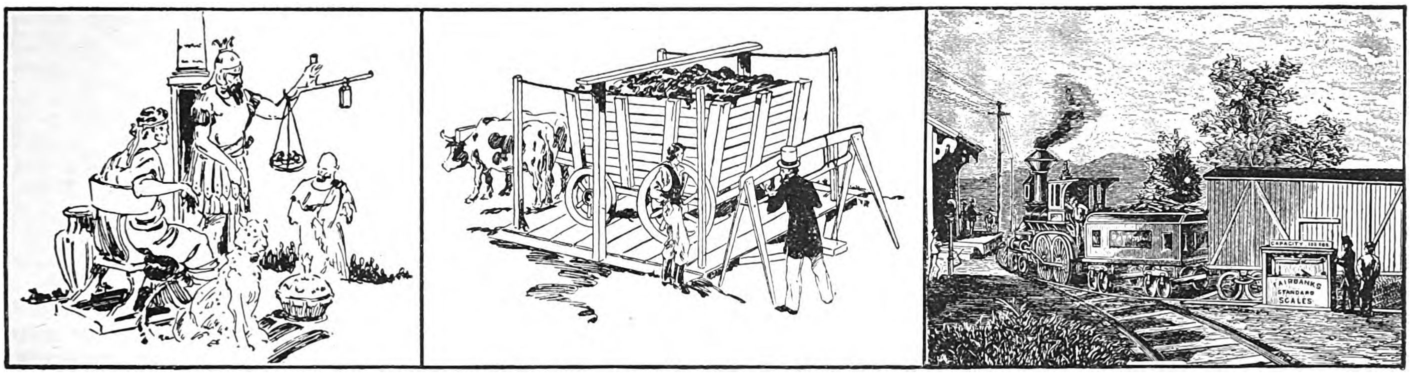
MANUFACTURING methods of today are concerned chiefly with mass production and the waste both of time and materials. It naturally follows that accurate weighing plays an important part in almost every phase of the production schedule. Thus it is that the year 1930, marking the centennial of the platform scale, is particularly interesting in that it shows what may come out of small beginnings.

From the steelyard of ancient days, there was no improvement in methods of weighing until, in 1830, Thaddeus Fairbanks invented the platform scale, the prototype of all modern scales.

It was in 1815 that Major Joseph Fairbanks moved from Brimfield, Mass., to St. Johnsbury, Vermont, and set up a grist mill and saw mill on the banks of a little creek that ran through this old Vermont town. His sons, Erastus and Thaddeus, had even broader visions and established a wheelwright and foundry business and then developed the manufacturing of saws, pitchforks, cast-iron plows, and stoves. In about the year 1830 the "hemp craze," as it was called, struck Vermont and the farmers expected to make substantial fortunes in raising hemp instead of corn. Contracts for making hemp-dressing machines were awarded to the Fairbanks brothers. The question now arose—How was the hemp to be weighed? The old steelyard was of little use for this service and so Thaddeus conceived the idea of constructing a huge steelyard beam suspended from a high frame with chains to grapple the axle of the cart. An approximate weight was thereby obtained by a process that was both slow and laborious.



The smallest lamp ever made to operate on the 110-volt household circuit is shown contrasted with one of the largest incandescent lamps. The smaller is a quarter of an inch in diameter, and will burn continuously for a year on a nickel's worth of current. The larger is rated at 100,000 candlepower. Both were developed by the General Electric Company



Evolution of the modern scale. At the left is shown the steelyard which was used by man from early times until Fairbanks invented the platform scale. Fairbanks' scale, in center, was the prototype of the one at right

Thaddeus studied the problem and finally conceived the idea of supporting the platform upon an A-shaped lever with the tip of the lever connected to the steelyard by a rod. Though not suspected by Thaddeus at the time, he had revolutionized all weighing methods and at that moment the steelyard of old Rome took its departure.

From this small beginning the platform scale in all of its ramifications was developed until today the same principle is in use, whether in a health scale, a laundry scale, or the ponderous ones used for weighing the largest railway locomotives.

Pump Dry Cement Across River

ALL the cement required for the recent construction of a 16-mile concrete highway along the Allegheny River in mountainous Warren County, Pennsylvania, was pumped across the river in dry bulk through a three-inch pipe.

Compressed air at 100 pounds pressure carried the cement in powdered form from freight cars a distance of 768 feet, the length of the pipe, to the batching plant. This unusual method of handling cement proved thoroughly practical and economical. The pipe was suspended across the river from a cable.—*Science Service.*

Ford Profits—81,797,861 Dollars

AFTER showing a deficit for 1927 in excess of 42,000,000 dollars due to the shut-down the latter half of the year for re-tooling incident to the production of the new model, and a deficit of over 72,000,000 dollars for 1928 due to large expenditures to bring up production, the Ford Motor Company showed a profit of 81,797,861 dollars for 1929, the second year of production of the Model A. These figures are given in the annual balance sheet filed recently with the State Commissioner of Corporations of Massachusetts.

Profits for last year were equal, according to *The New York Times*, to $473.79 a share on the 172,645 shares of stock, all of which are held by Henry Ford, Mrs. Henry Ford, and their son, Edsel Ford.

Floodlight Units Help Prevent Liquor Smuggling

BY an odd twist of the illuminating engineer's mind, the Aqualux underwater floodlight, usually operated under water for the illumination of swimming pools and fountains, is now used to help keep the United States dry.

A unique method for enforcing the Volstead Act has been worked out with the United States customs and immigration officials. One of the installations has been made on four of the traffic lanes on the Buffalo end of the new 4,000,000-dollar Peace Bridge linking the United States with Canada.

It was found that a few of the cars returning to the United States over this bridge had hiding places constructed on the underside designed to contain quantities of contraband. Such hiding places, it was thought, could not be detected. It was a different story, however, after the floodlights were installed.

Three Westinghouse floodlights are buried in the concrete in the center of each traffic lane, and are equipped with 100-watt Mazda lamps which are completely enclosed by the waterproof housings. The spread lenses are protected by a heavy iron reinforcing rod embedded in the concrete over each light. The Aqualux floodlight is a cubical cast-aluminum box 8⅞ inches on a side with a gasketed cover containing an 8⅜-inch spread roundel. A chromium plated metal reflector is supplied in order to withstand the severe operating conditions.

With the car well illuminated on the underside, a view is obtained by merely looking downward into mirrors which are located for a distance of 10 feet along the curb, and set at an angle of about 45 degrees. These are five and one half inches high and are also protected by iron rods set in the concrete.

When a car stops in the lane for the usual inspection, the customs officer can see at a glance the details of the underside of all cars. If he sees the usual machinery and open spaces, there can be but little concealed. But, if the mirrors reflect large areas of sheet iron, or suspicious boxes or tanks, the car is ordered out of line for closer inspection of under-body parts.

Learning to Use Our Wings

Latest Facts About Airplanes and Airships

CONDUCTED BY ALEXANDER KLEMIN
In charge, Daniel Guggenheim School of Aeronautics, New York City

Experiments in Fog Flying

EXPERIMENTS in blind flying, under the auspices of the Daniel Guggenheim Fund for the Promotion of Aeronautics, were recently related by Lieutenant James H. Doolittle before the Society of Automotive Engineers.

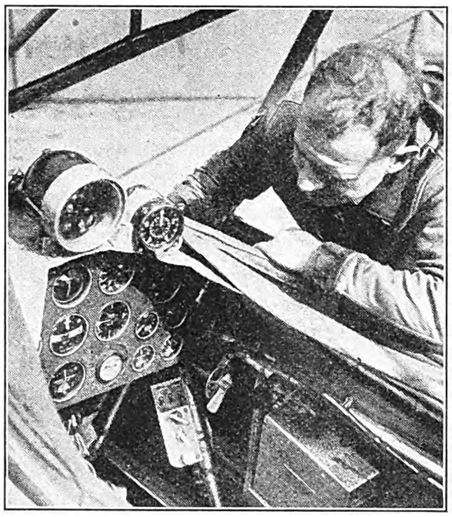
A number of flights including 180-degree turns were made with remarkable accuracy, with the pilot seated in an entirely covered cockpit, and an assistant in the rear cockpit to take charge in case of emergency.

Success was due as much to the remarkable instruments employed as to the skill and pluck of the pilot. The instrument board of the *N Y 2*, Consolidated training plane employed in these tests, is shown in one of our photographs. The instruments included standard tachometer; oil pressure gage; oil-temperature gage; airmeter; voltmeter; compass; bank-and-turn indicator; air-speed indicator; altimeter; and rate-of-climb indicator. In addition, a very sensitive Kollsman altimeter, graduated in 10-foot intervals, a Sperry artificial horizon, and a Sperry directional gyroscope are shown in the photograph.

The directional gyroscope is not truly a gyroscope compass because it does not seek the north, but once set in a given direction, it will maintain that direction without serious error for a two-hour period.

Another very useful instrument employed was the Sperry artificial horizon. Here again a gyroscope is employed (driven by a small air turbine which is connected to a Venturi placed in the airstream) in this case with its axis placed in a vertical position. The instrument is so constructed that a tiny airplane is seen by the pilot to be in normal attitude, climb, dive, left wing low, or right wing low, according to the position of the plane on which the instrument is mounted.

The ground radio equipment consisted of (a) an audible-type radio-beacon, the purpose of which was to direct the incoming airplane to the vicinity of the field or to keep the outgoing airplane on its course, (b) a visual type localizer-beacon, the function of which was to lead the pilot to the exact point where he should touch his wheels in landing; and (c) a ground receiving and transmitting set.



An airplane cockpit equipped for experimental flights under conditions simulating flying in fog

The visual-type indicator consisted of two vibrating reeds, indicating to the pilot his position with respect to the beam center. When to the right of the beam, the right reed vibrated through a greater amplitude. When to the left of the beam, the white streak caused by the vibration of the left reed became longer. When exactly over the center of the beam path, the reeds vibrated with equal amplitude. Upon approaching the beacon house, the intensity of the signal increased rapidly. At the exact moment of passing over the beacon house, the reeds stopped momentarily, and then started to vibrate again in the opposite direction.

The beacon employed was of the loop type entirely enclosed in a small building, with no wires on the outside. In the center was the goniometer which tunes the loop aerial, so that the correct guiding beam was transmitted to the pilot.

The airplane was taxied out onto the field in position for the take-off, and directly on the radio beam. The altimeter was set at zero, and the gyros speeded up. At take-off the pilot was able to hold the airplane straight by the gyro and the tail in the proper attitude by the artificial horizon.

The localizer beam was followed for about four miles and the plane climbed to about 1000 feet. A 180-degree turn was made at this point and the beam followed to the beacon. As the beacon was approached the beam became narrower, and the course more exact.

Upon passing over the beacon house again, the reed stopped vibrating, the engine was throttled so that the plane came down to a speed of 60 miles per hour, the plane was kept absolutely level by the artificial horizon, and then flown directly to the ground without leveling off. The

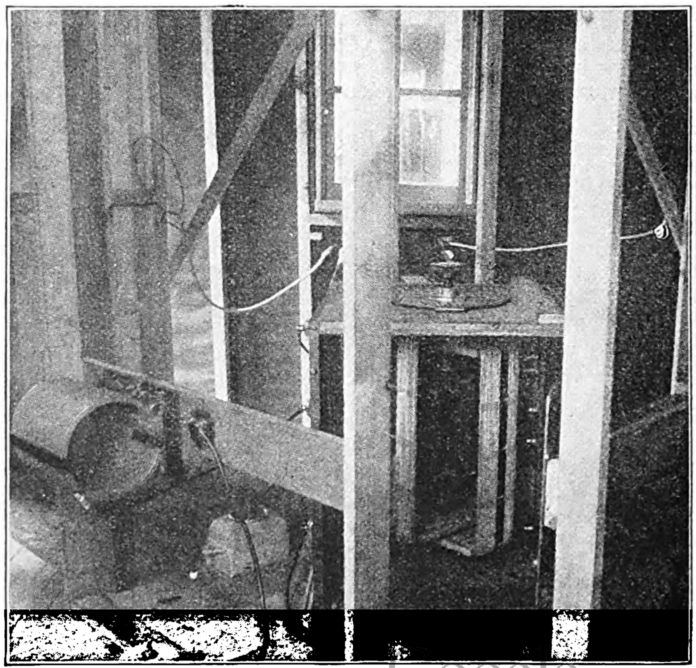
The Sperry artificial horizon. See text above



Goniometer in the ground radio transmitting station shock of landing was uncomfortable but could probably be eliminated by correctly designed landing gear.

"Had the airplane actually been coming into a fog-bound airport from a distant point," said Lieutenant Doolittle, "it would have come in along the audible-type beacon until it arrived at a point which indicated the intersection of the audible and visual-type beacon beams. At this point the pilot would radio in and request that the more powerful beacon be shut down to avoid interference. He would then follow on along the localizer-beacon beam, and at the same time request the ground barometric pressure, wind direction, ceiling, and visibility under the fog. Next the pilot would set off the correct ground pressure on his altimeter and put himself in the proper position to land into the wind."

These tests covered several months, and hundreds of landings were made without breakage. They are extremely encouraging, even if they cannot yet be considered commercially applicable.

Plumbing and Heating in the Air

IT is extraordinary how the airplane constructor has to reach out into every industry and trade to make his craft really comfortable for the passenger. In the matter of plumbing and heating, the aircraft designer has had to become his own plumber because the trade could not supply him with sufficiently light and compact equipment. John F. Hardecker, writing in *Domestic Engineering*, describes some of these very interesting developments.

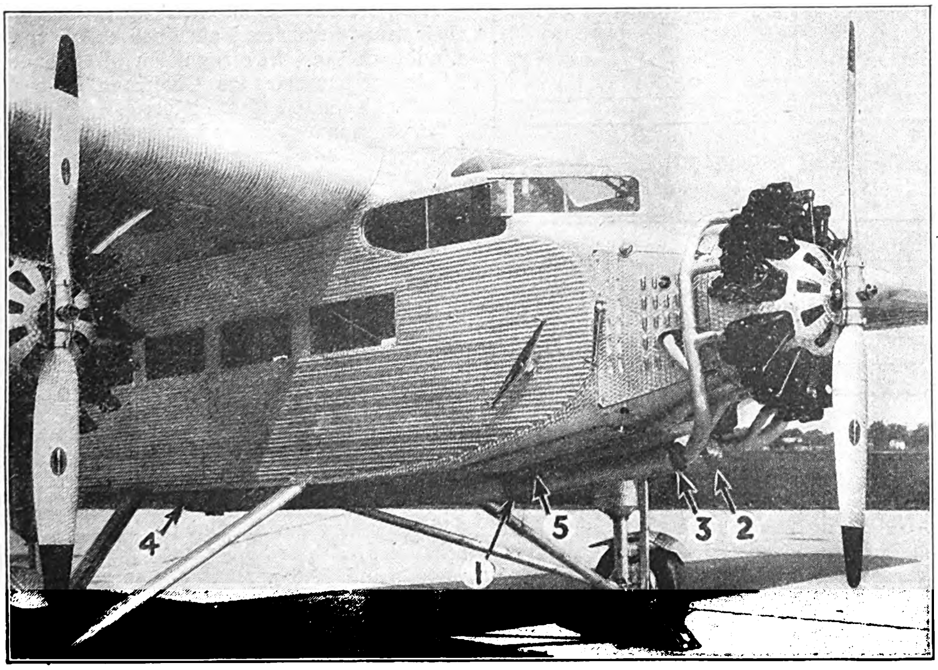
In the matter of plumbing, the limitations in the airplane are very severe. The fixtures must be light and small, because space is very valuable. Governmental regulations rigidly prohibit the discharge of any waste while in flight.

Designers have met these limitations by providing light combination water tanks and washstands of polished metal, weighing less than five pounds. Water tanks have been made of triangular and quarter-cylinder shapes so as to fit in corners and against cabin walls. A folding washstand has been developed which weighs only three pounds and fits snugly against the wall when not is use. Chemical hoppers have been provided, with sloping bottoms so as to fit sloping floors. Lavatory compartments on large passenger planes are fully equipped with washstands, closets, towel racks, small cupboards, and so on.

In the matter of heating, similar ingenuity has been displayed. Thanks to the courtesy of *Domestic Engineering*, we are able to show a special photograph indicating the heating arrangements on the Ford tri-motors now in use on the T. A. T. lines. The center motor exhaust pipe is installed along the under side of the plane. Over the exhaust pipe a large housing is placed with a clearance of approximately one inch on all sides. The bottom of the plane is protected by a heavy sheet of asbestos.

Fresh air is taken into the housing at the point 1 on the photograph. As the air passes through this housing it is warmed by contact with the hot exhaust pipe. The warm air is directed into the cabin by pipes of sufficient size, located in the floor at the center of the cabin. Registers may be opened or closed at the will of the passengers. The valve located at the end of the exhaust housing, at point 4, is operated by the last register in the cabin. When this register is closed, the valve is opened and allows the hot air to pass out to prevent overheating of the cabin. The funnel shaped opening, at point 2, and the register, at point 5, lead heated air into the cockpit. The opening at point 3 is for heating the air for the carbureter and operates in the same fashion as the cabin heater.

This simple and inexpensive method of heating has proved entirely satisfactory in practice, although temperatures under operating conditions vary from 35 degrees below zero, Fahrenheit, to 135 degrees above, and the flying ranges to 12,000 feet altitude.



Illustrating "Plumbing and Heating in the Air" above at left

A New Inverted Engine

THE in-line air-cooled inverted engine for small planes is still growing in popularity. This type offers somewhat less head resistance than the star or radial air-cooled engine and also less hindrance to the vision of the pilot. The pilot's vision is particularly satisfactory when the in-line air-cooled motor is inverted. The development of a six-cylinder in-line air-cooled engine by the Fairchild Engine Corporation is therefore of considerable interest to the aviation industry as a whole. The Model 6-390, as this new engine is called, has the following specifications:

Bore 4″
Stroke 5⅛″
Total displacement 386 cu. in.
Compression ratio 5.2 to 1
Weight dry 335 lbs.
115 h.p. at 2000 r.p.m.
Fuel consumption—.55 lbs. per BHP/hr at rated power and speed.

The engine has undergone a satisfactory 50-hour non-stop run at approximately full power.

The crankcase of the 6-390 is in two parts, and designed with special reference to ease of maintenance. A novel feature in the design is the use of four finished pads, two on each side, for mounting the engine. This makes for ready installation and removal of the engine from a plane.

The camshaft and rockers at the bottom of the engine are supported and enclosed by a housing, the cover of which serves as the engine oil sump. This makes for less noise and greater cleanliness.

The airplane pilot and mechanic should be particularly pleased with the grouping and location of the accessories on this engine, which are all placed towards the rear. Through a single opening about 12 inches by 16 inches in the cowl over the engine, it is possible to get at all the accessories as well as the starter and generator, oil pressure relief valve, and tachometer drive connections.

Glider Carnival Postponement

POSTPONEMENT of the New York Glider Carnival till late in June was announced by Edward P. Warner, chairman of the Carnival Committee. The event was originally scheduled for April 25 and 26 at Queens Borough Golf and Country Club, Bayside, L. I., N. Y.

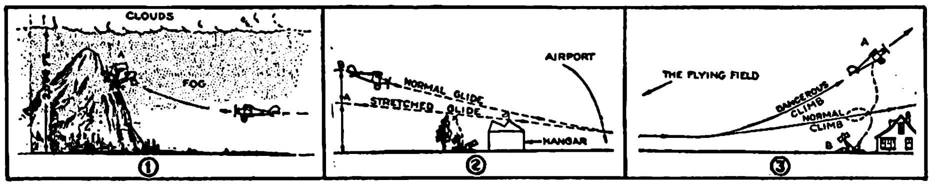
The Carnival was postponed in order to allow a number of organizations which had entered, sufficient time to complete the construction of gliders which they will fly. This action was taken following a meeting of the executive committee, which consists of Miss Amelia Earhart, Norman Siegel, C. T. Stork, and E. P. Warner.

Postponement to a date late in June also will enable a number of the collegiate glider organizations to take part in the event, Mr. Warner pointed out. The program of 14 events for novice, second, and first class glider pilots will remain the same as scheduled for the earlier date.

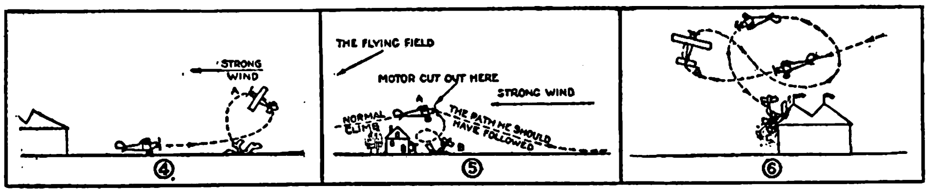
Avoidable Causes of Accident

A FORMER Bulgarian army pilot, A. Jordanoff, has graphically depicted some avoidable causes of airplane accidents in the *New York Times*. These sketches are reproduced below.

1, indicates a plane striking the side of a mountain in a fog. Some sensitive warning of the presence of the mountain is an invention still to be made. The present remedy is to land rather than to attempt to fly through fog at low altitude.



Above and below: Illustrations of six avoidable types of accidents



A misguided effort to stretch a glide by putting the plane at a large angle of incidence and so getting it out of control is illustrated in 2. The longest glide from a given altitude occurs at an angle of attack of about four degrees for the wings. Raising the nose slows down the speed of the glide, but actually diminishes the gliding radius.

The dangers of too steep a climb are shown in 3. If the climb is too steep, the engine may not provide enough power to maintain the climb, the wings may stall, and loss of lift and control lead to trouble.

Turning in a sharp climb may be dangerous, as shown in 4. We beg to differ with the author-artist here. Once the airplane is up aloft in a steady wind, the wind has no effect on its maneuver relative to the air—whatever may be its effects from the point of view of ground speed.

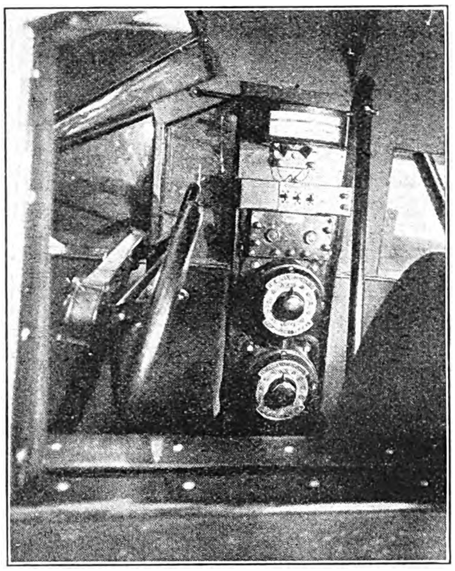
The golden rule is illustrated in 5. Never attempt to turn back when the engine quits. Turning without power may result in a stall, with consequent disaster.

Illustration 6 speaks for itself. Stunting at low altitudes is always dangerous.

Such diagrams published in the daily press may give the public an erroneous idea of the hazards of flying, but, on the other hand, if every pilot took such rules to heart the number of accidents would be greatly diminished.

Testing Gasoline in the Air

THE importance of using the best gasoline for aircraft is of course obvious and a great many of the large oil companies now have special aircraft gasoline departments with experienced aviation men at their heads, ready to supply pertinent information to aircraft engine builders and operators.



Equipment in cockpit for use in testing gasoline during flight

The Natural Gasoline Association of America, in collaboration with the Phillips Petroleum Company, has gone a step further by equipping a Wasp engined Travelair monoplane with a complete set of instruments for testing gasoline under conditions of actual flight.

The accompanying photograph shows the installation of the switch panel and recording instruments in the cabin of the plane, using delicate thermocouple and resistance thermometers. A most comprehensive survey of temperatures may be made at any one time; namely, temperature of the right wing, temperature of vapor space and gasoline in the tanks, temperature in the gasoline feed line, temperatures in the carbureter bowl, fuel pump, strainer, air intake, cylinder heads, and temperature in cylinder-head flanges.

If these temperature measurements are accompanied by the usual determination of altitude, air speed, and climbing and gliding angles, it is clear that a very thorough study of the motor's operation will be available. The temperature of the engine parts has an obvious bearing on the reliability of the motor.

Model Meet

A NEW YORK State model airplane meet will be held at Binghamton, New York, on May 30 and 31. Junior events will be for boys under 15 years of age, and senior events for young men from 16 to 21 years of age.

Outdoor models are to be twin pushers or tractors with 40-inch fuselages and a minimum wing surface of 125 square inches. Indoor models are to be somewhat smaller, with single tractor or pusher, propellers and with 15-inch fuselages and 24-inch wing spreads.

Nothing spreads interest in actual flying as much as the education of our youngsters in model work.

Radio "Flag Stops" in Air Transport

A MOST interesting development is the introduction of flag stops by the Transcontinental Air Transport. In order to serve more cities along its route, the T.A.T. has created three flag stops along its transcontinental line; one at Vandalia, Ohio, about nine miles north of Dayton; one at St. Elmo, Indiana; and one at Terre Haute, Indiana. Passengers will be able to board the planes at these points by simply notifying the company's representatives in time to have the pilot instructed. This will be done by radio while the plane is in the air.

Progress on the Lindbergh Line

WORKING in active co-operation with the Pennsylvania and Atchison Railroads, Transcontinental Air Transport Lines have issued interesting figures regarding the first six months' operations of their transcontinental air lines called the Lindbergh Line, in recognition of Colonel Lindbergh's service as Chairman of the T.A.T. Technical Committee.

Since its inauguration last July, T. A. T. has carried 4346 passengers for a total of slightly more than 2,000,000 passenger miles.

Its operating ratio, obtained by balancing the number of miles scheduled against the miles flown, has been 90.5 percent. There were 603,700 miles scheduled and 545,354 miles flown. Out of the 669 trips scheduled, 578, or 86.5 percent, were completed, and 70.6 percent of the plane arrivals were on time. These figures are quite encouraging and it is to be expected that, as confidence increases, a great many more passengers will be carried during 1930.

Chemistry in Industry

Advances Made in Industrial and Experimental Chemistry

Dead Sea Becomes Center of Live Industry

THE Dead Sea, in Palestine, long known to contain potash and other valuable salts, is now being exploited by a chemical company which will recover potash from its historic waters. Palestine Potash, Ltd., has been formed in London with 2,000,000 dollars in capital to exploit the chemical resources of this body of water. Actual work will be begun immediately at the confluence of the River Jordan and the Dead Sea, where elaborate drying plants have been erected and 400 workers engaged.

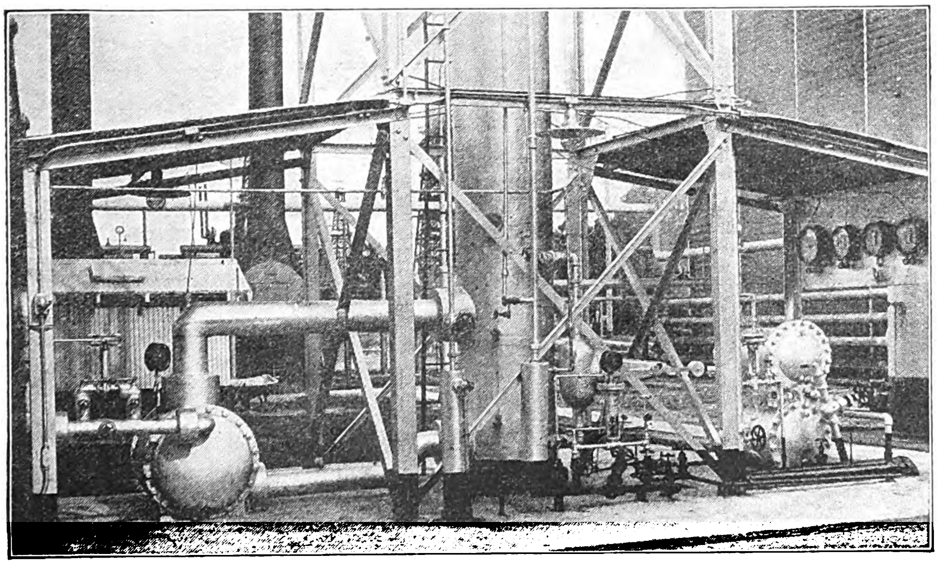
The Earl of Lytton, former Viceroy of India, is chairman of the new company, which intends to increase its capitalization as business warrants. Shares already have been subscribed by the British and American directors, but additional shares will be offered to the public in accordance with the terms of the concession. Among the American directors are Felix Warburg and Bernard Flexner of New York.

Although the start necessarily will be slow, the company is bound by its concession to produce at least 50,000 tons of potassium chloride annually after the tenth year. The work will be carried out by means of huge drying tanks built on the hills on each side of the mouth of the Jordan.

The water of the Dead Sea, which is 300 feet below sea level, is said to be among the world's richest repositories of valuable salts, and potash is expected to become one of Palestine's most important products. The potash will be taken by motor truck to Jerusalem and thence to Haifa by rail for export.

Automatic Control of Gasoline Plant

THE chemical engineer is not slow to adapt the ingenious devices of the electrical and mechanical engineer to his own problems, thus providing automatic control for the operations with which he is concerned. Often, a few degrees variation in temperature will make the difference between success and failure in a chemical reaction, so the automatic thermostat is called into use to keep its tireless vigil over many a vat, still, or digester. An equal degree of mechanization is now being realized in the control of pressure. Thus, for example, in the recovery of gasoline from natural gas, a very careful control of pressures in pipe lines and towers is essential. J. V. Thomas, in a recent issue of *Chemical and Metallurgical Engineering*, describes the almost human devices which take the place of manual control in plants of this kind.

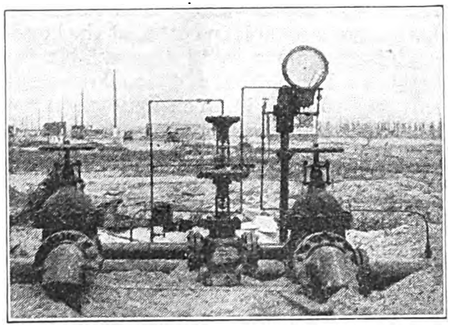


These pressure regulators, liquid level controllers, and temperature controllers are used in automatically maintaining a stabilizing column in a gas plant

Not only are pressures and temperatures controlled automatically, but liquid-level controllers maintain constant levels in tanks and absorption towers.

Mystery of Poison Island Solved

WHEN a large number of workmen, engaged in building a new power plant for the Duquesne Light Company, on Brunot Island in the Ohio River near Pittsburgh, were mysteriously overcome on the job, the engineers decided it was time to call in the chemists. A hurry call to the United States Bureau of Mines, Pittsburgh Experiment Station, brought a corps of specialists equipped with breathing apparatus, gas masks, and gas detecting devices. On arriving at the construction project, it was found that the employees affected by gas had been overcome or partially overcome while changing clothes in a change-house before going to work. Tests made by the Bureau of Mines safety engineers with a carbon monoxide detector showed that there was approximately 1 to 2 percent of carbon monoxide in the atmosphere of the building.



Automatic regulator used in gas line to reduce the pressure from 250 to 5 pounds, and maintain it

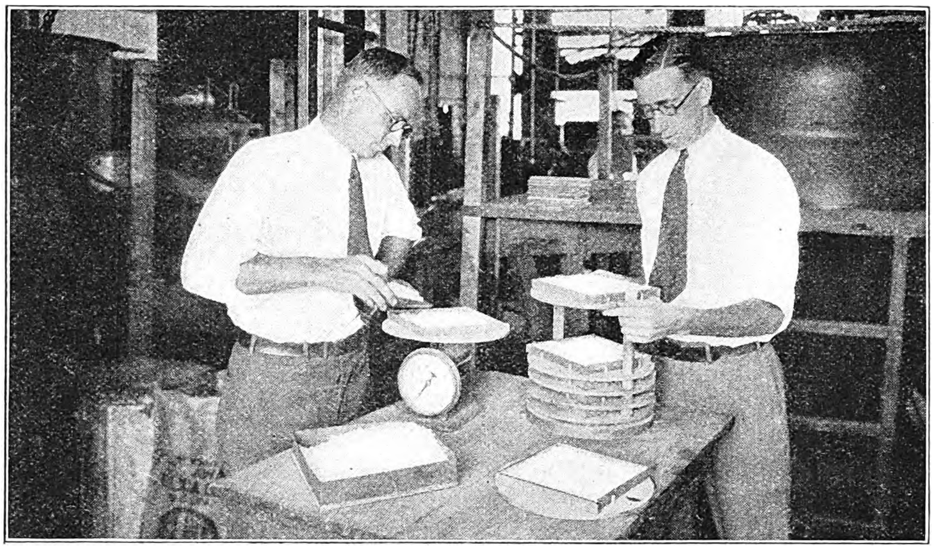
Investigation as to the source of carbon monoxide disclosed one of the most novel occurrences of the gas that has ever come to the attention of the Bureau of Mines specialists. The entire upper end of the island has been formed by the dumping of cinders from a boiler plant operated for a period of at least 20 years. This bed of cinders and ashes is at least 40 feet in depth in various places. Various sections of this cinder-ash field had been on fire as recently as two or three months previous. Thus a great area was giving off carbon monoxide, the formation of the deadly gas from the cinders being similar to the formation of water gas.

An intake tunnel was being constructed under the cinder-ash field, and the compressed air from the tunnel, under about 7½ pounds pressure, was being forced up through the cracks and the interstices similarly to the passage of air through a blacksmith's blower. This air movement increased the production of carbon monoxide, the formation of which was also considerably aided by the melting of a fairly heavy snow followed by rain, resulting in little or no air movement on the surface. The change-house in which the employees were overcome was located several feet from the site of the tunnel, illustrating the widespread distribution of the carbon monoxide.

Electrocute Methane to Form Acetylene

AT the Kaiser-Wilhelm Institute für Kohlenforschung, Germany, chemists have developed an "electrocuting" apparatus through which they pass a gas such as methane, whereupon it emerges as acetylene. Almost any of the hydrocarbons, when subjected as gases to the "shocking" effect of this electrical device are converted to something else, indicating that the effect of the discharge is to blow the molecules of gas into atoms which then rearrange themselves into new combinations, something like a game of electrochemical puss-in-the-corner.

Of the several kinds of electrical discharges which have been applied to chemical reactions, the most important from the practical standpoint are the arc, the silent discharge, and the low-pressure discharge. The arc process has been used, notably in Norway, for the conversion of the nitrogen in air into nitric acid. Another use of the arc discharge in chemistry is the production of carbon black and acetylene from



Weighing quartz crystals in the trays in which they will be melted to form window panes, and loading the trays on the holder for the electric furnace

hydrocarbon gases. The silent electric discharge is useful for its polymerizing effect and for activating gases. Its industrial use is limited by low yield and low current density. Low-pressure discharge gives a useful means of effecting endothermic and ionic reactions at relatively low temperatures.

The Germans have now found that not only methane but the higher hydro-carbons (naphthalene, anthracene, petroleum oils, and even pitch) can be converted into acetylene by a low-pressure discharge. In the presence of nitrogen, prussic acid can be obtained. Removal of products as formed makes possible excellent yields in the laboratory trials. Production on a commercial scale has not yet been accomplished, but energy relations and other considerations which affect costs do not indicate any fundamental obstacles.

Making Glass Which Passes Health-giving Rays

WHILE it is only recently that electrical manufacturers have developed lights which artificially produce the health-giving rays formerly available only in natural sunlight, nevertheless, the beneficial effects of these rays has been known for centuries. The ancient Egyptians were familiar with the benefits of sunlight.

The importance of ultra-violet rays of the sunlight to health and the fact that ordinary window glass cuts out nearly all of these beneficial rays has long been recognized. Several years ago Professor Elihu Thomson, director of the General Electric's great research laboratory at Lynn, Massachusetts, took up the work of developing a material which would transmit the health rays, to replace window glass. Fused quartz was known as the best medium for the purpose but to make window panes of it was a problem that required years to solve. The difficulties of making quartz windows can be appreciated when it is realized that the melting point of quartz approaches a temperature of 3200 degrees Fahrenheit, about three times that of glass. Moreover, it is extremely viscous, or thick. Many methods were investigated and special furnaces were developed before the engineers finally succeeded in making quartz in sheet form, and at a reasonable cost.

One of the first methods developed to produce a high quality quartz glass consisted in fusing, in a vacuum, specially selected and treated quartz crystals in a square fabricated graphite box, and pressing the fused mass of quartz at 1000 pounds per square inch while in the molten state. A block of quartz 8 by 5 by 5 inches was thus obtained. This block when cooled was sliced into sections one eighth inch thick and each pane was ground and polished by hand.

This method of manufacture was considered too expensive for common use, and further research was carried on to get a satisfactory quartz window that would be sufficiently reasonable in cost that the benefits of fused quartz could be available for more general use. This additional development work resulted in an entirely new process which cut the cost of manufacture to about one fifth of previous costs and made it feasible to use quartz in large solariums.

In the present process, quartz crystal, crushed to one quarter inch mesh, is fused in a vacuum on flat graphite disks between thin graphite slabs in the form of a 7½ inch square. A number of these trays are stacked in a form and placed in a high-temperature furnace. When the quartz is fused, nitrogen gas is admitted to the furnace at a pressure of 150 pounds per square inch to compress the bubbles. The resulting quartz plates, upon cooling, require only squaring of the edges by grinding. The plates themselves are 7½ inches square by one quarter inch thick. This new method does away with cutting, grinding, and polishing each pane, and the trays can be used a number of times.

United States Alcohol Consumption only Half Capacity

ETHYL alcohol ranks first in quantity and value of production of all organic chemicals. It is a basic raw material in the chemical and process industries and finds application in a multitude of products: An approximate distribution of denatured alcohol by uses is as follows:

	Wine Gallons
Anti-freeze	40,000,000
Cellulose industries	25,000,000
Shellac and varnish	8,000,000
Toilet and perfume preparations	5,000,000
Miscellaneous	15,000,000

The total available capacity in the United States for producing alcohol, says W. N. Watson, of the United States Tariff Commission, writing in a recent issue of *Chemical and Metallurgical Engineering,* is about 220,000,000 wine gallons, of which about 15,000,000 wine gallons is for production from grain, and the balance, 205,000,000 wine gallons, from molasses. The annual consumption is about 100,000,000 wine gallons, or somewhat less than one half the present capacity. The capital invested in molasses alcohol plants is about 55,000,000 dollars and in grain alcohol plants about 5,000,000 dollars.

In the manufacture of alcohol from corn, the by-products consist of distillers' grains, a valuable cattle feed, which has sold in recent years for from 35 to 45 dollars per ton, or on an average of about 2 cents per pound. Each bushel of corn gives about 12½ pounds of distillers' grains. In addition, fusel oil is another by-product of small importance, and in certain cases, corn oil and corn-oil meal are obtained.

It is estimated that if all the alcohol produced in America were made from corn,

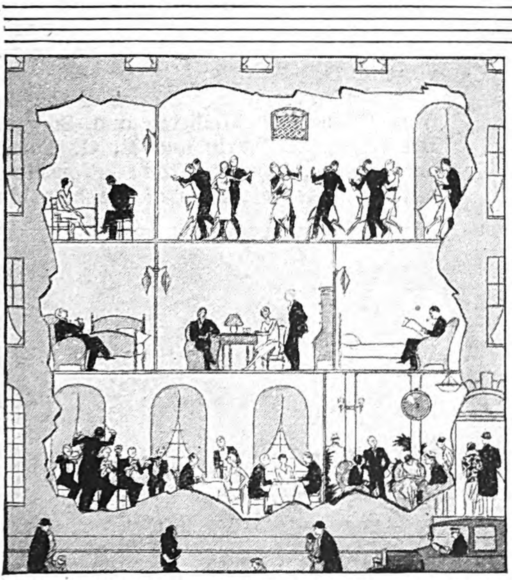
BUILT-IN-MUSIC



A MODERN IDEA MADE POSSIBLE BY WESTERN ELECTRIC

Many progressive hotels now fill their walls with music—yours to enjoy by simply switching on the loud speaker in your room.

Western Electric Public Address System enables a single orchestra to be heard in every room desired. And the same system—hooked up with a radio receiver or with the Western Electric Music Reproducer — distributes through the building broadcast programs or music from phonograph records.

In large meeting rooms this Public Address equipment makes all seats good. Even though you sit in the last row you hear every word as clearly as though up front. Schools, hospitals, public buildings, amusement parks and airports are using this system to widen the range of hearing.

This equipment, in refinement of workmanship, tonal quality and reliability, reflects the experience gained by Western Electric in 50 years of telephone making.

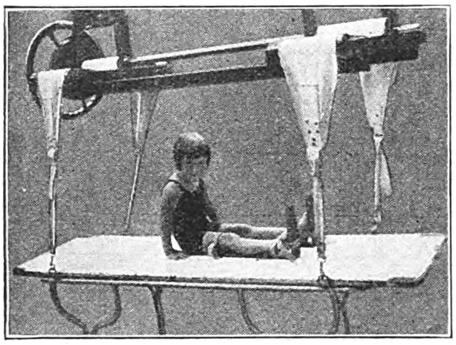
Progress in the Medical and Surgical Fields

By MORRIS FISHBEIN, M. D.
Editor of the Journal of the American Medical Association *and of* Hygeia

The Care of the Crippled

WITHIN the last few years special attention has been paid throughout the world to the use of the swimming pool method for developing and educating tissue that has lost its function through infantile paralysis. Among the leaders has been the Orthopedic Hospital of Los Angeles. There a special pool was built in which all forms of paralysis are treated. The chief values of the pool treatment seem to be the greater ease and freedom of movement in painful conditions, the easier handling of painful joints and easier development of weakened muscles, the fact that the water bears the weight, the enjoyment and interest, and the special value of the baths on the general morale of the patient.



Traveling hoist with hand control. New apparatus for carrying patients will be electrically controlled

In developing a pool particularly for this purpose, arrangements have been made for carriers which deliver the patient at the pool and for special sprays to clean the patient before entering the pool and on leaving. Foot baths are provided and cleanliness is carefully controlled by chlorination, and by the use of copper salt for algae. Metal equipment is made of bronze, chrome nickel or enamel so that it will not be corroded by the chlorine in the water.

Special tables have been arranged which allow the head and shoulders of the patients to be supported out of the water, and permit the attendants to manipulate the tissues while the patient is in the water.

As may well be imagined, such special equipment is exceedingly costly, but it is of value in the relief of pain and the cure of defects, which makes cost a secondary consideration.

First-Aid for Motorists

APPARENTLY European countries are far beyond our country in anticipation of the difficulties associated with modern tourists and their safety. France has had established for some time a series of first-aid stations along many of the highways. The Red Cross Society of Belgium established its first-aid stations three years ago and now has a complete series of them in working order along the roads from Brussels to Ostend, Antwerp, Liege, and Namur.

Because of the tremendous number of roadside accidents in this country, the American Red Cross might give serious consideration to this work. Persons who are injured are usually carried by the first passerby to some hospital. Hospitals are dubious about taking care of such patients, particularly when they come from outside the state, and the whole problem of responsibility for the care of the patient is in doubt.

Operations on the Heart

IT is not so long ago that any operation on the human heart was considered invariably fatal. With gradual improvement in methods of operation and in the use of anesthetics attempts were made to do various surgical operations involving the vital organ. In this country men have had wounds of the heart sewed up, a bullet has been removed from the heart, and in one instance the heart was opened, a constricted valve cut, and the patient recovered.

In a recent meeting of the Vienna Medical Society several interesting cases were presented in which operations had been performed on the heart. In one case a man was stabbed and when the patient was opened the wound was found to have penetrated the outer covering of the heart and the heart itself. The heart had apparently stopped beating. The space between the outer covering of the heart and the heart itself was filled with blood clots. The sac was opened and the blood clots were removed, whereupon the heart began to beat. The heart was sewed, the outer covering was sewed, and the wound in the chest closed.

Another instance was reported in which a bullet had penetrated the heart. When the body was opened and the heart examined, an opening was found into the heart, but no exit opening was found. The opening was closed and during the operation the heart stopped. After massage it began beating again. The use of the X-ray some three months later showed the projectile buried in the tissue of the heart, but the patient up to that time had not suffered any unusual symptoms.

Hospitals of the United States

ONE of the most interesting phenomena of the last quarter century has been the rise of hospital care in this country. There are today 6665 reputable hospitals providing 907,133 beds and 47,939 bassinets. This is an increase of 486,068 beds or 115.4 percent since 1909. The average number of people constantly in hospitals in 1929 was 726,766. There are approximately 150,000 physicians in this country, of whom about 125,000 are in practice. It is almost impossible to realize that 98,491 doctors have connections with hospitals and indeed 84,579 are actually attending in such institutions.

Sinus Infection and Vitamins

IT has long been known that vitamin A deficiency produces an inflammation of the eyes. More recently it has been quite definitely shown that vitamin A is related to the resistance of the human body against infection. Following a deficiency of vitamin A in the diet, rats develop inflammations of the eyes, infections of the nasal passages and sinuses, of the ears, the tongue, and even of the lungs. Most investigators are now convinced that the value of cod-liver oil in preventing colds, if it has any such value, is due to the vitamin A in the cod-liver oil and not to the vitamin D.

In the research laboratories of the Detroit College of Medicine and Surgery, Drs. Burt R. Shurly and R. G. Turner made a special study of the relationship of vitamin A to infections of the breathing tract, and particularly of the sinuses. They made a special study of the bacterial organisms found in animals which had been on vitamin deficient diets. They found certain organisms in such cases which were especially virulent.

Hoist for transporting patients between pool and dressing room

In the University of Iowa, in 1916, Doctors Daniels and Armstrong showed that deficiencies in diets encouraged infection of the sinuses as well as of the ear. There seems to be no doubt that deprivation of vitamin A permits germs to exercise extraordinarily virulent effects.

The *proof* that Ethyl develops more power

Right: This is the instrument board of a knock-demonstration machine. The wattmeter (at the left) registers power. The tachometer (at the right) records engine revolutions per minute. When this picture was made, the engine was running on ordinary fuel.

R.P.M.-Engine Speed Note increased speed represented by revolutions per minute when running on Ethyl

GOOD GASOLINE plus ETHYL FLUID equals ETHYL GASOLINE

"Knocks out that 'knock'"

ETHYL
GASOLINE

"SEEING is believing." These pictures of a knock-demonstration machine let you *see* how Ethyl Gasoline will increase the speed and power of your motor.

A simple valve switches the fuel from ordinary gasoline to Ethyl and back again. When Ethyl goes in, "knock" goes out, R. P. M.'s (engine revolutions per minute) increase, power goes up. That is how Ethyl improves motor car performance.

The Ethyl anti-knock compound in Ethyl Gasoline makes the difference. This remarkable fluid was developed by General Motors Research Laboratories after years of experiment to find an ingredient which would make gasoline a better fuel. Make this convincing experiment in your own car. Use up the ordinary gasoline in the tank; then fill up with Ethyl. You'll see and feel the difference.

* * *

Wherever you drive—whatever the oil company's name or the brand associated with it—*any* pump bearing the Ethyl emblem represents quality gasoline of anti-knock rating sufficiently high to "knock out that 'knock'" in cars of average compression and bring out the additional power of the new high-compression cars. Ethyl Gasoline Corporation, Chrysler Building, New York City.

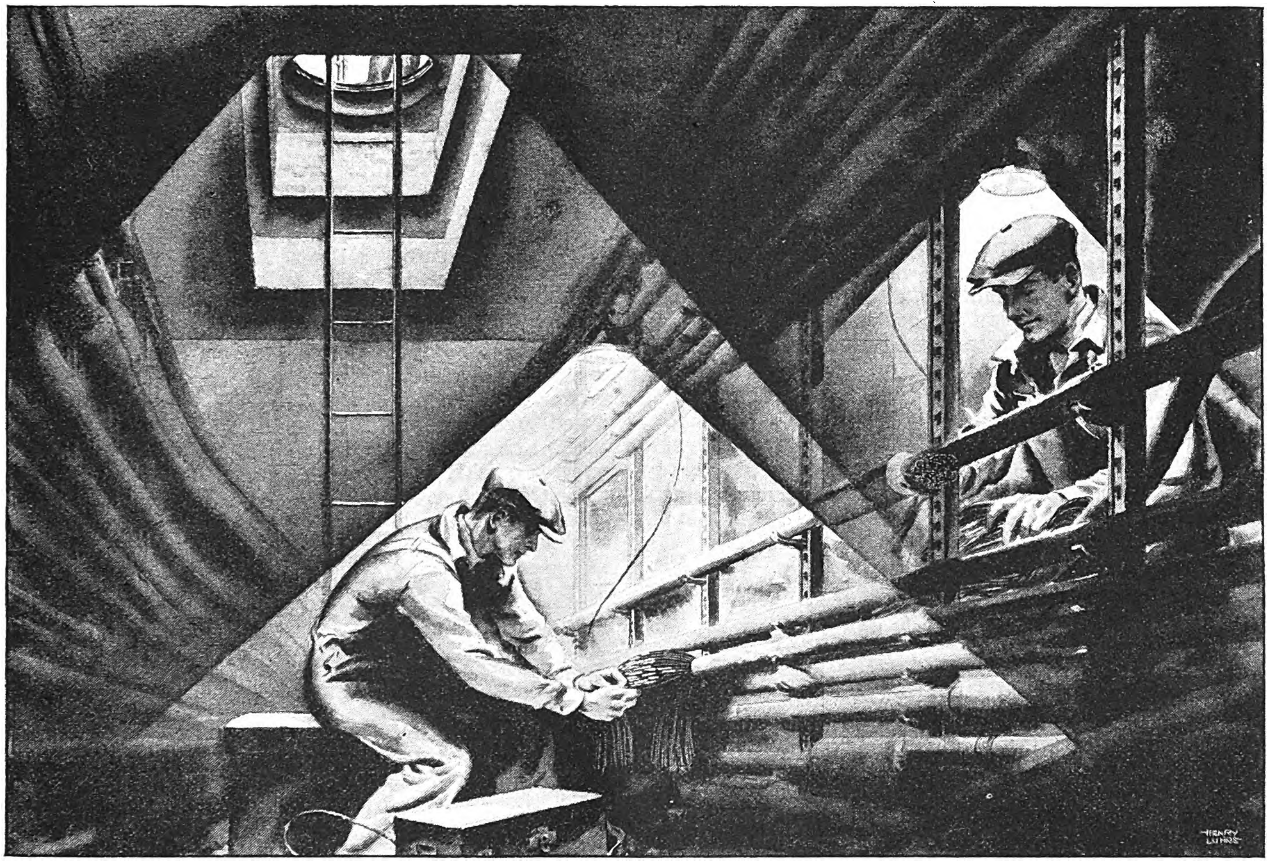
Rayon as a Paper-Making Material, by Merle B. Shaw and George W. Becking, (Research Paper No. 143) is a reprint from Bureau of Standards Journal of Research. The test data indicates that rayon is valueless in the rag stock for high-grade papers and may actually be detrimental to their quality.—*Superintendent of Documents, Washington, D. C.—5cents, coin.*



THE INCREASING USE OF THE TELEPHONE REQUIRES THE EXPENDITURE OF HUNDREDS OF MILLIONS ANNUALLY FOR EXTENSIONS AND IMPROVEMENTS

It keeps faith with your needs

An Advertisement of the American Telephone and Telegraph Company

You have found a constantly growing use for the telephone. You have learned its value in business. You have found it helpful in keeping contact with family and friends. Its increasing use has given the telephone its humanly important place in modern life and requires the expenditure of hundreds of millions annually for extensions and improvements.

In 1929 the Bell System's additions, betterments and replacements, with new manufacturing facilities, meant an expenditure of 633 million dollars. During 1930 this total will be more than 700 millions.

Definite improvements in your service result from a program of this size and kind. They start with the average time required to put in your telephone—which in five years has been cut nearly in half. They range through the other branches of your service, even to calls for distant points—so that all but a very few of them are now completed while you remain at the telephone.

In order to give the most effective, as well as the most economical service, the operation of the Bell System is carried on by 24 Associated Companies, each attuned to the part of the country it serves.

The Bell Laboratories are constantly engaged in telephone research. The Western Electric Company is manufacturing the precision equipment needed by the System. The staff of the American Telephone and Telegraph Company is developing better methods for the use of the operating companies. It is the aim of the Bell System continually to furnish a better telephone service for the nation.

The Amateur Astronomer

A Monthly Department

THE reader who decides to take up the home hobby of building and using an astronomical telescope—grinding and polishing his own glass optical parts and becoming one of a growing host of amateur astronomers—is urged to tackle nothing larger for his first effort than an instrument of six-inch diameter. Such a telescope will, however, magnify 50 to 200 diameters, depending on conditions. At a cost of about 25 dollars for materials (which can be obtained in a "set," that is, ready-to-use), if he possesses only average handiness he can make an instrument equaling in performance one he might purchase for 500 dollars. Hundreds of our readers scattered far and wide already have done this, using the practical working instructions in the SCIENTIFIC AMERICAN book "Amatuer Telescope Making," where numerous types are clearly described.

MR. W. L. Chamberlain, 519 Liberty Street, Meriden, Connecticut, sends in a photograph of his telescope and writes as follows:

"A talk on telescope making by one who had made a very successful telescope himself, inspired me to attempt the same thing. A friend loaned me a copy of 'Amateur Telescope Making,' and after securing glass disks and other materials, a start was made. The photograph submitted shows the finished instrument, a six-inch Newtonian reflector of 48-inch focal length.

"In grinding the mirror mistakes were made, as is usual with the novice, but the work proved to be so fascinating that the extra time required to make corrections was not regretted, for it was a good schooling in the art.

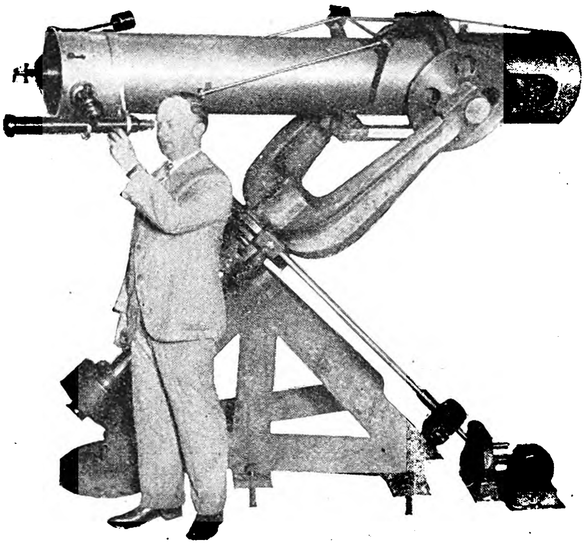
"Not wishing to be confined to a post and one location, it was decided to make the mounting of the alt-azimuth type, so that a tripod could be used as well. The sockets for the fork stem are identical on each. The fork, which has an offset angle, allows the tube to clear the post when directed at the zenith. The whole sky is seen.

"The post is an iron pipe 3½ inches in diameter, surmounted by a metal ball which just fits the inside diameter of the pipe. This ball is drilled and tapped for a short piece of steam pipe which makes the fork socket, and is held in place by three pointed set screws which are inserted through threaded holes near the top edge of the post into countersunk holes in the ball, one half of which protrudes out of the post. Two of these set screws are placed so that they form an axis on which the ball socket tube can be tilted over toward *Polaris*, thus forming a polar axis by which the telescope can be converted quickly into an English equatorial. The third set screw locks the ball in either position. The fork has two removable pins at the angle which, being reinserted in other properly located holes, straightens the fork as is usual in equatorial mounts.

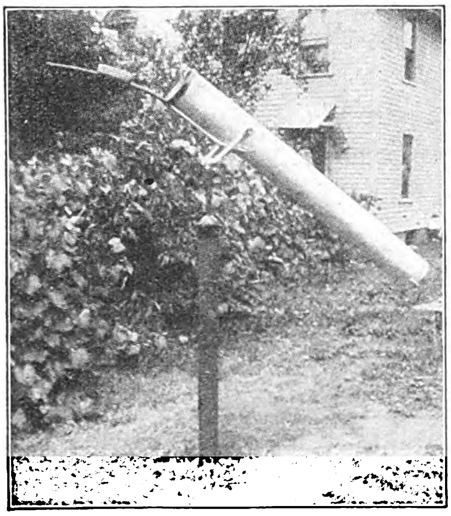
"When the telescope is used as an alt-azimuth, the eyepiece is inserted in the end of the declination axis. This gives the observer the great satisfaction of always having the eyepiece at the same height from the ground no matter where the telescope is pointed, and always directly above the post. This makes it possible to use a detachable bicycle seat on the post.

"The performance of the instrument exceeds my expectations. The definition is good. With my strongest eyepiece, estimated, with my focal length, to give 90 diameters magnification, the components of *Zeta* in Ursa Major are thrown wide apart, that is, *Sidus*, *Alcor*, and *Mizar;* and then the larger component *Mizar* is again split up into a close but clearly defined double. Star cluster M13 in Hercules gives momentary glimpses of individual components.

"I want to say a good word for honeycomb foundation strips in bringing up a low center when figuring a mirror. It is a most valuable addition to the possible methods of doing it."



Mr. Patton and his one-ton telescope



Chamberlain's reflector

AN interesting, though brief, letter has been received from Mr. G. O. Neser, Senior Science Master at the Boys' High School at Paarl, South Africa. He writes:

"Sir:

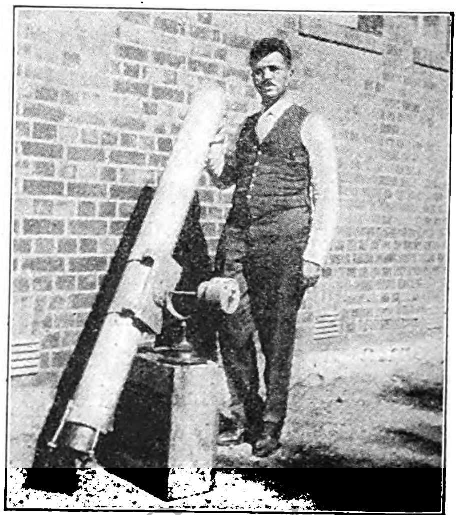
"As I recollect seeing only one photo of a South African amateur's telescope published in your journal, I am sending you a snap of my reflector. It has a six-inch mirror, focal length fifty-two inches, and is mounted temporarily and rather precariously as shown.

"I am very much indebted to the SCIENTIFIC AMERICAN for initiating me into the mysteries of mirror making. I am starting on a 10-inch one shortly. Kindly have your book department forward me a copy of the latest edition of 'Amateur Telescope Making'."

MANY amateur telescope makers have jumped from six inch to eight or ten inch size on their second instrument, or even to larger sizes. Few have jumped quite so far, however, in refinement of mounting, as Mr. Ralph C. Patton of the Patton-Macguyer Co., Baker Street and Virginia Avenue, Providence, Rhode Island, makers of stampings and novelties. At our request Mr. Patton has prepared the following description of his instrument:

"The telescope shown in the illustration has a clear aperture of 12 inches and a focal length of about eight feet. The mounting is of the English fork type, which is inherently balanced without counterweights. A tapered cylindrical aluminum casting, threaded inside throughout its length to break up light reflection, forms the main tube, and is forced into the short cast-iron barrel which acts as the lower end of the tube. This barrel is also threaded inside, so that no part of the interior presents a reflecting surface.

"The cast-iron fork has a tight, forced fit on the end of the polar axis. The latter is made of chrome vanadium steel,



Made in South Africa

heat treated and ground to exact size.

"The principal mirror is about 12¼ inches outside diameter, and is about two inches thick. It weighs 20 pounds and is mounted in a revolvable cell, with three sets of push-and-pull screws for adjustment. The revolving feature was devised so that true axial alinement of the mirror could be determined readily.

"The sky end of the tube has a cast-aluminum revolving head, carrying eyepiece and finder to insure a comfortable position for the observer, regardless of the altitude of the object being observed. The finder has a two-inch aperture.

"Five eyepieces are provided, and these can be used interchangeably in the finder or main telescope. In the latter they give magnifications varying from 64 diameters to 500.

"The mounting has closely divided circles, and is provided with clamps and slow motions for both declination and right ascension motions. The principal right ascension dial is rotated continuously during observation by means of a synchronous induction motor, which drives it through three sets of worm reduction units, having a combined ratio of more than 2,500,000 to 1.

"In using a synchronous motor drive for a telescope, it is necessary to interpose a pair of meshed gears having respectively 365 and 366 teeth, in order to change mean solar time into sidereal time. These have helical teeth to reduce vibration.

"The frame which carries the main tube is provided with two precision spirit levels for zenith setting. The declination axis and the polar axis run in eight ball bearings, which are protected from dust by felt washers within brass guards. All gearing is totally enclosed and runs in grease.

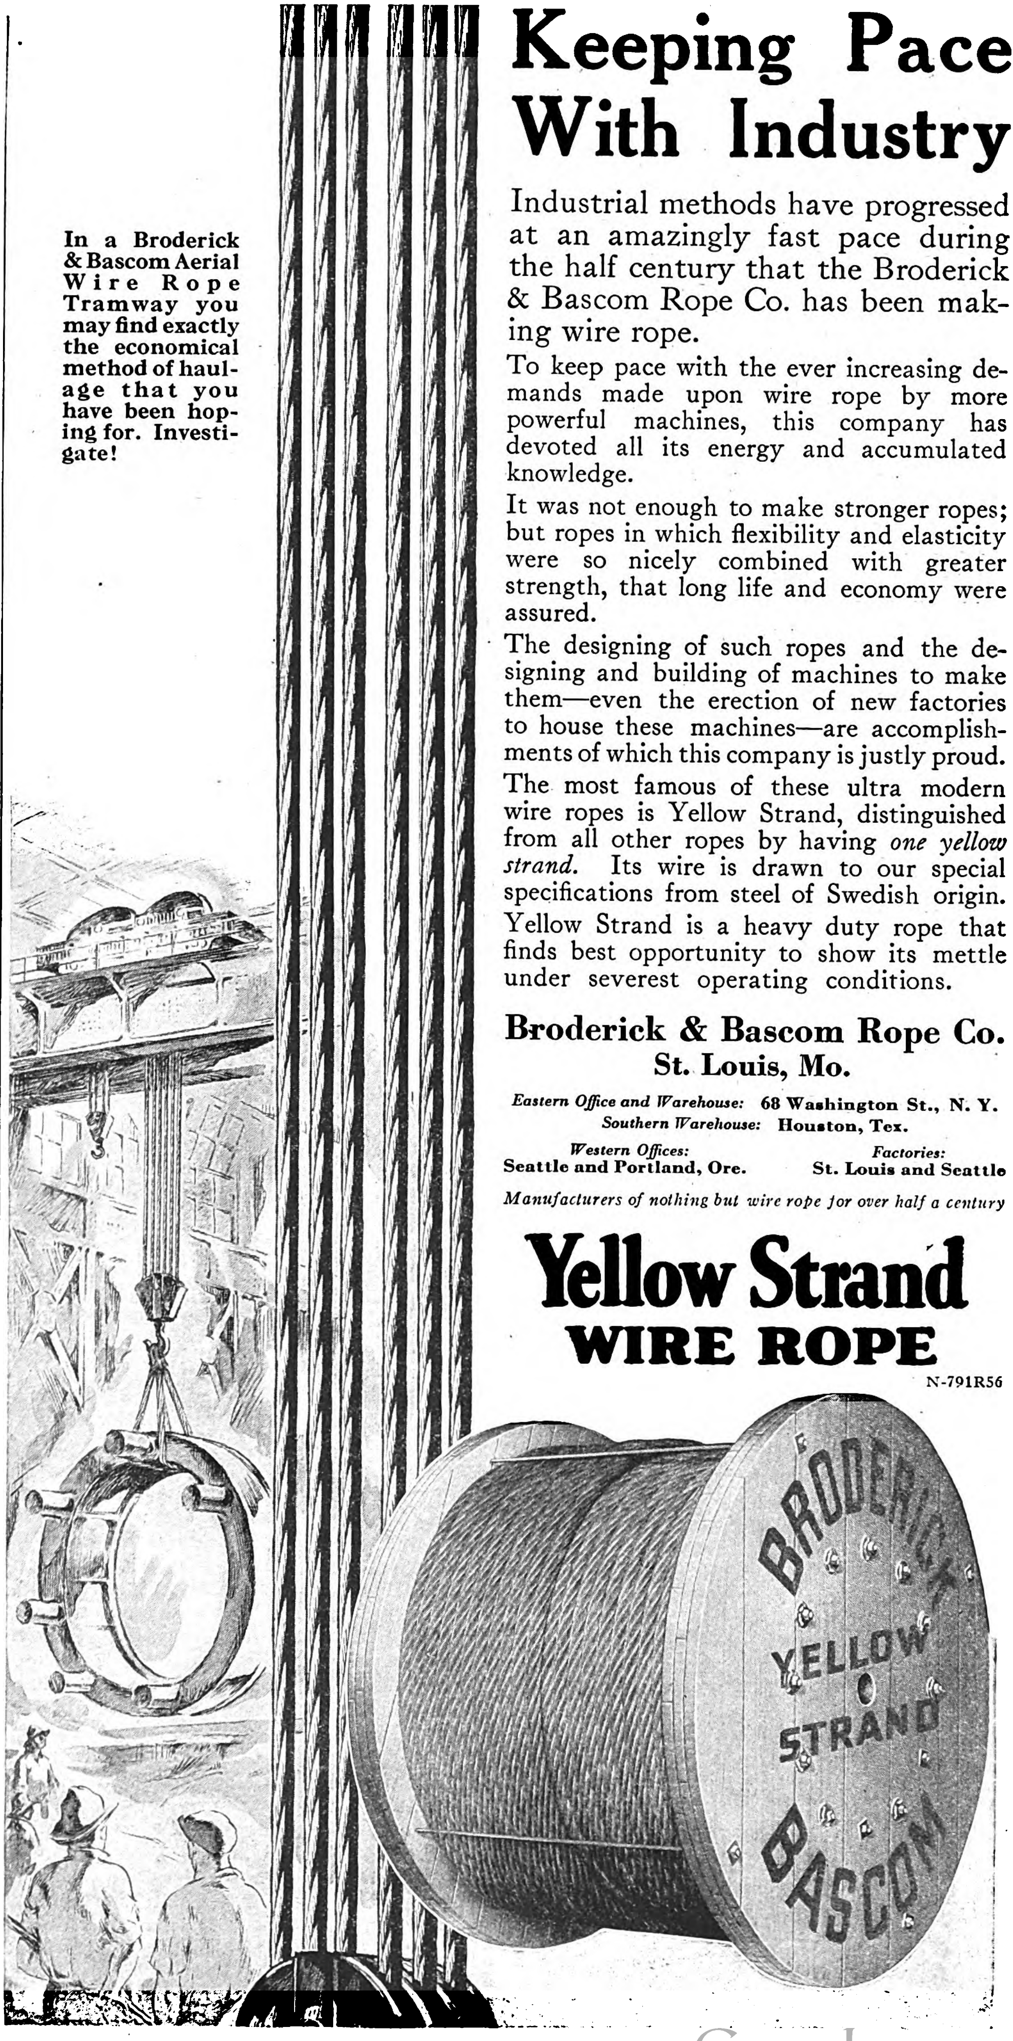
"The approximate weights of the principal parts are: base 1060 pounds; fork 410 pounds; polar axis shaft 104 pounds; assembled tube in ring with trunnions, mirror, cell, finder, and so on, 492 pounds; the total weight being over a ton.

"The telescope is housed in a sliding roof observatory, 15 feet by 18 feet, and the roof, which weighs about 2600 pounds, is moved on and off the building by a small electric motor, operating through sprockets, racks, and pinions.

"The telescope was designed, constructed and built in about two years. The mirrors were furnished by Mr. Wilbur Perry, of Springfield, Vermont. Inspiration for the work was furnished to a great extent by your book 'Amateur Telescope Making.'"

Amateur telescope makers may be surprised to learn that the first man to see the image of the new trans-Neptunian body on the photographic plate at Lowell Observatory was one of their number, Mr. Clyde W. Tombaugh. When the find was announced all the newspapers told how Tombaugh had made a telescope. Suspecting he might have used "Amateur Telescope Making" as his guide we looked in our file of purchasers, which is arranged by states, and found that he purchased the book in 1926. A wire brought from him the reply, "I used 'Amateur Telescope Making' in the construction of my telescope." Apparently, however, when he made his telescopes he never sent in a picture of the instruments for publication.

In a letter he now tells us that he has been swamped with correspondence since the discovery was made but appreciates



In a Broderick & Bascom Aerial Wire Rope Tramway you may find exactly the economical method of haulage that you have been hoping for. Investigate!

Keeping Pace With Industry

Industrial methods have progressed at an amazingly fast pace during the half century that the Broderick & Bascom Rope Co. has been making wire rope.

To keep pace with the ever increasing demands made upon wire rope by more powerful machines, this company has devoted all its energy and accumulated knowledge.

It was not enough to make stronger ropes; but ropes in which flexibility and elasticity were so nicely combined with greater strength, that long life and economy were assured.

The designing of such ropes and the designing and building of machines to make them—even the erection of new factories to house these machines—are accomplishments of which this company is justly proud.

The most famous of these ultra modern wire ropes is Yellow Strand, distinguished from all other ropes by having *one yellow strand*. Its wire is drawn to our special specifications from steel of Swedish origin.

Yellow Strand is a heavy duty rope that finds best opportunity to show its mettle under severest operating conditions.

DR. DICKEY TO SEEK SOURCE OF ORINOCO
Party to Take Store of Trinkets to Win Over Savages, Who Have Thwarted Five Expeditions.

ANOTHER FAMOUS EXPLORER CHOOSES THE LEICA CAMERA

Because of its compactness and unfailing service on an instant's notice, Leica, the universal camera, was the choice of Dr. Dickey when he and his party of five started into South America to find the unexplored watershed of the Orinoco River.

Invariably this remarkable camera is the companion of explorers, scientists, professional photographers and amateurs who recognize superlative camera quality. Several Leicas are owned by members of the Byrd Antarctic Expedition. Others were taken on the Graf Zeppelin's World cruise, the Greenland Expedition, through the Carlsbad Caves, and on the transcontinental Glider Flight of Capt. Hawks, sponsored by the Texas Company.

If you want better pictures under all conditions of light and weather carry a Leica wherever you go. It fits the vest pocket or purse—and weighs less than a pound. Yet it is marvelously perfect mechanically and optically. Takes 36 pictures on a single roll of standard cinema film, double-frame size. And enlargements to 12 x 18 inches or more preserve and accentuate all detail. The ideal camera for snapshots, sport pictures, photomicrographs, or other exacting work. See it now at your dealer's or write for catalog 1174. E. Leitz, Inc., 60 East 10th Street, New York, N. Y.

our interest, as a brother in the mirror art. At spare moments he says he is working on an article describing his construction of three telescopes, an eight-inch, a seven-inch and a nine-inch. In a later communication he apologizes for failing to keep his promise, as he has been side tracked with extra work, but ultimately will do so.

We hope this matter will reach us in time for the next number. It appears that the construction of his telescopes led Tombaugh to throw in his lot for astronomy. He asked for a place as assistant at Lowell Observatory and was accepted. Quite romantic, as it turned out.—*A. G. I., Tel. Ed.*

NIGHT SKY: JUNE AND JULY

MERCURY is a morning star and is best seen about the 15th when he rises about 3.30 A.M. Venus is an evening star setting about 9:30 P.M., and is extremely bright. Telescopically she looks like the moon about half way between the quarter and the full. Mars rises a little after 2 A.M. in the middle of the month and still counts as a morning star. Jupiter is in conjunction with the sun on the 20th and is therefore unobservable. Saturn is approaching opposition and is observable in the latter part of the evening, though his low altitude is unfavorable to good telescopic definition. Uranus is a morning star and rises about 1 A.M. on the 15th; while Neptune sets at 11 P.M.

The moon is in her first quarter at 5 P.M. on the 3rd, full at 1 A.M. on the 11th, in her last quarter at 4 A.M. on the 19th, and new at 9 A.M. on the 26th. She is nearest the earth on the 27th and farthest away on the 16th. During the month she passes near Neptune on the 2nd, Saturn on the 12th, Uranus on the 20th, Mars on the 22nd, Mercury on the 24th, Jupiter on the 26th, Venus on the 28th, and Neptune for the second time on the 30th.

UNLESS protests are received from a sufficient number of its regular users the present feature, The Heavens (but not of course Dr. Russell's main articles), will be dropped and the space otherwise employed. Some believe there is but small overlap between the increasing numbers who are keeping up with the newer astronomy, mainly astrophysics, which is ably covered in Dr. Russell's monthly articles, and those who use the star maps and planet data. If the proposed change is made, a series of maps from the same plates will be especially printed in a small pamphlet for distribution to regular readers on request, and the same planet data as well as much other data not contained in the space allotted to the present department, could be obtained by the reader from the annual "Observer's Handbook" of the Royal Astronomical Society of Canada, at an outlay of only 25 cents, or from some other similarly accessible source.—*The Editor.*

Chemistry in Industry

(*Continued from page* 474)

the production of distillers' grains would amount to from 225,000 to 250,000 tons.

Beware of Noisy Grapefruit

READERS may recall the old story about the Italian fruit vendor who, annoyed by the critical examination of his wares by canny housewives, exclaimed, "If you mus' pincha da fruit, pincha da coconut!" After all, "pinching" does not prove much about the quality of the fruit and it is not surprising that a more scientific method has been sought. Now, the Bell Telephone Laboratories have developed a method of determining whether or not a grape-fruit is "good" without cutting it open.

This rather spectacular application of science is a method of detecting the Mediterranean fruit fly when it is inside citrus fruits. So far, says *Food Industries*, no way has existed for the detection of the larvae of the fruit fly inside the fruit without cutting it open—an operation which, of course, renders the fruit unsalable. The skins may appear to be healthy and yet cover a fruit that is infested with larvae that should be destroyed.

Since the worm eats by tearing off morsels of fruit, it has been argued by government entomologists that a noise should be caused by the operation, and if this sound could be sufficiently amplified by means of the thermionic valves, or tubes, used in radio, the noise of the larvae eating in the fruit should be audible to human ears. Apparatus in the nature of a glorified stethoscope has been constructed to test out the theory, and it has been found that "suspected" grape-fruit were noisy, and on cutting them open they were found to contain the offending pests, whereas noiseless grape-fruit were found to be free from larvae.

Human Chemist Can't Compete With Art of Lowly Bug

THE tremendous popularity of rayon as a substitute for natural silk must have created an unemployment problem among the silk worms. While the chemist with his wood pulp has outdone the worm with his diet of mulberry leaves, there is another insect, even humbler, which still retains his supremacy as a chemical factory. His name is *Carteria lacca* and his product is a resinous material which he produces to enshroud himself; but which man converts into the substance known as shellac.

W. H. Zinsser, writing in *Chemical Markets* reveals some of the many industrial applications dependent upon this louse-like inhabitant of India and Siam. Shellac is an organic resin produced through chemical processes taking place in the life of an insect and which, because of resiliency and soluble qualities stands out in world commerce in contrast to the vegetable resins. It has qualities possessed by no other gum and is soluble in alcohol or in an alkali water solution, but is not soluble in turpentine.

As long ago as 1590 there is a record of shellac having been dissolved and used as a coating or crude varnish, and from that date, uses, to which it is now so universally put, have been developed until to-day it

How to Buy Life Insurance, and Where

Convenience and Low Cost are found in the

Postal Life Insurance Co.

It Presents a Consultation Service

and a record most convincing. It has a Way different from all other companies—the Non-Agency Way. It is not only an easy and convenient way, but has a well understood, definite economy. It is a guaranteed saving—the 9½% commission dividend—guaranteed because you confer with the Company by letter or in person and earn it. You perform the service of coming for the insurance: the POSTAL LIFE does not send one to fetch you.

This Non-Agency way not only saves you money, it strengthens your will. It makes you better satisfied with yourself and the transaction. Taking out your insurance volitionally develops a sense of independence and intellectual pride. The POSTAL'S Non-Agency way, and its Health Bureau, functioning together, have a life-prolonging influence; its policyholders employing these two services, lengthen their days, and thereby reduce the cost of insurance.

Postal Life Bldg. Owned by the Company

They Who Measure the Diameter of the Dollar

This Company makes its appeal through the direct method, particularly to those who follow the quieter walks of life—those who do not feel that they can attain to greatness by a single bound, but are performing their tasks conscientiously and methodically, undergoing the training and the education that prepare for other and higher responsibilities. They are the frugal class. They are discriminating. They measure the diameter of the dollar. They are those who are ready when momentous duty calls. Yes, maybe they are the plodders, practiced in the kind of plodding that developed Charles E. Hughes, Grover Cleveland, Calvin Coolidge and Herbert Hoover, the kind that can hold the ship of state steady when the storms of hysteria are rampant. The strength and prestige they have acquired are due not to dint of magic—they just keep on doing the things they ought to do. Fortunately, there are a good many of that kind. They buttress the nation against the selfish opportunist. Out of the number of these the Company receives its recruits. Therefore, it will *grow and grow and grow*.

Handbook of Chemistry and Physics

By C. D. Hodgman and N. A. Lange
Case School of Applied Science

For tables of infrequently used characteristic properties of matter, gases, chemicals, etc., this is just the reference that should be in your library—it contains as well the necessary formulas and tables which are constantly consulted. Leather. $5.20 postpaid.

Modern Pisé Building

By Karl J. Ellington

A complete explanation of house-building with compressed or rammed earth. The system which has been practiced for hundreds of years in North Africa, India, Korea and Southern France. This book is a manual which gives the details of construction so that anyone following them can erect permanent structures at minimum cost. $2.65 postpaid.

SCIENTIFIC AMERICAN

is the "open sesame" to all phases of the painting and decorating art; the friend of the sculptor, electrician, and metal worker, and the companion of the woodworker and furniture finisher. It is the facile aide of the foundry pattern makers, the base of buttons, phonograph and talking machine records, telephone parts such as receivers and mouthpieces, and imitation ivory products such as billiard balls and poker chips. It is shellac that holds the filament of the electric light bulb in place, and it is the "size" or stiffening used by the hat maker, which makes possible the many shapes and styles that fashion demands. Shellac is one of the chief ingredients in sealing wax, light drying inks, shoe dressing, and wood cements; it is the "snap" in playing cards and the artful finish for leather, imitation leather, wall paper, hardwood floors, pencils, broom and brush handles, autos, pianos, and what not. Shellac is the modern finish of the up-to-date rubber rain coat; it is the sealer used to make "leak-proof" the myriads of gasoline tanks that line the highways; and is even used as a cement for sealing the seams in the manufacture of cans for foodstuffs and liquids. It is used in the manufacture of brushes as a cement to hold bristles firmly in place. It is an important ingredient in lacquers, giving them body, adhesion, and flexibility.

Chemists have spent years looking for a substitute for shellac for use in industry but have thus far been unable to better the job done by the diminutive *Carteria lacca.*

Black Light Betrays the Bootlegger

"BLACK" light, the invisible rays which are the longer wavelength part of ultra-violet, may be used to discover the source of industrial alcohol diverted to the bootleg trade, according to Dr. Herman Goodman in a recent paper presented before the Society of Medical Jurisprudence. By adding an invisible trace of certain fluorescent dye to their industrial alcohol, the manufacturers can always identify their own product, no matter how much it has been distilled or rectified, by turning on it the invisible rays of black light.

Moisture Affects Telephone Cords

TELEPHONE cords are insulated with silk and cotton threads, but chemists in the Bell Laboratories found that the insulating quality of the fibers is different according to dampness of weather.

Research located the cause, says *Chemistry and You,* house organ of the Arthur R. Maas Chemical Laboratories. These fibers contain fine traces of chemical salts, which attract and hold moisture, and lower telephone efficiency. So methods have been worked out for washing the salts from the fibers before they are braided onto telephone wires.

The water cannot be used twice, for the infinitesimal trace of chemical salts carried away, causes it to be regarded as "contaminated."

Lake Michigan water was found better for the purpose than water from the city supply at another plant. It was even better than distilled water. This was due to a slight proportion of helpful chemical in Lake Michigan water, and too much harmful chemical in the other water, but the latter has been made satisfactory by delicate chemical treatment.

Our Point of View

Questionable Success in London

(*Continued from page* 429)

The three powers will scrap tonnage as follows:

	United States	Great Britain	Japan
Capital Ships	70,000	134,000	29,000
Destroyers	76,000	35,000	17,000
Submarines	8,000	none	14,000
	154,000	169,000	60,000

This tonnage does not include any obsolete vessels; the capital ships do not go back of our modernized *Florida* class, and only reckons destroyers less than 16 years old and submarines less than 13 years old. So, on the credit side of the Conference is a substantial reduction in tonnage. Great Britain and Japan, having already built practically up to the limit of their cruiser allowance, will have a very small cruiser program to complete. Congress has already authorized a cruiser program that will eventually complete our cruiser quota under the treaty; it will require several years to finish. In the meanwhile we are well below our strength. The President should vigorously resume the program suspended while the Conference was in being. By a happy coincidence this program will help the unemployment situation.

To obtain an agreement our delegation was forced to concede Japan parity in submarines and an increase in the 5 to 3 ratio in six-inch cruisers. We thought we had conceded Japan enough in 1922, when we agreed to cease fortifying our Far Eastern bases; certainly this concession should terminate our constant yielding to our neighbor across the Pacific.

It is reported that there is a clause in our agreement with Great Britain that might permit her to increase her cruiser strength relative to ours in the event that France increases her program; there should be no uncertainties in this treaty. In 1922 we thought parity meant parity in all classes; we so interpreted it while Great Britain and Japan built cruisers, destroyers, and submarines until they upset the ratio entirely. It would be a blow to the future confidence of our people in the efficacy of international agreements if any fine-spun interpretations are placed on this agreement.

In spite of the reductions actually obtained, Americans generally are disappointed by the events of the London Conference; and they will not quickly forget the display of European jealousies so openly disclosed by the negotiations. Americans had been told that the failure at Geneva in 1927 was due to the unyielding attitude of naval officers who sacrificed accord rather than to yield a few cruisers; at least that theory is exploded for only the Japanese delegation contained a naval officer and he was carefully classified as a statesman. Yet these selected delegations of civilian statesmen have been entirely unable to bring about a five-power pact, and only succeeded by extreme concessions to Japan in effecting an agreement for a three-power pact.

Their failure is more significant because

IT MAGNIFIES 250 DIAMETERS

WOLLENSAK MICROSCOPE

$16.50 MADE IN U.S.A.

The most interesting things in nature are hidden from the unaided eye. Insect, plant, and mineral life have thousands of fascinating mysteries that can be perceived only by means of a microscope. One of these fine WOLLENSAK Microscopes should be in every *home, office, school, or laboratory where students, dentists, physicians or scientists* can spend many hours in interesting and instructive research. The WOLLENSAK Microscope offers a range of magnification from 100 to 250 diameters in steps of 25. Elaborately finished, nickel trim, tilting stand, plush-lined case, prepared slide, and complete instructions. If your dealer can't supply you, we will send you one postpaid. *Money back guarantee.* Lower-powered WOLLENSAK models $2.50 to $8.50. Catalog free.

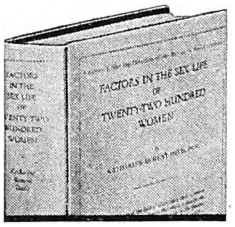
they patiently explored every avenue of approach that held any promise of agreement; and it is also possible that the delegations at London, in their desire to reach an accord, may have gone beyond the wishes of their own countrymen. After carefully following the developments at the Conference, it is hard to escape the conviction that the world powers today are not ready to confide their future to treaties, but still prefer to trust in the efficiency of their own armed forces. This is the most significant fact that has come out of the Conference.

Italy and France have not conceded an item one to the other. The reason for this inflexibility is scarcely concealed. France heads one continental group that includes Jugoslavia, Czechoslovakia, Rumania, and Poland. Italy heads another group that embraces Hungary, Albania, Bulgaria, and hopes to include Turkey. Italy would like to have England dissolve the entente with France and join her group. But for the present at least, British opinion will not hear of any continental entanglements. The old European balance of power has reasserted itself but this of itself need cause us no alarm, for it is the classical European method of preventing a continental colossus; and whatever may be urged against it by world reformers, the balance of power did preserve the peace of Europe between 1871 and 1913.

The desire to create an agreement between France and Italy caused MacDonald and Stimson to suggest a "consultative" pact to be given to France in lieu of the security guarantee she demanded for a reduction of her naval program. It is reported that MacDonald could not carry his own cabinet with him on this proposal and both Baldwin and Lloyd George are known to be against any further guarantees to France.

The reaction in this country was overwhelmingly against any form of consultative pact, on the very sound ground that if it committed the United States to intervention in European affairs it was against all our traditions and if it did not, it would mislead France. All efforts by advocates of the consultative pact to explain that the United States was already committed to an intervention by the Kellogg-Briand renunciation of war and the four-power Pacific treaty failed. And our delegation was unable to explain its complete change of attitude in this matter. Perhaps Mr. Stimson allowed his eagerness for an agreement to blind his judgment temporarily, or he wished to canvass the American public to determine if, for the sake of a reduction in armament, they were willing to re-enter Europe's political orbit. If the latter, the negative answer was plain, and cannot be misunderstood. It further developed that Great Britain is scarcely less reluctant than the United States to guarantee France's position in the Mediterranean so it was not possible to reach a real five-power agreement.

In the early days of the Conference there was some evidence of a desire on the part of the British and American delegations to put pressure on France to make concessions by a threat of a four-power agreement that would leave France isolated. When France failed to respond, the same treatment was applied to Italy without success. Then it was realized that if a five-power treaty was impossible, it was better for the good-will of Europe to go at once to a three-



—an important publication for readers of the *Scientific American!*

FACTORS IN THE SEX LIFE OF 2200 WOMEN

By KATHARINE BEMENT DAVIS, Ph.D.

This pioneer volume offers concrete factual data on the events in the sex life of normal women, supplying needed information on a topic which has long been the subject for uninformed conjecture.

Under the expert direction of Dr. Davis, two groups of selected women—married and unmarried—replied anonymously to questionnaires designed to elicit information on every phase of woman's sexual life. Full data on the various periods of life, as well as on so-called "abnormal" experiences were received.

This information was first tabulated. Then comparative statistical studies were made on the most important topics. The book offers specific data on many questions like: What factors seem to enter into the "happy" and "unhappy" married life? What are the causes and extent of abnormal practices? What is the importance of sexual education, etc.?

The clear and simple treatment makes the book invaluable to social workers, physicians, parents, educators; first, in developing a saner attitude toward the whole subject; second as a tested method in throwing light on sexual maladjustments as affecting personal relations.

The SCIENTIFIC AMERICAN says: "Almost to a certainty this book will upset a number of fondly cherished beliefs. It is a thoroughly scientific record of scientific work in sociology, performed by a noted scientific authority. The discoveries recorded were based on actual data secretly obtained." For free examination, use the coupon now. Price $3.50

Address..

power treaty, leaving in the framework places for both France and Italy, rather than to create a four-power treaty that would isolate one of them.

Just when the vexed situation seemed at its worst, Italy raised the specter of the League of Nations, by the very pertinent, if unpleasant, suggestion that the London Conference was not a competent tribunal to determine the nature of the security guarantees made by League members and suggested that the French delegation address such queries to the League Secretariat at Geneva rather than to MacDonald and Stimson. This action convinced Mr. MacDonald that Italy was immovable and efforts to secure a five-power pact were abandoned.

The original position of the United States was that if a five-power agreement could not be obtained, a three-power agreement would not be attempted, for it was feared that an agreement between the three largest naval powers would almost surely cause the rest of the world to believe that Great Britain, Japan, and the United States are seeking to dominate the world by their navies. When we recall the persistent French suspicion of a British-American entente after the Rapidan conference, the dangers of a three-power agreement are plainly evident. Nothing we would save in dollars by a reduction in naval expenditures would compensate for wholesale suspicion aroused throughout the world by the belief, however unfounded, of an understanding between the three naval powers. Our delegation must believe they can reassure the rest of the world on this point, else they would have adhered to their original position.

The result of the Conference may be summarized as follows: Great Britain concedes us cruiser parity provided we take part of it in six-inch cruisers and France and Italy restrict their programs; Japan agrees, provided she is allowed equality in submarines and a 10 to 7 ratio in cruisers for the present and the right to re-open the question when and if we build up to a 10 to 6.4 ratio; France and Italy will not join the pact. In 1922 we scrapped battleships and battle cruisers to arrange a 5 : 5 : 3 : 1.75; 1.75 ratio among these five powers. As an additional incentive to Japan, we ceased all work on our bases in the Far East so that the continued passage of time puts them more and more at the mercy of a hostile fleet operating in those waters. In addition to her fleet, Japan possesses the second strongest army in the world; it is futile for her to urge that additional naval strength is needed for defense of her already impregnable position in the Far East.

Yet for the sake of a three-power agreement that only a short time ago we said we would not accept, our delegation has accepted a conditional equality with Great Britain, and has granted Japan an equality in submarines and a 10 to 7 to a 10 to 6 ratio in cruisers.

Surely our delegation has gone to the extreme limit in order to obtain an accord. The Senate leaders will consider the pact in detail, and it is most fortunate for our country that it cannot be committed to any foreign obligations without full discussion in the Senate. The delay entailed by discussion sometimes frets us, but such discussion informs the American people and enables American public opinion to make itself felt.

Small Motors for all types of devices!

Fans . . . vacuum cleaners . . . signs . . . hair dryers . . . movie projectors . . . automobile heaters . . . drink mixers . . . juice extractors . . . television sets . . . toys . . . and hundreds of other action devices require small motors. They are only as efficient as the motors.

Signal Fractional Horsepower Motors—induction or series wound—are designed and made for such devices, backed by forty years experience. Tell us what you require, we'll gladly submit recommendations—without obligation.

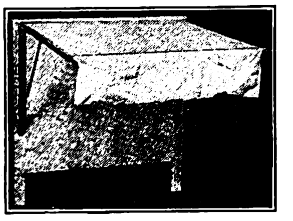
Invention for Sale



BABY DRESSING TABLE that fastens permanently to the wall over the tub in a small bath room, thus conserving all the floor space, eliminating carrying back and forth and storing. When folded projects from the wall two inches. Self supporting when open. Construction: All metal frame, canvas top. Patent pending. If interested in acquiring PATENT RIGHTS on a ROYALTY BASIS, write:
CHARLES V. SIMON 1543 Spruce Drive, Kalamazoo, Michigan

Sold by EVINRUDE Elto LOCKWOOD Dealers

World's Lightest Twin Outboard!

HERE'S the boat motor that all outdoor America is talking about. As "stowable" and compact as a traveling bag — *it f-o-l-d-s*, as shown, to only 11¼ x 13¾ x 17 inches. Weighs only 29 pounds — world's lightest twin cylinder outboard. Powerful, too — its 2¾ horse power giving *efficient* speeds on family and fishing boats and yacht tenders. Gallon of fuel lasts 2½ hours.

FOLD-LIGHT

Folding steering handle forms comfortable carrying handle. Twin cylinders for smooth performance, with an individual silencer for each. Self steering. First to minimize vibration by cushioning power head in rubber. Gas tank in front, thus easier to fill. Automatic circulation of oil to main bearings.

Write for Catalog.

Outboard Motors Corporation
Ole Evinrude, *President*
5581-27th Street Milwaukee, Wis.

Run on Battery 20 Minutes

Powerful 12-volt starting, used exclusively by Evinrude, Elto and Lockwood, will spin a large outboard motor 800 revolutions per minute for at least 20 minutes without draining the battery—four times as long as the conventional 6-volt system employed on automobiles. Ten minutes running of the motor will generate a starting charge in a drained battery.

ELECTRIC Starting

Books Selected by the Editors

Storage Batteries—*By G. W. Vinal, Physicist, Bureau of Standards*

SINCE the first edition of this important work appeared six years ago, it has been the authoritative reference, in fact the only one which completely covers the subject so that the average consultant may obtain the information he seeks without plowing through puzzling details. Clear, concise, conclusive, and exhaustive, it is a most able presentation. $5.20 postpaid.

Elements of Electricity—*By A. Zeleny, Prof. Physics, Univ. Minnesota*

AS a book of reference available to look up a wide range of questions that will arise in the ordinary course of reading or study, this text will be found of exceeding usefulness. Every phase is treated in a thorough, concise understandable manner, for the seeker who has no special knowledge, which means therefore that formulas and mathematics have been reduced to a practical minimum. We believe this to be one of the best general references of which we have knowledge. $3.20 postpaid.

Construction and Equipment of Chemical Laboratories

THE report of the National Research Council Committee, all of the members of which have planned and built chemical laboratories within the last ten years, definitely answers the leading questions as to the requisites for a practical laboratory building. Plans are prepared in detail for new buildings, or the improvement of existing ones, the data for which was obtained by sending out questionnaires to the directors of recently constructed laboratories. It is thus a compendium of present practice and as such is invaluable to this rapidly growing field of science. $1.20 postpaid.

BOOKS are one of the most intimate influences in our lives. They both entertain and sustain, they can be our companions in solitude and a stimulation in depression, they often are exhilarating and sometimes risible—of these our own mood is most frequently the gage. It is not an easy matter, therefore, to select from the large number that are now published, those titles which will interest a most cosmopolitan audience.

On these pages will appear each month the selections which The Editors believe likely to interest the greatest number of readers, but if you do not find here just what you like, or if you want to know what is available in some line of your own desire, do not hesitate to write to Louis S. Treadwell, Associate Editor, who is responsible for this department. Every attention will be given to your needs. We want to make these columns of real value to you.

Arithmetic of Electricity—*By T. O'Conor Sloane, A.M., E.M., Ph.D.*

BECAUSE the calculations are all in plain arithmetic, this practical little volume has been widely accepted as a boon for those who are rusty on higher mathematics, or for the many who need the information but have not had the training necessary for more difficult computations. A series of rules, all of the simplest forms, each rule illustrated by practical problems and detailed solutions. Extensive tables appear before the last chapter on networks which is added in this edition. $1.65 postpaid.

Standard Wiring—1930 Edition—*By H. C. Cushing, Jr., Fellow A. I. E. E.*

THE new edition of this authoritative work has been brought up to date by the inclusion of new sections and illustrations, the 1930 national electrical code, new tables on wire and wiring for every class of work, and the latest technical terms, and has been carefully checked to the last page. It is rightfully called "The national authority on wiring" for it contains detailed explanations of the proper methods of installing all kinds of electrical equipment. $3.20 postpaid—*F. D. McH.*

Photogravure—*By H. Mills Cartwright, F. R. P. S.*

THE subhead on the title page of this volume aptly expresses its scope: "A Text Book on the Machine and Hand-printed Processes." The author presupposes that his readers have some knowledge of engraving and printing systems and therefore plunges into his discourse with but brief preliminaries. His treatment of the subject, from the practical point of view, is masterly and it gives the interested reader a thorough grasp of this particular engraving and printing process. His summation of its advantages and disadvantages is concise and of unusual interest to anyone who uses printing for any purpose. $3.70 postpaid—*A. P. P.*

Modern Science—*By Professor J. Arthur Thomson, Univ. of Aberdeen*

IN the whole English speaking world there are scarce ten men who can write *accurately* on *every* branch of science and who can really *write*. Professor J. Arthur Thomson is one of them. Qualified critics think it is the direct simplicity of his style of writing which has won him deserved world-wide fame as a popularizer of scientific thought. Nearly everyone is familiar with his famous four volume Outline of Science. His newest book is a general introduction to science, ranging in scope from cosmology, through astrophysics and physics, to the origin and evolution of life, and ending with man and his psychology. The treatment leans rather more toward the elementary than some books in this category, and therefore provides easy delightful reading. 370 pages; illustrated. $3.70 postpaid—*A. G. I.*

Science and the New Civilization
By Prof. R. A. Millikan, Norman Bridge Lab. Physics

THIS is a collection of the author's recent essays put into permanent book form. Two of the eight essays—one which disposes of the former fond dream of inexhaustible atomic energy, and one which lists and describes the 21 greatest discoveries of the last 15 years of physics—are purely scientific. The others, on Alleged Sins of Science, the Future of Steel, the Relation of Science to Industry, Michelson's Economic Value, etc., are broader. Millikan's purpose in writing these classic essays was to make people think.

Two of the statements in the publisher's blurb on the jacket are untrue. The author does not write book-jacket blurbs—the publisher does. Too often those on scientific books are inaccurate, needlessly sensational, not dependable, misleading. Thus they mar good books. $2.15 postpaid—*A. G. I.*

Aeronautical Law—*By W. Jefferson Davis, Air Law Comm. Amer. Bar Assn.*

IN six parts. The scope of Federal and State control; ownership, operation, and control of airports; regulation of aircraft common carriers, liability, and insurance; aeronautical regulations, bibliography; each part broad in scope as a full reference of this kind should be. An important and necessary adjunct to the increasing importance of technical operation. 600 pages. Buckram. $10.00 postpaid.

AMERICAN CHARITIES AND SOCIAL WORK—*By Warner-Queen-Harper.*

FOR many years the fundamental work on this subject was the first author's "American Charities." The present book has been built on that solid foundation, two thirds being new text, but the original values are retained in this connotation. Everyone who has a vital interest either as worker or giver in this essential field of sociology should have this book—it is a compendium of the research and knowledge attained by the most acceptable authorities who have studied this question during the past thirty-six years. $3.95 postpaid.

SOVIET ECONOMIC DEVELOPMENT AND AMERICAN BUSINESS—*By Saul G. Bron*

HERE are given the results of the first year under the five-year plan and future perspectives. It shows that during 1928-29 national income increased 12.4% as against a scheduled gain of 10.7% while production costs were reduced 11.5% against the original plan of 7.5%. Complete economic statistics will furnish ample food for study to all who desire the facts as ascertained by the author, who was formerly Chairman of the Board of the Amtorg Trading Corp. $1.65 postpaid.

HARTRAMPF'S VOCABULARIES

A CONDENSED workable list of synonyms, antonyms, and relatives indexed under a general classification of group meanings. The index in the back identifies the group to which belongs the word sought, and reference to this group will give related words with their meaning. Quite the best arrangement we have seen and one readily adapted for hurried reference. Cloth. $5.20 postpaid.

ANTARCTIC ADVENTURE AND RESEARCH—*By Griffith Taylor, F. R. G. S.*

A COMBINED short history of all past Antarctic expeditions (including Byrd's) and treatise on the several sciences—geology, glaciology, climatology, botany, biology—in the Antarctic Continent. The author is an Australian scientist who accompanied Scott to the Arctic as geologist, and is now professor of geography at the University of Chicago. The title of this book might be naively (and truthfully) paraphrased as "everything an intelligent reader would like to know about all branches of science as applied to Antarctica." This is no mere book of narrative; nor is it on the other hand too abstruse for the average reader who, anticipating further explorations doubtless to be made in Antarctica, wants to be prepared to read future accounts of them more intelligently than others. $2.15 postpaid—*A. G. I.*

TITANOTHERES OF ANCIENT WYOMING, DAKOTA AND NEBRASKA—*By Henry Fairfield Osborn, Sc.D., LL.D.*

THIS monumental, two-volume, 953-page work is an exhaustive monograph on the titanotheres—extinct, primitive, massive mammals of the Tertiary Period more than 10,000,000 years ago. It represents 19 years of effort on the part of its distinguished author, noted paleontologist and head of the American Museum of Natural History, and in itself will create a new epoch in Tertiary paleontology. While the work is primarily for the professional paleontologist, much of it will be understood by the serious reader of elementary works on evolution. Supt. Documents, Washington, D. C. $9.00 currency—*A. G. I.*

HARVARD ADVERTISING AWARDS

FOUNDED by the late Edward W. Bok to stimulate an improvement in the general quality of advertising, this book records the awards 1924 to 1928 and depicts the examples for which they were given. It presents most excellent material for study as to what is most effective and worthwhile in various campaigns that were inaugurated by some of the best agencies for world-known clients. A fascinating study of illustration and typography well worth close scrutiny by everyone who has aught to do with any phase of the art. We predict it will eventually be found in almost every business library. $2.65 postpaid.

CLEMENCEAU—*By Jean Martet*

ONE is rather confused at the number of titles which have appeared concerning this dynamic and forceful patriot. This one is by his secretary and later intimate personal friend in whose hands were placed the full documentary records and these were supplemented by intimate conversations day after day; for Clemenceau was fully aware Martet was to be his biographer. In fact one long chapter is in Clemenceau's own hand. All facets of this amazing personality are turned to the light. In many ways, therefore, this is the most important portrayal of all the books that have appeared. $5.25 postpaid.

FROM THE MISSISSIPPI TO THE SEA—*By Rear-Admiral R. E. Coontz, U. S. N. (Ret).*

BORN inland, near Mark Twain's home, it seems strange that so much of the author's life should have been spent at sea. But the background serves only to enhance this story from the early seventies through a very large part of the World War. Few careers cover the breadth of experience, exploration, training, supervision of construction, navigation and finally, highest command, that is narrated here with characteristic reserve yet interlined by amusing anecdote and salty yarn. Altogether a most pleasing, interesting, and historically worthy recounting of a life devoted to country and fellowman. $4.20 postpaid.

JOHNSON OF THE MOHAWKS—*By Arthur Pound*

IRISH immigrant, Mohawk war chief, American Major-General, empire builder, Sir William Johnson was one of the commanding figures in our early history. Of tremendous influence with the Indian tribes and powerful among Colonials because of his immense wealth, his was a personality of vital import at a time when civilization was hard pressed to maintain itself on the frontier. Factual accuracy is attained by long and painstaking historical research and yet the story runs smoothly and makes most interesting reading. $5.25 postpaid.

MATA HARI. COURTESAN AND SPY—*By Major Thomas Coulson, O. B. E.*

AMONG the women spies of the Great War, certainly Mata Hari was the most interesting. "A pagan adventuress with nothing feminine about her but physical grace and quick intelligence," her operations, however, are said to have been responsible for the death of 50,000 allied troops. The author strips away the fiction and myth concerning her and gives the facts as far as they can be determined. The sustained interest of this exciting narrative almost cloaks the loathsomeness of its moral fiber. $3.20 postpaid.

Facts and Notes of Interest to Inventors,. Patentees, and Owners of Trademark Rights

Rules on Patent Appeals Amended

THE Commissioner of Patents, Thomas E. Robertson, has announced an order amending the rules of the Patent Office relating to appeals from its decisions and the printing of the record for use on appeal. The order follows:

Acting under the provisions of section 483 of the Revised Statutes and with the approval of the Secretary of Commerce, rules 148, 149, 150 and 162 are amended as follows, to take effect March 1, 1930:

Rules 148, 149, and 150 by striking out the words, "Court of Appeals of the District of Columbia" wherever they appear and inserting in lieu thereof: "Court of Customs and Patent Appeals."

Rule 162, by striking out in the fourth line thereof the words "Court of Appeals of the District of Columbia" and inserting in lieu thereof: "Court of Customs and Patent Appeals."

And by canceling the last sentence of the first paragraph thereof and inserting in lieu thereof the following:

"The size of the record shall be 7$^5/_8$ by 10$^1/_4$ inches and the type matter shall be 4$^1/_6$ by 7$^1/_6$ inches. They shall be printed in 11-point type and adequately leaded; and the paper must be opaque and unglazed. The names of the witnesses must appear at the top of the pages over their testimony, and the record must contain indices with the names of all witnesses and reference to the pages where copies of papers and documents introduced as exhibits are shown."

Patents for Plants

THE inventor or discoverer of a new variety of fruit tree or plant would receive the same protection by a patent as the inventor of a machine, through an amendment to the patent statutes introduced by Senator Townsend of Delaware, himself an orchardist, who said that he wished to remove the present "discrimination" against agriculture.

The patent would be granted to the experimenter under almost identical conditions governing other inventions and the law would be operative throughout the Patent Office, costing the government nothing, Senator Townsend explained, inasmuch as the Patent Office is self-supporting.

His measure, which has been passed by the Senate and approved by the House Patents Committee, reads, in part:

"Any person who has invented or discovered . . . any new and distinct variety of asexually reproduced plant other than a tuber-propagated plant or a plant which reproduces itself without human aid, not known or used by others in this country before his invention or discovery thereof, and not patented or described in any printed publication in this or any foreign country, before his invention or discovery thereof, or more than two years prior to his application, and not in public use or sale in this country for more than two years prior to his application, unless the same is proved to have been abandoned, may, upon payment of the fees required by law and other due proceedings, obtain a patent therefor."

In evidence of the value of his proposal, Senator Townsend, who owns 130,000 acres of orchards, pointed to the accomplishments of engineers during a century of patent protection.

Pointing out that "it is a notorious fact that the most successful plant breeders have lived and died in comparative poverty," Senator Townsend named as examples Ephraim Bull, Luther Burbank, Peter Gideon, C. G. Patten, J. R. Reasoner, and Dr. Van Fleet.

Californians Lead in Patent Grants

RESIDENTS of California are the nation's most prolific contributors to mechanics and the sciences, according to the records of the Commissioner of Patents. The record of patents granted during the year 1929 showed that citizens of Connecticut pressed closely on the heels of California's inventors, and three other New England states put in strong bids for the *per capita* honor. These were Massachusetts, New Hampshire, and Rhode Island.

As would be expected, the State of New York led by a wide margin in the total number of patents granted to its residents. The compilation, made by Mr. L. Edward Flaherty of Washington, D. C., shows the grants issued to the various states, the leaders ranking as follows:

New York .	7755
Illinois	4658
Pennsylvania	3639
Ohio	3595
California	3087
New Jersey	2630
Massachusetts	2309
Michigan	2218
Wisconsin	1321
Connecticut	1121

A total of 42,251 patents were issued in 1929, compared to 40,322 issued during the preceding year.

Shoe Trademarks

THE Assistant Commissioner of Patents has denied a rehearing of the appeal before him in which he decided that the notation "Foot Preserver" is registrable as a trademark for boots and shoes, despite the opposition of the owner of the mark "Arch Preserver" for the same type of goods.

It was held that the essential feature of the mark "Arch Preserver" is not "Preserver," but that "Arch" is the dominant characteristic, and hence "Foot Preserver" is not deceptively similar.

By reason of many trademarks for shoes of like import, the Assistant Commissioner stated that neither party is entitled to such broad protection of its mark as to exclude from registration the mark of the other party, and that the public must exercise unusual care in discriminating between them.

Massachusetts Bans Car Radios

RADIOS may not be operated on automobiles driven in Massachusetts, according to a ruling by the registrar of motor vehicles, George A. Parker.

The ruling followed a conference with the governor's committee on street and highway safety, which recommended that the use of radios on automobiles be discontinued, it was announced.

Automobile and radio manufacturers have joined in a protest to the department, of which the registry of motor vehicles is a part, under a law providing that any ruling by the registrar is subject to appeal to the Department of Public Works.

"Permanize" Granted Trademark Registry

ALTHOUGH two trademarks may have the same suffix, and the goods upon which the marks are used are of the same descriptive properties, they are not deceptively similar if they neither look alike, sound alike, nor convey the same thought. This decision of the Assistant Commissioner of Patents was made in the case of the Simoniz Company *vs* Permanizing Stations of America, Inc., opposition number 9230 to registration of trademark "Permanize" for a polish for auto bodies, et cetera.

The opposer, the Simoniz Company, had appealed from the decision of the examiner of interferences dismissing its opposition to the registration of the mark. The opposition was based on the fact that the mark "Simoniz" for a compound for cleaning and polishing automobile bodies, et cetera, had been adopted and used previously. Although the two compounds contain specific differences, they were held to possess the same descriptive properties.

It was brought out that of the two marks in question, "Simoniz" is derived from the proper name Simon, and suggests the thought that Simon's reputation is back of the goods. On the other hand, "Permanize" is derived from the word permanent, and suggests permanency. The testimony failed to show that any purchaser had been deceived by the alleged similarity of the marks, and it was ruled that the marks are not deceptively similar.

Models for Advertising Purposes Denied Free Entry

ACCORDING to the majority opinion of the United States Court of Customs and Patent Appeals, models of "individual wheel drives" imported by the American Brown-Boveri Electric Company are not admissible duty free, as are models which come under Section 1620 of the existing tariff act. This action was taken because the models in question were imported for the purpose of free distribution with a view to prospective sales.

In the opinion of the Court: "It is apparent that the imported articles are made to be used not as models, but for advertising purposes alone."

The models in question consist of a solid brass foundation on which are mounted three supports, also of brass. From these supports are suspended an axle and two flanged car wheels. On the outside of one of these wheels is a brass cogged wheel with an attachment by which the axle and car wheels may move in various directions without affecting the cogged or drive wheel. Attached to the supports upon which the axle is mounted are two small levers with suitable arrangements whereby the operation of the mechanism can be demonstrated.

Because of the ambiguity of the language of the statute, it was deemed necessary to take recourse to its legislative history. Earlier tariff acts provided free entry for "models of inventions and of other improvements in the arts, including patterns for machinery, but no article shall be deemed a model or pattern which can be fitted for use otherwise."

The Court ruled that models intended for advertising use did not come under the statute. Judge Bland concurred with Judge Garrett in a dissenting opinion, holding that "advertising" use should be no bar to free entry, because it is inseparable from an inspection of the structure and is a legitimate part of the function of a model.

Old Mining Claim Upheld Over Invalid Homestead Patent

If the owner of a mining claim fails to do his assessment work for one or more years, the claim is subject to relocation by other parties, providing the relocation takes place before the original owner returns and resumes work upon the claim. However, in the event that the relocation does not take place within that time, the owner's rights may be restored to the same extent as though there had been no failure to do the assessment work. These rulings were made by the Supreme Court of the state of South Dakota in the case of Frank Hebert *vs* Frank C. Bond *et al*, on appeal from the Circuit Court of Pennington County.

The defendants had acquired title to the Tin City Lode Mining Claim from a woman who had obtained a homestead patent on the property by means of false statements made to the General Land Office. The Court held that she had practiced a fraud both upon the Government and the rightful owner of the claim, so that her patent was impressed with a trust in favor of the original patentee who might go into court and have his title quieted.

The evidence showed that in 1886, Frank Hebert had discovered on unappropriated government mineral lands in South Dakota a lode of ore bearing appreciable quantities of tin and mica. He filed a claim promptly, and did all of the proper and requisite things to secure a valid title to the property covered in his claim. Later in the same year, one Mary McDermott built a cabin on an adjacent piece of farming land. After the year 1900, she filed a homestead claim in the land office, later revising her claim from time to time. In 1916 she amended her homestead claim to include the Tin City lode. As late as 1918, the testimony showed, McDermott admitted to witnesses that the mining property was owned by Hebert.

Early in 1919, Hebert contracted to sell the Tin City Mining Claim to one W. N. Hunter, for a consideration of 30,000 dollars. Hunter, with Frank C. Bond, formed the Rare Minerals Company, and entered promptly upon the property, making preparations to mine and ship ore from the mine thereon. At this time, while Hebert was away temporarily, McDermott drove the defendants (Rare Minerals Company) from the property, claiming title under a homestead patent issued by the government. The Rare Minerals Company decided that McDermott had a better title than Hebert, and purchased the McDermott homestead for the amount of 10,000 dollars. Then, attempting to repudiate the old Hebert title, the defendants filed a new mining claim on the Tin City lode.

The only questions involved in the case were: First, did the plaintiff ever make a valid location of the said ground? Second, is the ground covered by the Tin City Lode Mining Claim mineral in character? And third, if such location was made, did the plaintiff lose his rights therein by abandonment prior to the issuance of the McDermott patent? These points were decided definitely in favor of Hebert, and it was established that McDermott had practiced a fraud on both the plaintiff and the government. Under such circumstances, it was held, a court of equity has power to secure the rights of the plaintiff, and as a means best adapted to that end may declare a constructive trust in his favor. The decision of the lower court was affirmed, quieting title in the plaintiff.

"7-11" As a Trademark

The Court of Customs and Patent Appeals has affirmed the Patent Office in dismissing opposition to the application for registration of the trademark "7-11," for liquid medicinal preparations. The products of the applicant, liquid medicinal preparations for treatment of colds, et cetera, to be taken internally, and of the opposer, owner of the mark "4711," for antiseptic mouth washes and scalp remedies, cold cream, face powder, dental preparations, et cetera, were held not to be of the same descriptive properties. It was also pointed out that the labels were dissimilar and further that the opposer had made no protest to other registrations of the numbers "7-11" for other goods.

Anyone desiring the address of a patentee listed in this section may obtain it by addressing Munn & Co.; those desiring official copies of patents herein listed, may secure them by remitting 15 cents for each one (state patent number to insure receipt of desired copy) to Munn & Co., 24 West 40th Street, New York City.

Pertaining to Aeronautics

Propelling Device—For air and water craft, whereby increased force is obtained, a quicker take-off will be possible and shorter landings at steeper angles, a gyroscopic action being generated to keep the craft steady while in flight. Patent 1750382. Westinus Boer.

Aircraft—Having a fuselage, laterally extending wings, stabilizers, and a rudder mounted at the tail, the special feature being a sail adapted to use the wind for producing the lifting action and motion to put the craft in flight. Patent 1752241. John Domenjoz.

Pertaining to Apparel

Necktie-Lining Fabric—Composed of a woven integral piece of material, adapted to be cut to serve as tie linings, having areas at one or both ends, which are of different grade of material than the remaining area. Patent 1749634. Edgar K. Frank.

Protective Garment—Designed to be worn by a messenger carrying money or valuables, so that the articles may be distributed throughout the compartments on the inner face of the garment, and securely locked on the user's body. Patent 1749714. Herman A. North.

Shoe Construction—Which has novel means for removably securing a heel to the body portion of a shoe, a frame receiving the heel, whereby a worn heel may be removed for repair, or a new one disposed in place. Patent 1749864. Joseph Weiss.

Cravat Attachment—For the small end of four-in-hand cravats, may be easily applied to provide an abutment to prevent its withdrawal through the knot, whereby the neck loop is at all times maintained without retying the cravat. Patent 1750232. Segfrid J. Lindskog.

Chemical Processes

Photographic Chemical Process and Material—For printing from tracings, etc., comprising diazotizing an aqueous solution of pyridine sulphonic acid, then reacting the product with an aqueous tartaric acid solution and an aqueous solution of a nickelous sulphate, coating photographic paper therewith, printing by contact under tracings, and developing the latent image with fumes of ammonia. Patent 1752174. Oliver A. Hall.

Designs

Design for a Table-Receptacle Holder. Patent 80626. Samuel Lapin.

Design for a Novelty Spur. Patent 80563. Grover C. Welter.

Design for a Dress.—The inventor has been granted two ornamental designs for dresses. Patents 80658 and 80659. Dorothy Long.

Design for a Dress. The inventor has been granted four patents on ornamental designs for dresses. Patents 80795, 80796, 80797, and 80798. Dorothy Long.

Electrical Devices

Modulator for Radiotelephones—For use in connection with the transmitter, use being made of carborundum, selenium, magnetite, etc., to vary in electrical conductivity, hinder action of heat or light, in producing a changing current in the talking circuit. Patent 1750579. Henry H. C. Dunwoody.

Electric Insulator—A tubular casing especially adapted for outdoor aerials in protecting then from moisture, the formation of ice, snow and water, which might tend to bridge the gap and electrically connect the wires. Patent 1750352. John F. Phillips.

Electric Storage Heater—A hollow body of heat absorbing and retaining material in which a large amount of electrically produced heat may be stored under control for use at such time as desired for various purposes. Patent 1749115. Gunnar S. Tune.

Electric Switch—The construction of which makes it impossible for an operator to leave the blades close enough to the contact to allow any passage of current, unless manually pressed into contact for closing the circuit. Patent 1752236. Vernon A. Conklin.

Of Interest to Farmers

Egg-Protecting Means—An outer protective covering adapted to be used with egg crates, as generally formed, and packed, for the complete closure and special protection of eggs in transit, when the temperature is below 32°F. Patent 1749675. Paul A. A. Rouis.

Door for Silos—Which may be readily removed to provide an opening for the discharge of grain, the door securing means also providing rungs, whereby an operator may climb to the upper portion of the silo. Patent 1750600. Levi D. Houghtaling.

Potato Separator—For use in connection with a potato digger, the tension of the balanced separating fingers permitting the lightest stone to drop from the potatoes as the digging, sorting, cleaning, and sacking operation progresses. Patent 1751391. William G. Bunker.

Doffing Device—For stripping or doffing the needles of a cotton-picking machine after the former has removed the cotton from plants, and for removing any accumulation of gum collected during abrasions of the plant stalks. Patent 1751389. Oscar F. Bledsoe.

Shipping Box for Baby Chicks—Each compartment of which has ventilated chambers of varying temperature so that the chicks may move at will to warmer or cooler places to meet their individual needs, and yet remain fully protected against drafts. Patent 1752177. Albert B. Hilkemeyer.

Of General Interest

Ventilator—For use in conjunction with a window allowing air to enter a room, but dividing the air in such manner as to prevent drafts, and also to exclude rain and other elements of weather. Patent 1750413. Albert R. Laube Nstein.

Air-Cooling Apparatus—Comprising a water supply pipe, overlapping absorbent fabric strips mounted to retard the water in its descent, and a drip pan on the window sill, the device cools and filters the air as it passes. Patent 1750047. Gustave A. Metzger.

Bag Gusset—So formed as to join the opposite ends of the side sections that they will be neat in appearance, and define a pocket which will prevent small articles from falling out. Patent 1750375. Anthony M. Vinciguera.

Combined Article of Furniture—A cabinet which includes hingedly connected sections defining storage compartments, a horizontally disposed swingable table, and swingable mirrors, normally housed, the whole serving in the capacity of a dressing table, desk or storage cabinet. Patent 1749686. Theodore Agazzi.

Brush Holding and Cleaning Device—A receptacle for receiving a quantity of turpentine or other detergent for cleaning paint brushes, scraper elements being arranged for the removal of the paint and detergent, and valves for draining off the waste matter. Patent 1748789. Harry I. Orkin.

Hair-Waving Device—Wherein the cooperating hair-waving members may be closed in engagement with the hair fully and effectually, to produce the desired waves without injury or tearing the hair. Patent 1749748. Martha A. Tienken.

Cartridge Guide for Repeating Guns—So formed that its head portion which is provided with a guiding surface shall penetrate into the breech casing between the magazine and the rear end of the barrel, or the firing chamber. Patent 1749726. Rudolf von Frommer.

Fence Post—Polygonal in cross section, and formed with means for interlocking engagement by tie wires, in securing the line wires, a projecting member at the lower end being adapted for setting into a fresh concrete base. Patent 1749640. Richard D. Martin.

Container—A simple and convenient envelope or wrapper for easily and quickly confining articles of personal wear, such as shoes, etc., when traveling, within a relatively small space, and without soiling other articles in transit. Patent 1749680. Gertrude P. Visscher.

Mop Handle—Having a simple and efficient means whereby a mop head, or mopping material, may be inserted or removed and when connected will spread out over the end of the stick to prevent contact with floors or furniture. Patent 1752250. John H. Gillis.

Display Holder—Particularly adapted for strap-watches, and formed from a single cardboard blank and a single sheet of velvet, a pocket being formed for the watch, means for displaying the strap, and supporting the holder in tilted position. Patent 1752246. Leo Flier.

Sea Tub—A hollow construction, of rigid buoyant material, such as balsa wood, adapted for floating persons in the water, the size being large enough to permit the average person to lie down in the water, as in a bath. Patent 1752191. Jere C. Moray.

Jar-Cover Remover and Fastener—A device which may be attached to a wall or other suitable support, for receiving and gripping the metal cap of a jar, while the latter is being turned for screwing or unscrewing, without spilling the contents. Patent 1752189. Joseph Lotz.

Watch Stand—Comprising a substantially dome-shaped base and a plurality of arms, pivotally mounted, wherein a watch may be quickly mounted or demounted, particularly adapted for use in repairing watches. Patent 1751286. Frank X. Mantsion.

Mop—With mechanism so constructed as to eliminate all necessity for the hands of the user to come in contact with the water in mopping, scrubbing, or wringing, the operation being easily accomplished without undue exertion. Patent 1751349. Clifton O. Morgan.

Holder for Graphic-Instrument—A holder connected with a base, for temporarily holding a fountain pen, or the like, in angular position, so that the instrument may be easily removed or inserted, the holder accommodating instruments of various sizes. Patent 1751354. Ernest Oldenbusch

Washbasin Appliance—A transportable storage tank for water, the top portion being depressed to form a basin, a lift pump transfers the water to the basin, the device is covered, very compact, and adapted for use in confined places, such as vehicles. Patent 1751294. Clifford Spital.

Hardware and Tools

Screw—Having the usual slotted head for receiving the screw driver, but being provided with lips adjacent the slot so that after the screw has been forced into position, said lips, or wings, may be swaged over the slot. Patent 1749043. Joseph Neiser.

Flat Iron and Steamer—Particularly adapted for ironing or steaming a hat, and permitting the crown or brim of the hat, or both, being ironed or steamed in a convenient manner; may also be used for other purposes. Patent 1749667. David Freedlein.

Knife Attachment—An attachment for the back of a knife blade, affording a broad support for the fingers, and preventing soreness after long use, particularly adapted for paring knives, as used for vegetables and fruit. Patent 1750577 Joseph de Bracht.

Casement-Window Latch—Which provides means for securely latching a casement window in slightly opened position for the purpose of ventilation, but in such manner as to prevent an intruder forcing or manipulating the latch to gain access. Patent 1750423. Walter S. Oglesby.

Fire-Fighting Tool—Comprising a handle, a metallic extension, and a blade with lug-receiving opening and a clamping member for securing the blade against rotation, the wooden handle being removed at quite a distance to prevent charring. Patent 1749103. John C. Kortick.

Rotary Reamer—For reaming oil wells, the reamer blade having two cutting eges, thus twice the efficiency of ordinary reamers, the tool requiring withdrawal for sharpening with but half the frequency of a single blade, thus saving time and labor. Patent 1750953. Alexander Boynton.

Safety Shackle Snap—A snap hook which when engaged about a shackle will automatically close and lock in instances of strain, but may be easily unlocked and relocked by manual operation in the absence of strain. Patent 1751458. John J. Van Valkenburg.

Pipe-Bending Tool—Which may be employed to bend the usual standard, or thin wall conduit, in various sizes, will not cause the conduit to flatten, and will prevent slipping or incidental injury during the operation. Patent 1752220. Andrew B. Allen.

Machines and Mechanical Devices

Automatic Well-Flowing Device—A combination pressure fluid and liquid velocity control device embodying a flap movable toward one side by the velocity of the stream and returning to its original position as the stream force diminishes. Patent 1749124. Alexander Boynton.

Rod Guide—Comprising a walking beam, for maintaining a polish rod of an oil well pump jack in true alinement, while providing a maximum stroke and the greatest quantity of oil, with the least sucker rod trouble and wear. Patent 1749626. Charles H. Brown.

Stripping-Finger Adjustment for Thrashing Machines—Whereby the rows of stripping fingers of machines used for operating upon the pod or hull type of crops may be projected or withdrawn at will, according to the weather conditions at the time of working. Patent 1749040. Carl R. Livermon.

Conveyer—Of the endless belt type, applicable for quenching and removing furnace or gas producer ashes, or metal articles after heat treatment, or may be applied as a hydro-mechanical conveyer and separator. Patent 1750426. Harry E. Partridge.

Device for Separating Water from Oil—A valve and float automatically acting to separate water which has gravitated at the bottom of a settling tank for oil and water, the action being accomplished in a continuous and clean manner. The float may be readily adjusted or removed from the separator tank. The inventor has been granted two patents, 1750489 and 1750490. John W. Pippin.

Mouth Wiper—For linotype machines of the Mergenthaler type, the movement being actuated by the ejector mechanism and includes a flexible wiping piece resiliently held in taut position and readily removable from or replacd on the structure. Patent 1750402. Henry G Guire and Albin L. Chalfonte.

Piston-Ring-Fitting Machine—A machine by which the grinding of piston rings incidental to fitting them in engine cylinders can be accomplished with a mathematical exactness, the machine is adjustable for practically all forms and sizes of rings. Patent 1750195. Granison M. Sanders.

Pump Plunger—A built-up plunger wherein most of the plunger is made from vitreous or other acid-resisting material capable of resisting the action of chemicals in water to be pumped from mines. Patent 1751350. Fred W. Moyer and Frank J. Reninger.

Box Forming and Sealing Device—Adapted to receive a blank which has been indented for determining the side walls, bottom and top, fold the blank, and apply a sealing tape to the abutted edges after the box-like structure has been formed. Patent 1751390. Walter W. Vrust.

Cutting Device—An attachment in the form of a rotary cutter comprising a disc-like body which may be readily mounted in connection with a paper tube forming machine for automatically cutting the product into predetermined lengths. Patent 1751293. Harold W. Sherman.

Water-Locking Suction Valve for Hydrocarbon-Fuel-Storage Tanks — Whereby fine dirt, scale, etc., frequently present in gasoline, and which settles in the water strata at the bottom of the tank, cannot be drawn up to prevent a proper closing of the check valve. Patent 1751371. John H. Viele.

Revolving Lathe Center—For the tail spindle of a lathe, which revolves instead of being stationary, thereby eliminating burning in wood turning, and is lubricated in such manner as to require less energy in running the lathe. Patent 1751711. Harold R. Ong.

Coin-Controlled Liquid-Dispensing Apparatus—Which can be operated in conjunction with gasoline and lubricant pumps, and will expedite the sale, by eliminating employees and permitting autoists to purchase the product at such times as the station is ordinarily closed. Patent 1752150. Ernest E. Cooper.

Long-Stroke Pumping Jack—Adapted for use with oil wells, may be easily unlimbered for temporary displacement preparatory to pulling a sucker rod, whereby weight elements may be added or substracted on the reciprocating chains to suit different loads. Patent 1752144. Lawrence G. Burt.

Medical and Surgical Devices

Orthodontic Dumb-Bell—Formed of a temporarily deformable elastic material, comprising a cylindrical shank with an enlarged integral spherical knob at one end, for the treatment of irregular teeth and development of the human maxillary and mandibular bones. Patent 1749632. Harry C. Ferris.

Tonsillotome—Of the guillotine type, including a pair of blades one initially directing an electrical current to the base of the tonsil, causing coagulation and reducing bleeding to a minimum, the other severing the appendages. Patent 1750874. Arthur C. Campbell.

Dental Mirror—Having a lighting attachment arranged in such a way that the rays are reflected from the surface of the mirror and illuminate the mouth so as to facilitate the inspection of the teeth. Patent 1750194. Carl G. A. Rydman.

Musical Devices

Phonograph Stylus and Sound Box—Wherein a plurality of stylus points may be associated with the sound box for consecutive use in combination with the sound groove of a record, and any one of the style positioned for playing. Patent 1750351. Auguste E. Pasche.

Plumbing and Fittings

Compound Faucet—A double faucet attachment to a single pipe whereby water may be drawn from one faucet inside the house while the other faucet is being used for a hose attachment outside the house. Patent 1750485. Gustav Muller, Jr.

Prime Movers and Their Accessories

Auxiliary Air Supply and Mixing Device for Internal-Combustion Engines—Which thoroughly incorporates the air with the explosive charge from the carbureter and causes the mixture to be automatically delivered in correct combustible quality to the manifold at all speeds of the engine. Patent 1748203. Gaston A. Brunelle.

Rotary Internal-Combustion Engine—Wherein carbon deposits are materially reduced if not eliminated, and which will develop a maximum horse-power with a minimum gaseous fuel consumption, utilizing substantially all the power before the exhaust products escape. Patent 1750502. Thomas A. Baker.

Internal-Combustion Engine—Designed to perform perfectly the four cycles of the usual four-cycle engine, and employs a new principle of compression and expansion which has distinct advantages over the usual type, the engine being comparatively light in weight. Patent 1751385. George P. Beaudry.

Two-Cycle Engine—Having a time-controlled valve which will force gases of combustion into a cylinder at the proper time, under the proper pressure and permit these gases to exhaust at the proper time. Patent 1750201. Gardner A. B. Spencer and Harry B. Cornish.

Internal-Combustion Pump — Whereby charges of fuel are controlled in such a manner as to avoid pre-ignition, thereby enabling greater compression, and so to make it possible for the pump to operate against heads of liquid in excess of two hundred feet. Patent 1752130. Eric W. MacKay-White.

Railways and their Accessories

Ballast-Dressing Machine for Railroads—A preliminary ballast spreading and leveling apparatus whereby ballast dropped upon a railroad in piles may be smoothed out or spread in an even and expeditious manner before the finishing operation. Patent 1750506. Solon F. Clapp.

Pertaining to Recreation

Doll—Constructed with a hollow hard casing and flexible swinging legs, whereby the doll may simulate the movement of human beings in walking by a forward turning movement first one side and then the other. Patent 1750404. Louis Herman.

Toy Target—In which the target elements are swingably mounted and have an indicia carrying portion adapted to be swung into position to expose the numerical value associated with each target, when struck by a projectile. Patent 1749689. Fred T. Baum.

Pertaining to Vehicles

Brake Mechanism—Wherein the braking elements will be self-centering, so that the active brake lining will be uniformly applied to the braking surface of the drums, and the wear evenly distributed over the entire area. Patent 1749624. Jonas W. Batson.

Road-Map-Exhibiting Apparatus for Motor Vehicles—Which is operable by the forward movement of the vehicle to be successively exhibited in a manner to continuously indicate to the motorist his precise geographical location, may be readily applied to an automobile. Patent 1749243. William L. Eglinton.

Gear Shift—An automatic mechanism whereby the shifting of gears from operative into neutral, and into another operative position, during one continuous movement of the clutch, prevents the gears shifting from second or third speed into reverse. Patent 1749837. Arthur C. Nickell, Jr.

Tire-Deflation Switch—A signal or alarm, electrically connected with the usual ignition or lighting circuits, and giving warning to the operator of an automobile of the deflation of one or more of the tires during travel. Patent 1750563. Joseph Berger.

Steering Mechanism—For vehicles, whereby the operator will be relieved of much manual labor, the operation requiring practically no effort regardless of whether the vehicle is moving or at a standstill, so long as the vehicle's motor is operating. Patent 1749816. William R. Hendrix.

Vacuum-Cleaner — Whereby the suction created in the intake manifold can be utilized to perform the functions of a vacuum cleaner, the dust being prevented from passing into the manifold or interrupting the normal operations of the engine. Patent 1750800. Sydney R. Gould.

Internal Spring-Metal Reenforcing Member—Which will take the place of the ordinary inner tube, may be readily inserted within a vehicle tire, and conform to the inner walls, and will force the tire beads outwardly against the rim. Patent 1751741. Victor Karbowski.

Auxiliary Control for Motor Vehicles—Which permits the driver of a house-to-house or short-stop delivery zone truck, to automatically start or stop his car, either from the usual driver's seat, or from the delivery door, thus saving much time. Patent 1748041. Herman T. Backhus.

Automobile Identifier—A frangible support for a license plate or other identifying mark, so that in a collision the supporting means breaks and causes the indicia to drop, thus leaving identification in case the driver escapes. Patent 1747446. Stephen G. Krile.

Hydraulic Power Transmission—In which a fluid is employed for effecting a silent driving engagement and cushioning effect of one shaft with another, thereby eliminating jolts and harsh mechanical connection, as in ordinary motor vehicle transmissions. Patent 1748436. Victor Arkin.

INDEX TO VOLUME 142, JANUARY-JUNE, 1930

Lack of space makes it impossible to give many cross-references or to enter a given reference in more than one place. Each article is therefore entered where it is believed it will be most easily found. In every case, the general subject should be sought rather than the supposed specific title of an article. We call special attention to the classifications "Aviation," "Engineering," "Medicine," "Miscellaneous," etc., under which many items will be found, the location of which otherwise would be very puzzling.

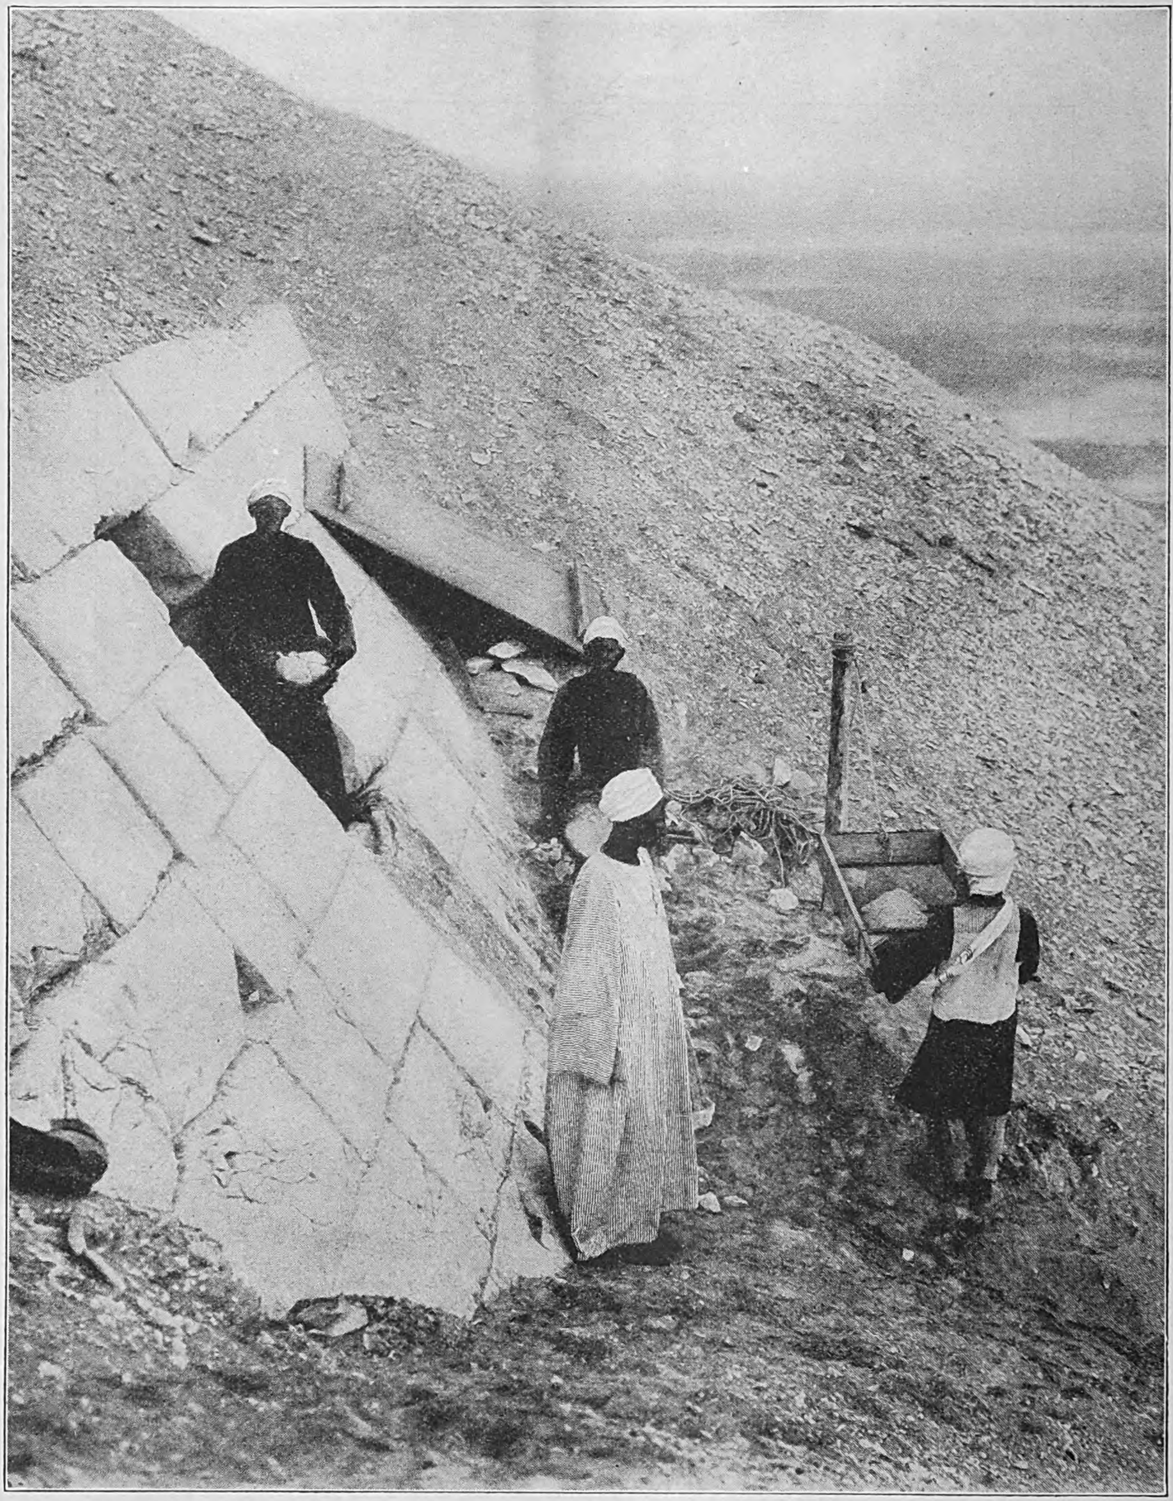
C. J. Davisson **L. H. Germer**

DOCTORS Davisson and Germer of the Bell Telephone Laboratories in New York performed experiments which furnished physics with concrete evidence that De Broglie and Schrödinger were right when they attributed a wave nature to the electron, hitherto regarded as a wholly material particle. The wave atom concept, explained on page 38, is now rapidly displacing the more familiar Bohr atom having analogy with sun and planets. This recent trend is likely to discomfit writers of popular science whose books have tended to create the unfortunate impression that the facts at last have been finally settled, instead of being constantly subject to revision in the light of new experimental evidence, as they actually are among physicists, and as they should be. Further discomfiture is in store for all who attempt to popularize the wave atom concept, for it has no cut-and-dried, familiar analogy like sun and planets and, strictly speaking, can be expressed only in the most agonizing of higher mathematics. Hence the planetary atom is likely to remain in style, popularly, some years after most physicists have discarded it. In the photograph Dr. Davisson holds in his hands the glass evacuated tube into which was sealed the same small apparatus shown on page 40. Dr. Davisson came to science via the University of Chicago and Princeton; Dr. Germer via Cornell and Columbia. They are typical examples of workers in pure science.



Clearing the Interior of a Pyramid

THE important excavations conducted by the Museum of the University of Pennsylvania at Meydum pyramid in Egypt are fully described in the article starting on the opposite page. A casing of well-cut limestone blocks completed the pyramid. On the slant of the pyramid this masonry outcrops from the debris and an opening in the casing gives access to the interior. A man is posted in the entrance who hands out the broken material passed up through the long passage by a chain of 60 men. All the loose material, earth, et cetera, is carefully sifted to see if it contains valuable material. The sifter in our photograph shows great inventiveness, for Egypt. The "boy" has attached a sieve to a post, thus taking up weight.

The Meydum pyramid of today, as reduced from the original form, showing the southern side. This illustrates the condition of the pyramid before last season's work began

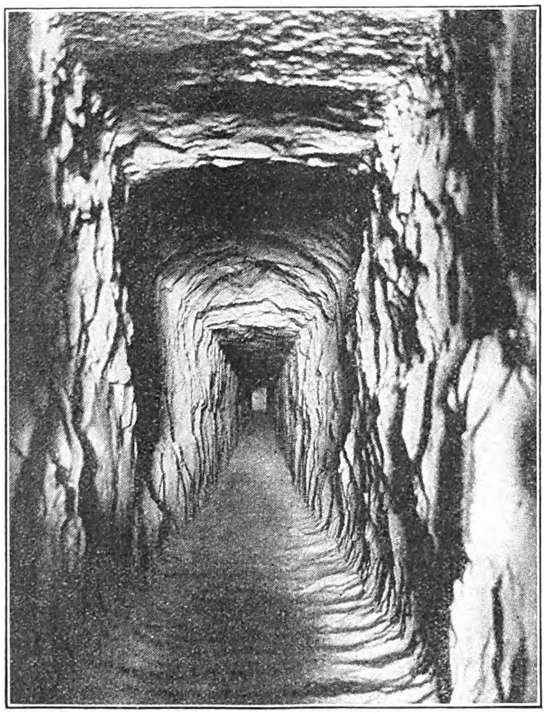
Exploring the Meydum Pyramid Site

By Cornelia H. Dam
Staff, Museum of the University of Pennsylvania

IN the age of Tutankhamen and of Rameses the Great, 1500 years before Christ, the Pharaohs of Egypt, whose empire extended from the heart of Nubia to the Mediterranean and included Libya, Sinai, Syria, and Palestine, used to boast of their exploits that "nothing like it had been done since the time of Seneferu." This venerable name, which echoes through Egyptian records for two thousand years, designates the first really great historic king of Egypt, father of that Cheops (Khufu) who built the great pyramid of Gizeh, near Cairo.

WITH Seneferu, who died about 2900 B.C., we are at last on firm ground in Egyptian history. He laid the foundations for the Fourth Dynasty, that remote, magnificent period of which the art was never again equaled, and of which the great pyramids of Cheops, Chephren, and Mycerinus are the immortal monuments. From later records, notably the Palermo Stone, we know something of his exploits: he united Egypt under his rule from Nubia to the Mediterranean, and invaded Libya, returning with 7000 prisoners; he sent a fleet of 40 vessels to the northern coast of Syria for cedar logs, and expeditions across the desert into the Sinai mountains for copper, so consistently that he was later regarded as the founder of Egyptian operations there, and stations on the desert route thither bore his name for 2000 years. He caused to be built vessels 175 feet long for his traffic on the Nile.

The marvels of his reign and the splendor of his court are referred to again and again in later records—the Westcar papyrus relates how the king, suffering from ennui, was taken to row upon a lake, with a gay party of youths and maidens, and all went well until one of the girls dropped a favorite malachite pendant overboard. But a court magician saved the day by piling up the waters of the lake, as Moses did the Red Sea, and recovered the jewel.

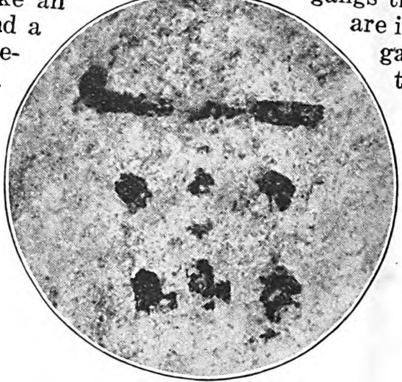


A long passage sloping downward leads to the tomb of a Pharaoh in the pyramid

At Meydum, about 50 miles south of Cairo, where the western desert edge touches the fertile floor of the Nile valley, Seneferu built the earliest known true pyramid, for the two similar earlier constructions at Sakkara and at Zawiet el Aryan seem never to have had added the outer casing which would have turned their stepped stages into a true pyramid form. And at Meydum, time and weather, and above all the depredations of man, have destroyed most of the casing and exposed the stages and the rubble core of its construction, so that today the pyramid presents a stepped appearance, not unlike the staged towers of Babylonia, and has therefore often been called a "false pyramid." Excavations, however, have revealed the original casing blocks on the lower stages, and the methods of construction, which are of considerable interest for the history of the development of architecture.

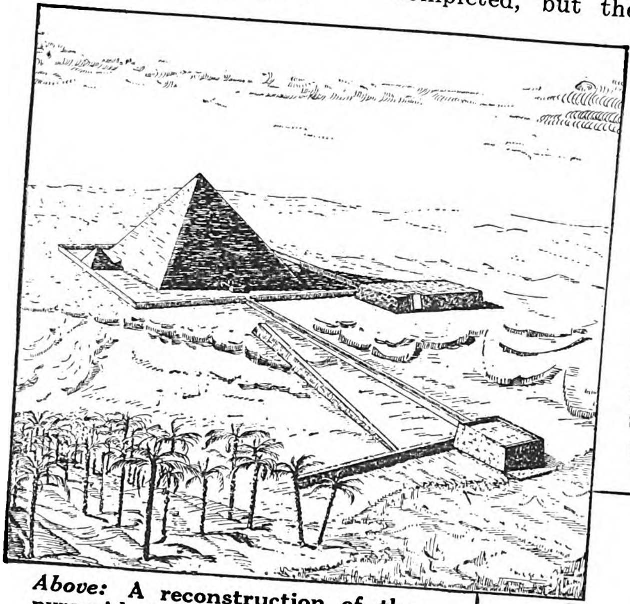
The pyramid seems to have been

built cumulatively, quite possibly over an original mastabah tomb, as a staged building of seven stories, to which a later coating was added, increasing the stories to eight; finally the steps were filled in to make an even inward slope, and a casing of well-cut limestone blocks, quarried far away across the Nile, and floated over during the inundation, completed it. The original height of the pyramid has been estimated as about 300 feet; the existing stages rise only 214, but it is still an imposing pile, visible from many miles around.



"Six cubits," a quarrymen's mark in black paint on a stone of the pyramid

The cumulative construction evident in this earliest true pyramid is particularly interesting for the light it throws on the probable development of that architectural form from a mastabah, because the next pyramid in date, that of Cheops at Gizeh, was obviously planned in its finished form from the beginning. We might say that Seneferu *invented* the pyramid!



Above: **A reconstruction of the pyramid site, showing pyramids and adjacent structures.** ***At the right:*** **Sections of the pyramid**

Three great Egyptologists, Mariette, Maspero, and Petrie, had each done work at Meydum before the Museum of the University of Pennsylvania undertook excavations there last November. But the site had never been thoroughly explored, and it was with reasonable, and soon justified, hopes of important finds that Mr. Alan Rowe took the field as director of the expedition.

The first work undertaken was on the pyramid itself, removing the centuries' accumulation of debris and rubbish from its base, and clearing the passages and chambers in the interior. It was a long and laborious task, involving the removal of hundreds of tons of debris, and the labor of a large party of workmen for the greater part of the season.

ON fragments of stone found in the debris around the base were painted inscriptions giving the dates of the 16th or of the 17th year of the king's reign, apparently the year in which the casing was put on, and the pyramid completed. These marks were put on the blocks in the quarry, before they were transported across the valley and presumably for the purpose of making a count of the number cut each day by the different gangs of workmen employed on the operation. The word *aperu*, which means "gang," also appeared. The names of a number of the gangs that worked at Meydum are identified: the "pyramid gang," the "north-gang," the "enduring-gang," the "vigorous-gang," and the "scepter-gang." Lines in red paint, the original levelling lines of the builders, and their measurements in cubits also appear on the stones still in situ on the pyramid.

The task of clearing away the debris outside is not yet completed, but the interior was finished in time for the visit of the king and queen of the Belgians on March 30. The entrance to the pyramid, once carefully concealed, is some 60 feet from the ground on the north side, thence a long narrow passage, less than six feet high, descends for 185 feet to an antechamber, about twice as wide as the passage, on its left, and another immediately following on its right. Thence a horizontal passage leads to the shaft which opens into the sepulchral chamber some 20 feet overhead. It is a tiny room, about 20 feet long and high, but only nine feet wide, with stone walls and floor, and a steeply corbelled ceiling.

To clear the interior a long chain of men, increasing as they worked inward to the number of 90, was formed to pass in empty baskets and pass them out full, for in the narrow passage only one man at a time could work with pick and hoe. "It is a long and tedious job," wrote Mr. Rowe, in his monthly report to the Museum, "as the farther we penetrate the worse the air becomes. In fact when we had reached the bottom of the sloping passage leading from the outer entrance, just at the point where the passage runs into an antechamber, we were able to work for only one hour each day. At the end of this time our candles went out, warning us that it was unsafe to remain inside any longer." Nothing of very great importance was found inside the pyramid, as it had been opened and robbed in antiquity—how soon after it had been sealed up we cannot say, certainly it was open in the Twentieth Dynasty (c. 1200 B.C.), for the names of two scribes who visited it then are still visible on the ceiling of the passage. "Fools' names" are often valuable evidence in archeology!

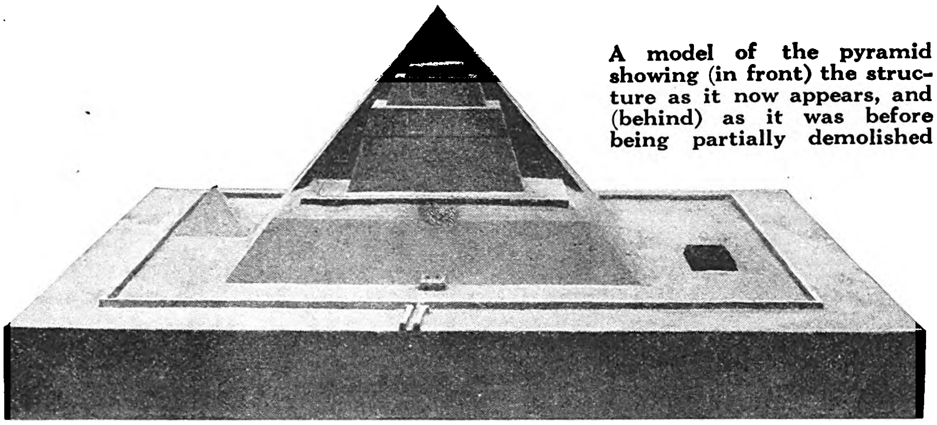
(a) PETRIE'S ORIGINAL SURVEY.
(b) AFTER PETRIE'S RESURVEY, "LABYRINTH," PL. XIV.

AGAINST the east face of the pyramid is a small temple, consisting of a vestibule and a little rectangular room, behind which, in a courtyard, stand two uninscribed stelae with an offering table between them. On the walls are pictures and scribblings put there by visitors to the sacred precincts 3500 years ago. One scribe of the time of Thothmes I. (c. 1500 B.C.), wrote on the wall that he "came here to see the beautiful temple of the Horus (king) Seneferu: he found it like heaven within when the sun-god is rising in it: and he exclaimed 'the heaven rains with fresh frankincense and drops incense upon the roof of the temple of the Horus Seneferu.' "

From the valley edge (the inundation level), where by analogy with other pyramid sites there should be a small entrance temple, although none has yet been found, there runs a long brick-faced causeway, by which pilgrims in ancient days might approach the sacred pyramid area, which was surrounded by a wall, and enter it by a gate at the end of the causeway, directly opposite the entrance to the temple. To the south of this causeway are the remains of another, which was evidently used as a road to haul material during the construction of the pyramid, then partly destroyed and covered over.

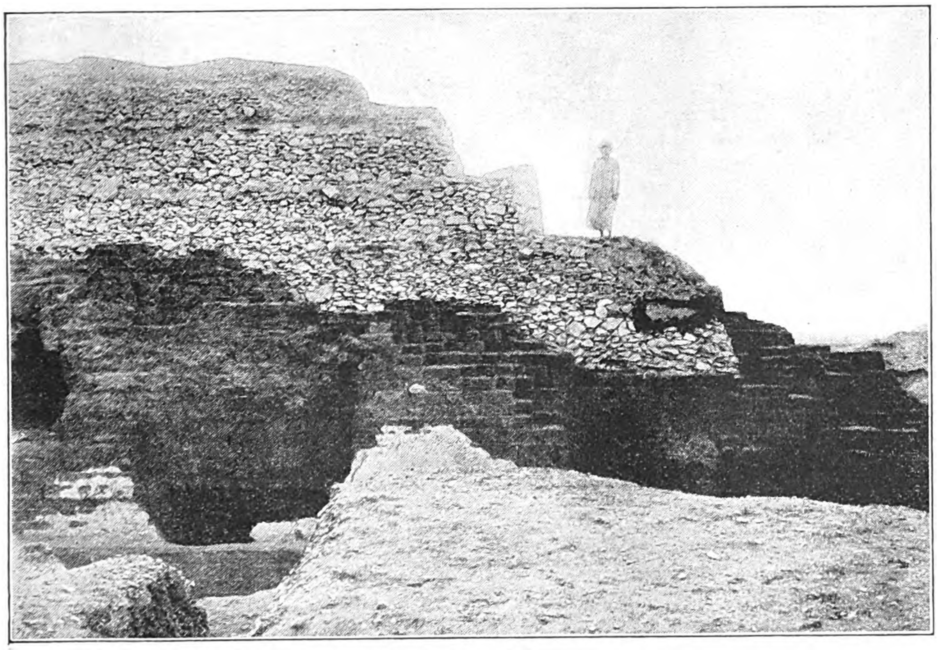


A model of the pyramid showing (in front) the structure as it now appears, and (behind) as it was before being partially demolished

WITHIN the pyramid precinct wall are the remains of a miniature pyramid, perhaps a queen's, on the south, and of a large, presumably a royal, mastabah-tomb on the north.

It is not known where Seneferu was buried. If it was at Meydum, his body was subsequently removed, either by tomb robbers, in which case it was probably destroyed, or by his pious successors who wished to avoid just such a catastrophe, in which case there is a fair chance of yet discovering it, either at Meydum, or at one of the other great Fourth Dynasty cemeteries of lower Egypt. The transferred burial of one of his Queens, Hetep-heres, mother of Cheops, was found recently by the Harvard-Boston Expedition near her son's pyramid at Gizeh, near which is also the tomb of Seneferu's eldest daughter, Nefert-kau, sister-wife of Cheops. His eldest son, Ka-Nefer, on the other hand, was buried at Dahshur, (where Seneferu had built a second pyramid, not as a tomb, but as a cenotaph) and two other sons and their wives were buried at Meydum. From the tomb of one of these royal couples, Ra-hotep and Nefert, came their portrait statues (now in the Cairo Museum) which many people consider the finest known Egyptian statues, and from the other, that of Nefer-Maat and Stet, the equally famous painting of Geese (also in Cairo) and a beautifully painted fragment in the Museum of the University of Pennsylvania.

In rock-cut chambers piled-up coffins gave the appearance of a forgotten lumber room



North end of east side of mastabah tomb No. 17 showing the stepped stages in the stone core which were later filled in to support a brick casing

All around the pyramid of Seneferu stretches a vast cemetery, including examples of various types of burials used in Egypt from the Fourth Dynasty down through Ptolemaic times (3000-300 B.C.), a strong indication of the enduring renown of the sacred character of the site.

Simultaneously with the work on the pyramid Mr. Rowe started clearing a large mastabah (Number 17), which is some 350 feet long and half as broad, and is situated just to the northeast of the pyramid. The name of the original owner has not yet been discovered, but it must have belonged to a member of the royal family or at least to a very important person. Its construction proved to be analagous to that of the pyramid; that is, it was built originally in three steps, which were later filled in to give the even inward slope of a mastabah. Two brick-faced ramps led from the valley up to the eastern face of the tomb. The northern one once led to the top of the mastabah, and the southern one to a little chapel, or niche, of which only the floor now remains, but traces of the walls, as thick as the chapel was wide, enabled Mr. Rowe to reconstruct the plan of an imposing building of pure white limestone. The walls were once highly polished, and the hard stones used in the process were found in the debris nearby.

PROFESSOR PETRIE found a tomb chamber behind the niche when he worked at Meydum, so the discovery this year of a second niche at the northern end of the same side, led Mr. Rowe to hunt for another chamber and possible burial in it, at that end of the tomb. When sending his last report, he had not yet found it, but the search goes on.

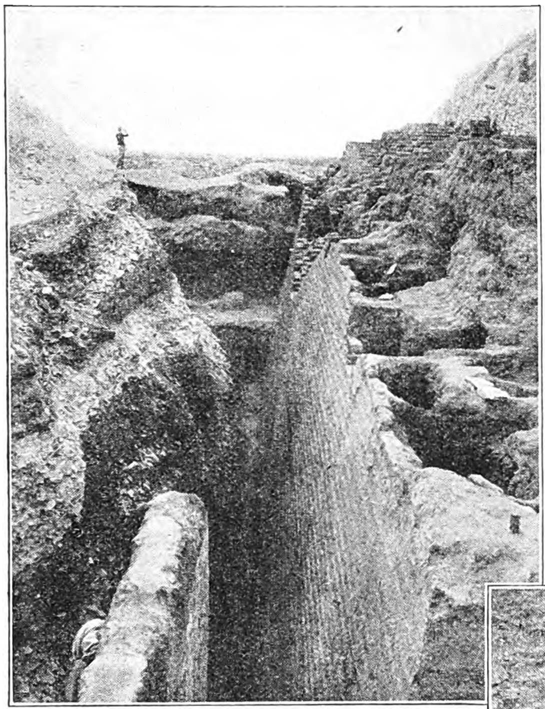
In clearing the heavy retaining walls of the mastabah, he found that they were honeycombed with intrusive (i. e.—later) burials, most of them dating from the New Empire (1500 B.C.) and later. They represent chiefly the burials of the common people, and fall into three main catagories:

(1) Unwrapped skeletons, and mummies buried simply in linen wrappings,

often fringed, occasionally with green borders;

(2) Mummies to which an additional covering of reed or palm-frond mats were added; and

(3) Mummies in coffins. Rectangular coffins were usually undecorated except for a coat of whitewash, and confined to the burials of children, adults being buried in rather crude anthropoid coffins of the type of "mummy cases" to be seen in most museum collections of Egyptian antiquities.



In the mastabah, or noble's tomb No. 17, the north (outer) casing wall is 56 feet high. Note the excellent brickwork

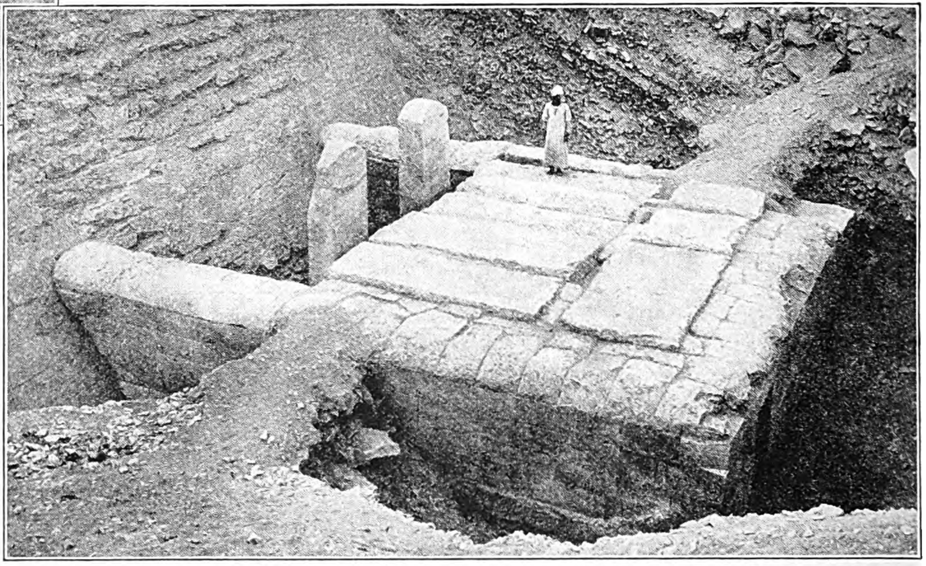
Pottery dishes and bowls buried with the mummies contained grapes, dates, palm-fruit, pomegranates, or other food, and of course there was an abundance of the essential equipment for a pleasant after-life which is usually found in Egyptian tombs: boxes of eye-paint, trinket-boxes of wood, amulets, scarabs, beads, earrings, pins and bracelets, combs of wood and haircurlers of bronze, the scribe's palettes and the craftsman's tools.

THE burial of so many persons in the actual walls of the mastabah, (not a very convenient place), indicates that the tomb was highly venerated 2000 years and more after it was built, and Mr. Rowe suggests that as the only person we know of who was so long venerated was a magician, Zedi by name, who lived in the time of Cheops, and who at the age of 110 ate 500 loaves of bread and a haunch of beef, and drank a hundred jugs of beer a day, the great mastabah might have belonged, either actually or traditionally, to this picturesque and very remarkable person.

Just to the east of the great mastabah Mr. Rowe found a miniature replica of it; it had been plundered in antiquity, and only one of the three pits beneath it contained the original Fourth Dynasty burials. Of the many types of burials already cleared in the neighborhood of the pyramid, the majority belong to the New Empire, a thousand years later than the pyramid and mastabah-tombs. There are however, a number of contemporary, that is Fourth Dynasty, tombs, most of them simply large pits with two or three recesses in the sides, in which lay skeletons, although two of the number so far excavated had large masonry chambers, illustrative of the increasing use of stone in place of brick for private as well as royal tombs in this period.

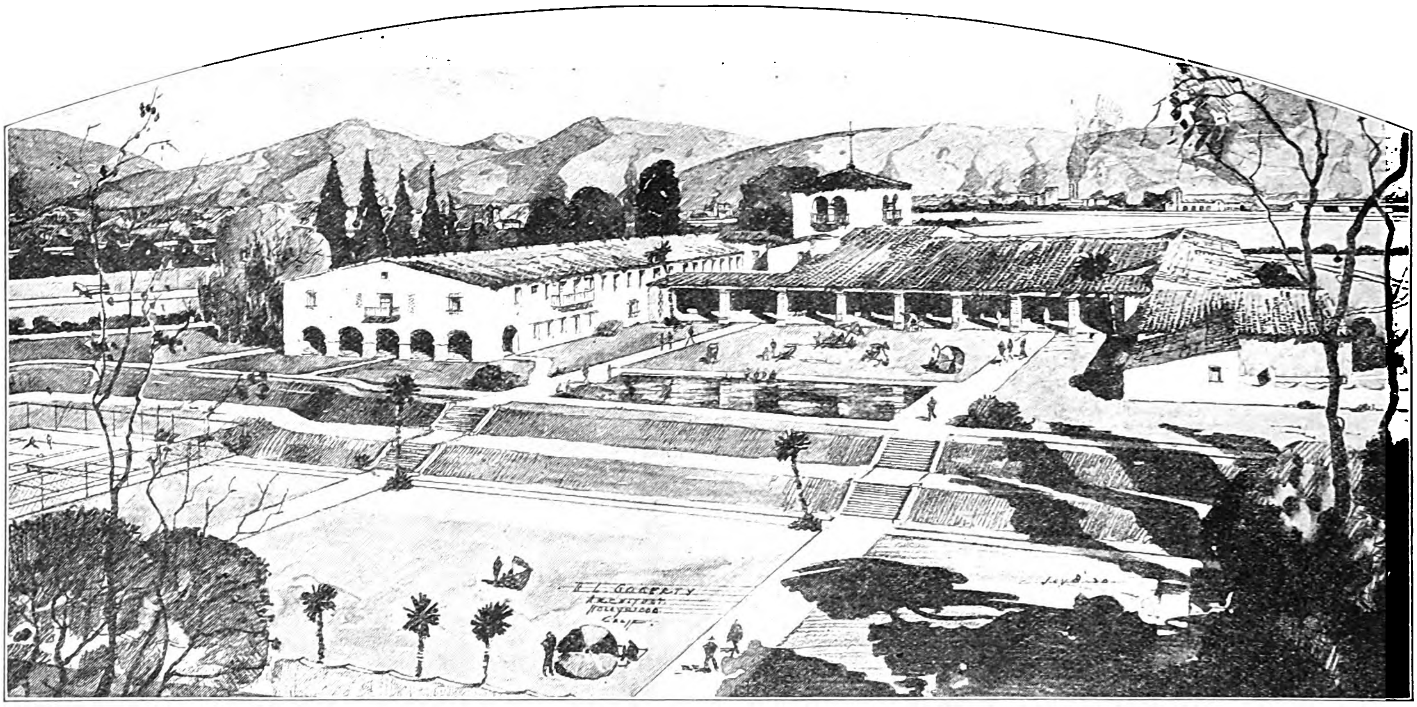
The most exciting and spectacular discovery of the season came in January, when, exploring a depression in the sand to the southwest of the pyramid, Mr. Rowe came upon a group of twelve rock-cut chambers, many of them stacked ceiling-high with coffins, "for all the world," he wrote, "like a forgotten lumber room." There were 101 mummies, besides 29 simple burials, the largest number of Ptolemaic mummies ever found together in Egypt. Of course the tomb had to be guarded day and night until it was cleared, and the first night the Arab workmen were afraid to sleep there until two of the staff joined them, and at that passed most of the night exchanging ghost stories. "They certainly had the right setting in which to relate their experiences," Mr. Rowe added, in his report on the latest discoveries.

The majority of the coffins belong to the Twentieth Dynasty (c. 1200 B.C.) or later, and one of these contained the finest mummy yet discovered at Meydum. Its outer coffin was badly damaged by rock falls within the room, but the inner one, beautifully decorated, was well preserved, as was also the mummy itself, covered with a network of glazed pottery beads; on its head was a gilded mask, and on its breast a golden winged scarab. Two of the coffins are Twelfth Dynasty (c. 2000 B.C.), delicately painted with texts from the Heliopolitan Recension of the Book of the Dead, prayers for offerings of cakes, ale, beef, geese, bread-rolls, clothes, incense, and oil on festival days. "O lady of the house, Sat-Her-em-hat, triumphant, revered before the gods who are in the other world, they transfigure thee. Take to thee thy head, and collect to thee thy bones," says one verse.



Against the face of the pyramid is a temple consisting of a vestibule and a room; behind stand two *stelae* or pillars, with an offering table between. The location of this temple is shown in the model illustrated on page 11

AND truly, the bones of those long-buried Egyptians who strove so hard to preserve them against time, and so cunningly to hide them in pits, pyramids, and shafts, from the impious tomb robbers of their own day, are safer now than ever, in the reverent hands of science. The careful excavator is bound to earnest respect for the remains of these long-forgotten people, lest he lose through heedlessness some minute bit of evidence of great scientific value, and he spares no pains to develop the all-seeing eye and the sympathetic mind that may enable him to reconstruct for us, vividly, accurately, and at last completely, the life and thought of this great civilization that vanished from the earth so many centuries ago.



An architect's drawing of the clubhouse and grounds at Grand Central Air Terminal, Los Angeles, which the Flying Club of California has leased from the owners of the airport. Further details are given in the text

Flying Clubs for Private Fliers

By Charles L. Lawrance*

THERE are three hundred and four flying clubs in the United States today owning plane equipment. This figure is derived from reports of the Department of Commerce covering the licensing of aircraft and includes all cases where a group of individuals have jointly bought a licensed airplane. Undoubtedly many of the clubs included in the figure are of extremely loose organization owning but a single plane and renting hangar space from the nearest airport. Yet the number itself is surprising. It is estimated that 50 percent of the clubs have sprung up during the past 18 months.

In other words, American men and women are taking to the air through the most practical means at hand—the flying club. By organizing into groups, people can afford to buy and to maintain an airplane the cost of which may be beyond the means of any one of the group. The small flying club is one of the most important manifestations of democracy in the airplane field today. It means that flying is not only for the rich but is possible for men of moderate means who are willing to work together so that they may fly.

In no place is this co-operative movement toward flying more clearly marked than in American colleges. While only at Harvard University do students own their own ship, yet the tendency to combine into organized units to promote flying has touched nearly all of the great universities. On May 10 in connection with the Air Show in New York City the first college aeronautical conference was held. Delegates from the flying clubs of 10 colleges were flown to New York in planes of the Curtiss-Wright Flying Service which picked up representatives from as far west as the University of Kansas.

OTHER universities represented included the University of Illinois, the University of Michigan, Ohio State University, and New York University. In every case it was reported that members of the clubs were putting in flying time with planes rented from the nearest airport. In some cases faculty opposition was reported, but as a rule professors themselves were said to be interested in the movement. The membership of every club included a number of licensed pilots, in some cases of the higher grades.

Thus the flying club, even where no equipment is owned, is a powerful factor in increasing the number of people who fly and know how to fly. At the same time larger clubs have made flying a far more comfortable and convenient thing than it ever has been before. This is especially true in the case of such a club as the Aviation Country Club of Long Island opened over a year ago. This club, modeled more on the flying clubs of England and Canada, owns its own clubhouse and field as well as four planes. It includes an associate membership of 180. Fifty planes are owned privately.

The formation of such a club represents a large outlay of capital and its membership is of necessity limited to the more wealthy type of individual. On the other hand the small, loosely organized club which rents hangar space from the nearest airport is under the handicap of having no clubhouse or headquarters. A compromise between these two types of club is now being worked out by the Flying Club of California which in July will move into the clubhouse being built for it at Grand Central Air Terminal outside of Los Angeles.

The expense of building the 200,000-dollar Spanish-style clubhouse is being borne entirely by the Curtiss-Wright Airports Corporation, the owners of Grand Central Air Terminal. The corporation is renting the clubhouse to the Flying Club of California for a period of 20 years. Because the rental is relatively low, the dues of the Flying Club of California are only six dollars a month. Its members, however, will enjoy one of the most luxurious clubhouses in the country, equipped with dining and sitting room, squash courts, and swimming pool, with tennis courts outside and two golf courses immediately adjoining.

---

*See "Among Our Contributors," page 5.

It is evident that membership in such a club is at once attractive to a man who, on the one hand, could not afford to join a club which owns its own house and field, and who, on the other hand, is unwilling to put up with the inconveniences inherent in a club which has no permanent headquarters. It is altogether probable that the next few years will see clubs similar to the Flying Club of California established at the great eastern and middlewestern airports.

In the vicinity of New York, for example, there are a number of fields at which flying clubs could establish themselves in co-operation with the owners. Land has been set aside at the Curtiss-Wright Airport at Valley Stream for the building of a clubhouse for lease to a private flying club. Residents of the Oranges and Morristown, New Jersey, on the other hand, may some day organize into a club which will make use of the facilities of Essex Airport at Caldwell. The fact that many New Yorkers live in the country during the summer makes such ports particularly well suited to flying clubs.

Members of a flying club which has its clubhouse at a large landing field naturally enjoy all of the facilities of the port. Hangar space, machine shops, and repair facilities are all at hand. Flying instruction, always an important consideration in forming a club, is available at most large flying fields.

It is interesting now, when the United States has plenty of flying-club news and activity of its own, to look back only a year when most of our knowledge of such clubs came from abroad. The retrospect shows that, although the flying club in America is a new thing, it has already exhibited marked differences from the clubs of Europe. In no case is the difference more striking than in the matter of subsidy from the government.

English clubs, which were the first in the field and developed soon after the war, were almost all subsidized. The English government gave 10,000 dollars to a club on its formation, for buying two airplanes and thereafter 5000 dollars a year for purposes of upkeep. Under this stimulus English clubs spread rapidly and gradually came to own their own flying fields instead of using the army fields. Today English clubs include many thousands of members with much flying time to their credit.

NO subsidy has ever been given to American clubs. Although the stimulus might have developed the movement here more swiftly, in the long run the absence of subsidizing should prove beneficial. American clubs gain an enormous amount of vitality by standing on their own feet financially. In this connection it should be noted that just as American clubs have proceeded without government aid, so, too, members of such a club as the Aviation Country Club of Long Island have tended to buy their own planes rather than to depend on the planes of the club. The fact that 50 planes are privately owned by members of this club is a distinct departure from European tradition.

A glance at the roster of the planes owned by members of the Aviation Country Club of Long Island discloses a third difference. The roster includes not only small planes such as the Moth but also cabin planes such as the Travel Air, the Robin, and the Keystone Loening amphibion. In other words, pleasure flying in America does not necessarily mean "light" flying as it does in England where distances are so much shorter. While the Englishman can use a small plane for getting to his week-end destination, New Yorkers who wish to fly to Florida or the Thousand Islands will of necessity turn to the heavier cabin type of plane.

The fact that American clubs have been developing rapidly and along their own lines should not obscure the fact that flying clubs have progressed in other countries. In Canada, for example, during 1929, members of its 23 large flying clubs flew over 1,232,000 miles in 15,400 hours of flying time. Total membership in Canadian clubs is 5092 and at the end of 1929 there were 396 solo flyers, 165 private pilots, and 58 commercial pilots—all of them trained in club flying schools. In France the flying-club movement has also developed on a large scale. There are at least nine regional clubs of the Aero-Club of France with a membership totaling close to 9000 individuals. In 1929 these members flew over 8000 hours.

The development of foreign flying clubs has in the past been a stimulus and guide to America and will no doubt remain so for some time to come. The rapid spread of small clubs throughout the country, however, in the past year indicates that America contains the possibilities of developing a system of flying clubs proportional to its size and wealth. The coming year should see more small clubs formed and the organization of many existing clubs into tighter and more efficient units. The building of private clubhouses at the great airports of the country should follow naturally and with far-reaching results. The flying club is important to American aviation: it is a powerful influence in leading people to fly and to learn to fly.

OUR POINT OF VIEW

Naval Officers in Aviation

IN view of aviation's unquestionable importance in the defense of the country, it will doubtless come as a distinct surprise to most people to learn that there is a considerable lack of knowledge of it among the older officers of the Navy. As a result of this fact, it is said that a certain amount of prejudice exists today within the Navy itself.

The natural way to overcome this prejudice and increase the efficiency of the Navy in these days when all naval activities are so closely associated in some way or another with aviation, would seem to be to train as fliers some of the older officers who naturally exercise the higher commands. Personal knowledge of aviation coupled with their years of experience on the water would enable these seasoned men to exercise their commands more intelligently and efficiently in co-ordinating the activities of the fighting fleet with those of the air fleet.

It is claimed that the Navy Department excludes the senior officers from all opportunity to take the flight training course at the Naval Air Training Station at Pensacola—this on an arbitrary basis whether or not they are physically and temperamentally qualified. It is the announced purpose to concentrate on younger officer pilots. At the same time, however, more than half the capacity of the training school at Pensacola is taken up by enlisted men and reserves on whom the government has only one to three years' claim at the outside. The thorough training there enables these men to qualify for positions in civil life at government expense.

Senior officers who are physically qualified, should not only be allowed to take this course, but should be forced to take it. It is believed that the efficiency of the Navy will suffer if the older officers who command it know nothing of aviation, and the only way they can understand it is through learning to fly.

Engineering Opportunities

TO the youth who expects to take up engineering but cannot decide in what branch of it to major, we suggest an investigation of the possibilities in highway engineering. Perhaps the fastest growing of the newer engineering fields, highway engineering concerns all the activities that have to do with the highway industry which has attained the rank of sixth of the nation's industries, financially.

With a production of over 5,000,000 motor vehicles and a total registration of 26,400,000 in this country last year, and a steadily increasing production each year, the need for more and better roads is impressively indicated. Registration of automobiles will grow at an amazing pace and highways must be built for them. For an indefinite period of years, there will be plenty of work for road builders, road machinery manufacturers, highway planners, cement and asphalt chemists, and others. The vast scope of the industry is of such a nature as to affect the daily life of practically every citizen of almost every country of the world.

Declining Conversational English

IS our coversational English or, more specifically, American language becoming debilitated through disuse? Many of us have thought so, but indications point that way more than ever if we are to judge by the results of an investigation conducted in New York City by American Telephone and Telegraph Company engineers who listened in on toll circuits over which business calls predominated.

Of the 79,390 words recorded, 30 simple words—principally the personal pronouns, prepositions, conjunctions, and a few verbs—made up nearly half. More astonishing still is the fact that 155 words, including the 30 already mentioned, made up more than 80 percent. Purists and philologists will be horrified to learn that "shall" was heard only six times; while "yeah," "uh-huh," and "er" were plentiful; and the grunts and monosyllabic replies recorded ran into the thousands.

It has been remarked that this study shows a "facility of expression and economy of vocabulary" that is apparently held to be congruous with the rapid pace of our age. But to the thinking man, it is appalling, in that it shows an utter lack of imagination among business men, a lazy mentality that does not fit into the picture of modern efficient business. It is hoped that this sorry record, spoken into the telephone by New York business men, is not representative of the country at large. If it is, we are sure to retrogress. If we take up once again the grunting "speech" of our prehistoric forbears, the "culture" of the machine age may be set down in the histories of a future Renaissance in a hastily written paragraph or two!

Of the total 3,016,281 miles of highway in the United States, only 660,000 miles are surfaced—or slightly more than 20 percent. Fortunately our people are highway conscious and it is certain, therefore, that this percentage will rapidly mount. This is borne out by the fact that Congress passed this year, with rare speed, a bill for adding 50,000,000 dollars to the present 75,000,000 which is given the states to build highways in the Federal Aid Program.

With so much work necessary on roads at home and an increasingly larger amount necessary abroad, it may be said without fear of contradiction that highway engineering today offers as fine a career as did electrical engineering in its early days—and with a decidedly wider field for the application of particular talents and aptitudes.

Analyzing the Naval Treaty

PRESIDENT HOOVER lost no time in transmitting the naval limitation treaty to the Senate. The Committee on Foreign Affairs and the Committee on Naval Affairs are giving immediate consideration to the treaty. They will scrutinize its provisions carefully and will hold extensive public hearings on the subject matter before giving their approval. The House Committee on Naval Affairs has demanded full information of the effect the treaty will have on the relative efficiency of our Navy. This consideration by Congress is essential. We are committing ourselves to an important agreement; no urgency demands the immediate approval of the treaty. The responsibility for our national defense rests on Congress; and it is the duty of Congress to examine minutely into all the aspects and ramifications of this treaty.

We confess that we are not enthusiastic over the part of the treaty fixing the ratios between Japan and the United States; we have the uncomfortable feeling that our delegation was embarrassed by our present naval inferiority and the Administration's eagerness for an agreement and could not properly support our country's position. In his prepared statement to the Senate Foreign Affairs Committee, Mr. Stimson tacitly admitted that, having already sacrificed our superiority in capital ships, we were handicapped throughout the negotiations. On the other hand, the position

Beautiful Roadsides

Move for Sightly Highways Is Becoming Countrywide

By Walter E. Burton

MILLIONS of American motorists who seek restful scenery, charm, and recreation on the open road are beginning to ask for better-looking highways. To a limited extent, their demand is being answered. But there is a surprising hesitancy of some states in making use of available public funds for highway beautification.

An act of May 21, 1928, gave authorization for the inclusion of tree planting as a part of federal-aid road construction. But, more than a year after the act became effective, the Bureau of Public Roads had received no request for aid in a single road-beautification program. This does not indicate that nothing has been done to increase the beauty of modern roads, for, on the contrary, considerable progress has been made in many states.

Signboards usually constitute the first objective of a road-beautification movement. All but 11 states exert some kind of regulatory influence over roadside signs, yet not one prohibits their erection. The situation is a ticklish one because it concerns personal property rights. Some of the larger advertisers have voluntarily abandoned roadside advertising, choosing to carry their message to the public through other channels.

"In practically all cases these roadside advertisements merely repeat, in the same form, appeals that are made quite properly and insistently through other agencies," Thomas H. MacDonald, Chief of the Bureau of Public Roads, stated in his last annual report. "They are not needed by the public, and are of doubtful value to advertisers. It is hoped that means may be found by suitable legislation to effect their complete elimination upon all roads constructed in part with money appropriated by the national government."

NEVADA is the only state having laws seeking to regulate the erection of signboards. No permit is issued for signs that will measurably mar the roadside beauty, or obstruct views. Connecticut regulates signs erected by filling stations and similar business places. Illinois controls erection of signs within right-of-way limits of trunk-line highways, but has difficulty with signs inside corporation limits. California issues permits only for signs located on the right-of-way adjacent to the business they advertise. Massachusetts keeps advertising matter 300 feet from the highway, except where it is contiguous to the business it concerns.

In recent years, with the rapid development of improved roads, there has been little attention given to their esthetic aspects. Lately, a few states, notably Massachusetts, California, Connecticut, Pennsylvania, and Florida, have begun to take the matter seriously. One surprising thing was learned: Road beauty is not a costly improvement.

By judicious planting of native trees, perennial flowers, and shrubs along rights-of-way; by removing objects that are in themselves ugly; by restricting sign-board placing; and by a few other simple processes, a plain or a downright ugly road can be converted into a thing of lasting beauty.

Massachusetts, which started improving the beauty of its roads in 1921, frequently is pointed out as a model for other states. The State Department of Public Works has charge of the work. When a new road is built, it is made wide enough to permit landscaping. The maintenance division does the actual work. At Palmer is a state nursery for the propagation of trees and shrubs. This also is a training station for men who care for the plantings.

The first step in the work is the preservation of trees and plants already established. Maintenance men remove dead trees and cut stumps six inches below the ground, trim away dead or broken limbs, treat wounds by trimming and filling with tar, repair cavities by approved methods of tree surgery, and re-inforce split

Courtesy Massachusetts Department of Public Works

A group of birches bordering a New England road. Thinned out and trimmed, they increase the scenic value and do not obstruct the view

and weakened parts with cables. Undesirable branches, such as those which rub together, are removed. When advisable, trees are sprayed.

Vistas are developed by trimming away underbrush and removing obstructing trees. Roadside springs are cleaned and made usable. Seats are provided at convenient points, and rubbish barrels are placed at strategic positions.

In new planting, only domestic trees and shrubs are used. Gravel and sand slopes are a constant source of trouble because of water erosion. They are treated by planting small pines, sweet ferns, and other suitable vegetation. Whenever there is enough soil of the proper kind, grass or shrubs are planted. Extensive tree and shrub planting is confined to new roads 60 or more feet wide, so that there will be little or no subsequent widening operations to destroy the beauty. Shade trees are planted in groups, not in monotonous, military lines.

THE procedure followed in landscaping is systematic. After construction is complete, a man trained in landscape planning locates with colored pencils on a blueprint the positions of shrubs and trees. Stakes are then placed on the area being treated, to indicate the plan of digging. Dynamite is used for forming holes because it loosens the ground over a considerable area, and is about half as costly as manual or machine digging. High-grade soil is used to fill the pits. An order for planting material is sent to the nursery, and the supplies are delivered by trucks. After new shrubs are planted and well established, a final grubbing is carried out.

California considers both beauty and practical aspects of roadside improvement. Trees are planted; native wild ferns, shrubs, moss, trees, and flowers are preserved; and weed areas attacked. For utilitarian reasons, dry grass is burned, and obnoxious weeds such as the puncture vine, yellow star thistle, and mustard weed, are removed. The initial cost of tree planting is largely borne by civic and other groups, but maintenance is carried on by the state. Periodic watering of trees frequently is necessary.

Pennsylvania is one of the most recent converts to the idea of highway beauty. In 1928 a forestry unit, consisting of five trained foresters and three landscape architects, was created to act under the highway forester. Field men are located in eight state districts, and their duties are to plant and care for shade trees, plant slopes and evergreen snowbreaks, and create open views.

Courtesy State Road Department of Florida

Artificial aids to safe motoring such as these neatly constructed guard rails can also be made very attractive

Outside organizations have helped considerably since the work started, by providing trees and shrubs.

In general, the ideas used in the majority of states which give attention to highway beauty are similar. In Florida, however, the conception of beauty is somewhat different. This is largely because of the peculiar quality of Florida's semi-tropical scenery. Officials believe that the most beautiful landscape in the state consists of a well-paved road, with ditches and slopes planted in grass and carefully groomed, and with the characteristic Florida scenery forming a background on each side. Rubbish is kept cleared away, and planting of large trees and shrubs along the right-of-way is not encouraged.

It is pretty well agreed that there are few ways in which a greater return, dollar for dollar, can be obtained with public funds than by spending a little more for beautifying highways. Aside from the purely esthetic aspects of the work, roadside property values invariably are raised. A beautiful road creates a better sense of self respect in the community, and it favorably impresses the visitor who, besides bringing a measure of profit to local business when he is persuaded to linger, carries away for distribution to other places impressions which he gained in passing through.

Oriental plane trees seven years after planting. The planting of these was carefully done so that they took root firmly and but little further care was necessary

Planet X

By Henry Norris Russell, Ph.D.

Chairman of the Department of Astronomy and Director of the Observatory at Princeton University
Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

THE widespread and justified sensation caused by the discovery of the new major planet of our solar system will have passed long before these words will have reached America—much less see the light in print. But the discovery itself is so important and illustrates so well the methods of modern astronomy that it should not fail to be set out in order here.

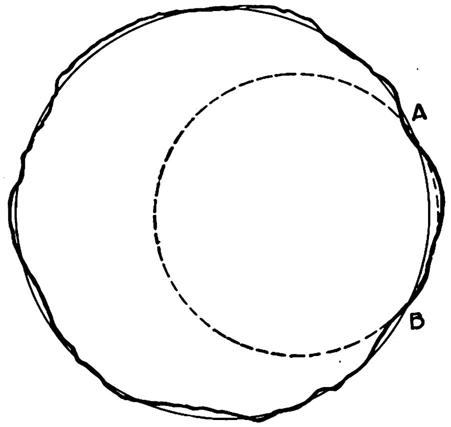
Everyone knows how the last great planet to be discovered was found. After Uranus had been known for half a century or more it was found to deviate from the orbit determined from the first 50 years of observations, after full allowance had been made for the attraction of the then known planets. Some unknown body must be pulling at it and this could only be a planet still farther from the sun. To calculate from the observed perturbations of Uranus' motion the orbit of the unknown planet which produced them was a very intricate matter. But the problem was solved by LeVerrier in France, and Adams in England, and the planet Neptune was found within a degree or so of the place in the heavens which these calculations pointed out.

Through all the 84 years since the discovery of Neptune until the present, the possibility that there was a still remoter planet has been realized, and now that it has been discovered the layman naturally may ask, "Why, if it was there all the time, did not the mathematicians tell us where to find it?" As a matter of fact they did, but through no fault of theirs their answer could not be as precise as it was for the earlier problem of Neptune.

To calculate the perturbations produced in the motion of one planet by the attraction of another is no small task, even when the orbits of both are accurately known in advance; and to work backward from the perturbations of a known planet to the orbit of an unknown one is much harder. But mathematical astronomers are used to hard problems and know how to solve this one. The worst difficulty is that to find the perturbations we must compare the observed positions of the known planet with those which it *would have had* if the unknown planet had not been attracted. To determine the latter is evidently difficult.

To see how it can be done let us ignore the attractions of the known planets (or suppose that, as in practice, their effects have been calculated and allowed for). We then know that, barring unknown influences, the planet should move in an exact ellipse about the sun in accordance with Kepler's familiar laws. What the size and shape of this ellipse may be can be found only by observing the planet. If no extraneous forces are acting, the planet will follow the same ellipse time after time, but if an unknown planet is perturbing it the tracks in the second and subsequent revolution will not be quite the same and the differences will reveal the amount and nature of the perturbations.

It is not actually necessary to wait quite so long. When a planet has been well observed half around its orbit its motion along the other half can be predicted closely enough to reveal any considerable disturbances after it has been followed in this half as well. But something like a full revolution around the sun is really necessary. With observations covering only half the orbit or less, it is possible to find a "fictitious orbit" such that a planet moving in it without perturbations (save by the attractions of known bodies) will, *over the given interval of time*, always be very near the real planet—subject though it is to additional perturbations, and though in earlier or later years this will not be true.



Why it is easy to go wrong in the prediction of planets—see the text

It may help to understand this to imagine a circular hoop which has been bent and battered a little out of shape (see drawing). If we can see the whole hoop or half a photograph of it it is easy enough to strike a true circle which follows its general course, and then find the amount of the deformations from point to point. But if our photograph covers but a small part of the hoop and we try to fit a circle to it as best we can, we may draw it too large or too small, according as this particular part of the hoop has been flattened or bent too sharply.

The heavy line in the drawing represents a battered hoop which in a rough way illustrates a perturbed orbit. The circle represents the hoop before it was deformed, or the unperturbed orbit. But if we knew only the part AB of the hoop we would suppose that the whole was like the dotted circle and would greatly underestimate the amount, and sometimes even the direction, in which this portion had been bent out of shape. In quite the same way we can not get any accurate idea of the perturbations of a planet unless we have observations extending pretty well around the orbit.

Now since its discovery in 1846 Neptune has been only half way around its orbit and it is therefore practically valueless for locating an outer planet by means of its perturbations. Uranus has completed two revolutions since its discovery and is fully available, but it is nearer the sun and farther from the trans-Neptunian planet and the perturbations to be anticipated are therefore small.

Several investigators have examined the question, the most comprehensive work being probably that of the late Dr. Percival Lowell which was published in 1914 but commenced more than a decade earlier. A careful mathematical investigation indicated the existence of small perturbations just within the limit of detection, and indicated that the unknown planet which produced them must be either in the direction of the constellation Gemini or just on the opposite side of the sun. The perturbations produced by planets in these two positions were so much alike that no decisive choice between the two could be made.

Lowell estimated the new planet's distance from the sun as 43 to 44.7 astronomical units (see illustration, page 22, section 9, *a'* and *a'*.—*Ed.*)—half as much again as Neptune's—and its mass as 1/50,000th that of the sun, six times the earth's, but only one third of that of Uranus or Neptune.

Accepting these conclusions the next question was, how to find the planet. Being less massive than Neptune it was doubtless smaller, and being far from the sun it must be faintly illuminated and far from conspicuous. Lowell estimated its probable brightness as from the 12th to the 13th magnitude (see illustration, page 22, section 10—*Ed.*). It is hopeless to search for such an object visually among the multitudes of stars and the only chance of success is by photography, employing substantially the same methods as have been proved so successful in finding asteroids; that is, the careful comparison of suitably duplicated plates of the same star fields.

Giving an idea of modern mathematical planet predicting—a typical page from Lowell's original prediction of 1914. There are many pages like this

A great deal of time and labor was thus spent by Dr. Lowell and his successors at the observatory which he founded at Flagstaff, Arizona, and which bears his name. In time it became clear that the distant planet was probably fainter than the original estimate, which in the nature of the case could only be very rough, and that a very powerful instrument would be required to find it. A gift from the President of Harvard, Percival Lowell's younger brother, provided an admirable instrument. It possesses a triple objective of 13 inches aperture which gives sharp star images over a wide field, and is withal very rapid.

THE new Lawrence Lowell telescope within a year of its installation has brought the long-sought planet to light. Photographs of moderate exposure covering the whole region of the heavens around the predicted position were obtained and on one of them, taken on January 21, 1930, Mr. Tombaugh of the observatory staff found "a very promising object." It was identified from its motion past the numerous fixed stars as revealed on plates of the same star field while being compared under the blink comparator. This showed that one faint star among many thousands had shifted its place by a certain expected order of distance, in the interval between the taking of the two plates. Since that date it has been carefully followed both photographically by Dr. Lampland with the 40-inch reflector and visually by E. C. Slipher and other members of the staff. Its motion in the heavens has been just what might be expected of a trans-Neptunian planet at about the distance anticipated by Lowell, and its longitude agrees closely with his predictions. There is no doubt that it is actually a new major planet much farther away than any which has previously been known.

This admirable discovery comes to the astronomers at Flagstaff as a reward of years of skillful development of methods and patient work. It is most gratifying that this long and devoted search has been crowned with full success, though we must all regret that the originator and inspirer of the campaign did not live to witness its triumphant close.

What of the new planet itself? Full knowledge comparable to that which we have regarding the other planets of our system can come only after years of further work. For example, it will be a long time before its orbit is accurately known. A fairly good orbit of a rapidly moving asteroid can be derived from three good observations separated by intervals of a week or so. For this slowly moving body intervals of a couple of months will be desirable. Before it was lost in the light of the sun, which happened in May, sufficient data to give a good preliminary orbit which will tell us where to look for the planet at the end of summer when it can again be observed, was worked out and published (April 12). Next year's observations will permit a considerably better determination; and so on.

Even after a decade, however, we will have observations covering only a very small fraction of the orbit and will still be somewhat in the position of having to determine the course of a whole circle from a small arc. It may happen that, calculating backward, the images of the planet can be found on photographs taken years before it was discovered, though it is so faint that the chance is not very good. And in this case the arc available for determining the orbit, and the calculated results, may be increased. At this early date we can be certain only that the planet is near the ecliptic, that it is moving around the sun in the same direction as the other planets, and that the inclination of its orbit plane, while greater than the other planets, as Lowell predicted (section 11.—*Ed.*) is not extremely great. The general agreement of its apparent motion with that calculated with Lowell's estimated distance of 43 to 44.7 astronomical units shows, however, that this prediction is near the truth.

Adopting provisionally this distance, which is 50 percent greater than Neptune's, what else can now be said about the planet? Its diameter must be rather small. With the 24-inch refractor at Flagstaff the planet appears as a faint stellar point and shows no sensible disk.

IF it were really as much as 10,000 miles in diameter it would show an apparent disk of 0".5, which the experienced observers who have examined it hardly could have missed under favorable conditions. We may conclude with some confidence therefore that the new planet is little if at all larger than our earth—provided, to be sure, that the estimate of its distance here adopted is correct.

Further evidence that the planet is a small one is found in its faintness. The assigned magnitude, about 15.5, is photographic. If it is of the average color of the inner planets it should be about a magnitude brighter visually than photographically, and we may base our estimates on a visual magnitude of 14 or 14.7. This makes the planet only about 1/250th as bright, apparently, as Neptune. If Neptune could be removed to this greater distance it would look only 1/5 as bright as it does now, but even so it would outshine Planet X fifty-fold. This suggests that the diameter of the new planet is about 1/7 that of Neptune, or a little less than 3000 miles. This estimate, however, may be too small, for Neptune has the highest superficial reflecting power, or albedo, of any of the planets and a planet of lower albedo would have to be larger to reflect the same amount of light. To go to the opposite extreme we may take for comparison the moon which has about the lowest known albedo. A simple calculation shows that if removed to a distance of 45 astronomical units from us and from the sun, she would appear as a star of visual magnitude 17. Planet

X appears three magnitudes or 16 times brighter, which on this hypothesis regarding its surface brightness makes its diameter four times that of the moon, or 8600 miles. It is probable that the truth lies between these two estimates, but little more can be said for there are very great differences of albedo even among the atmosphereless asteroids, and we have no means of estimating more closely what value we should use for the new planet. It may be considered, nevertheless, that it is fairly comparable in size with the four inner planets of our system, and much smaller than the four outer ones which were previously known.

The planet's mass can probably be determined at least roughly from the perturbations it produces in Uranus and Neptune when once its orbit is accurately known. The latter statement may seem inconsistent with what has already been said, but the problem here is not quite the same as before. Suppose that, in the drawing, we knew the direction in which the wavy line deviated from the circle at each point and the relative though not the absolute amounts of these deviations. We would then have much less latitude in drawing our theoretical circle than before, and could be fairly sure of its position in cases which before were hopeless, as explained on page 20.

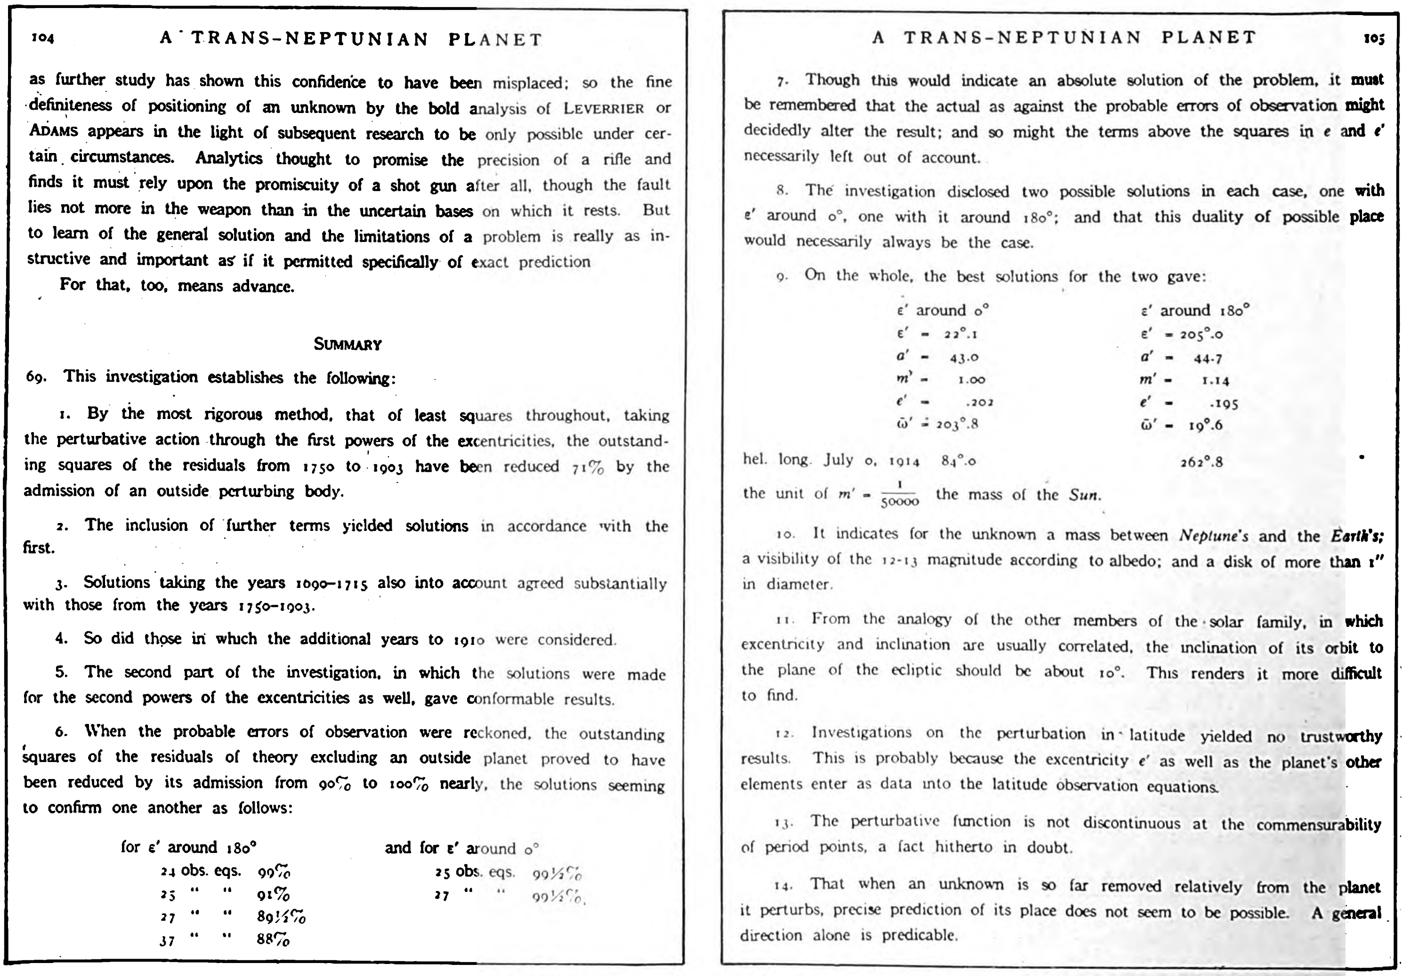
Percival Lowell

A planet less than 10,000 miles in diameter would be very unlikely to have a mass 1/50,000 that of our sun (section 9.—*Ed.*) for this would demand a mean density about 17 times that of water. The earth's mass is only 1/330,000th of the sun's, and if Planet X is no more massive it is hard to see how its attraction could produce the effects studied by Lowell. This discrepancy would be diminished if the planet's distance from the sun should turn out to be greater, but it is premature to discuss the matter further at present, without more dependable data.

The only hope of learning anything about the rotation of the new planet is by photometric means. If, like many of the asteroids, it should show regular periodic changes in brightness, these would reveal the rotation. But for so faint an object, the observations would be difficult.

Finally, there is little hope of detecting a satellite of the planet unless, like our moon, it should be almost comparable in size with its primary. Nevertheless it is probable that photographs will be made with the great reflectors, in order to investigate.

In conclusion, two tributes must be paid where honor is due: First, to the skill, assiduity, and devotion of the workers at the Lowell Observatory who have made this important discovery; and second, to the memory of Percival Lowell, traveler, man of letters and affairs, and observer of the planets. He did many things in the course of a crowded life and did them well. The mathematical researches took him outside his other fields of work and into a region full of traps for the unwary, yet the discovery of this new planet has justified him by his works despite the doubts of many of his contemporaries. His fame bids fair to increase as the years pass on.—*Athens, Greece.*



as further study has shown this confidence to have been misplaced; so the fine definiteness of positioning of an unknown by the bold analysis of LEVERRIER or ADAMS appears in the light of subsequent research to be only possible under certain circumstances. Analytics thought to promise the precision of a rifle and finds it must rely upon the promiscuity of a shot gun after all, though the fault lies not more in the weapon than in the uncertain bases on which it rests. But to learn of the general solution and the limitations of a problem is really as instructive and important as if it permitted specifically of exact prediction

For that, too, means advance.

SUMMARY

69. This investigation establishes the following:

1. By the most rigorous method, that of least squares throughout, taking the perturbative action through the first powers of the excentricities, the outstanding squares of the residuals from 1750 to 1903 have been reduced 71% by the admission of an outside perturbing body.

2. The inclusion of further terms yielded solutions in accordance with the first.

3. Solutions taking the years 1690–1715 also into account agreed substantially with those from the years 1750–1903.

4. So did those in which the additional years to 1910 were considered.

5. The second part of the investigation, in which the solutions were made for the second powers of the excentricities as well, gave conformable results.

6. When the probable errors of observation were reckoned, the outstanding squares of the residuals of theory excluding an outside planet proved to have been reduced by its admission from 90% to 100% nearly, the solutions seeming to confirm one another as follows:

for ε' around 180°		and for ε' around 0°	
24 obs. eqs.	99%	25 obs. eqs.	99½%
25 " "	91%	27 " "	99½%.
27 " "	89½%		
37 " "	88%		

7. Though this would indicate an absolute solution of the problem, it must be remembered that the actual as against the probable errors of observation might decidedly alter the result; and so might the terms above the squares in e and e' necessarily left out of account.

8. The investigation disclosed two possible solutions in each case, one with ε' around 0°, one with it around 180°; and that this duality of possible place would necessarily always be the case.

9. On the whole, the best solutions for the two gave:

	ε' around 0°	ε' around 180°
	$\varepsilon' = 22°.1$	$\varepsilon' = 205°.0$
	$a' = 43.0$	$a' = 44.7$
	$m' = 1.00$	$m' = 1.14$
	$e' = .202$	$e' = .195$
	$\bar{\omega}' = 203°.8$	$\bar{\omega}' = 19°.6$
hel. long. July 0, 1914	84°.0	262°.8

the unit of $m' = \frac{1}{50000}$ the mass of the *Sun*.

10. It indicates for the unknown a mass between *Neptune's* and the *Earth's*; a visibility of the 12-13 magnitude according to albedo; and a disk of more than 1″ in diameter.

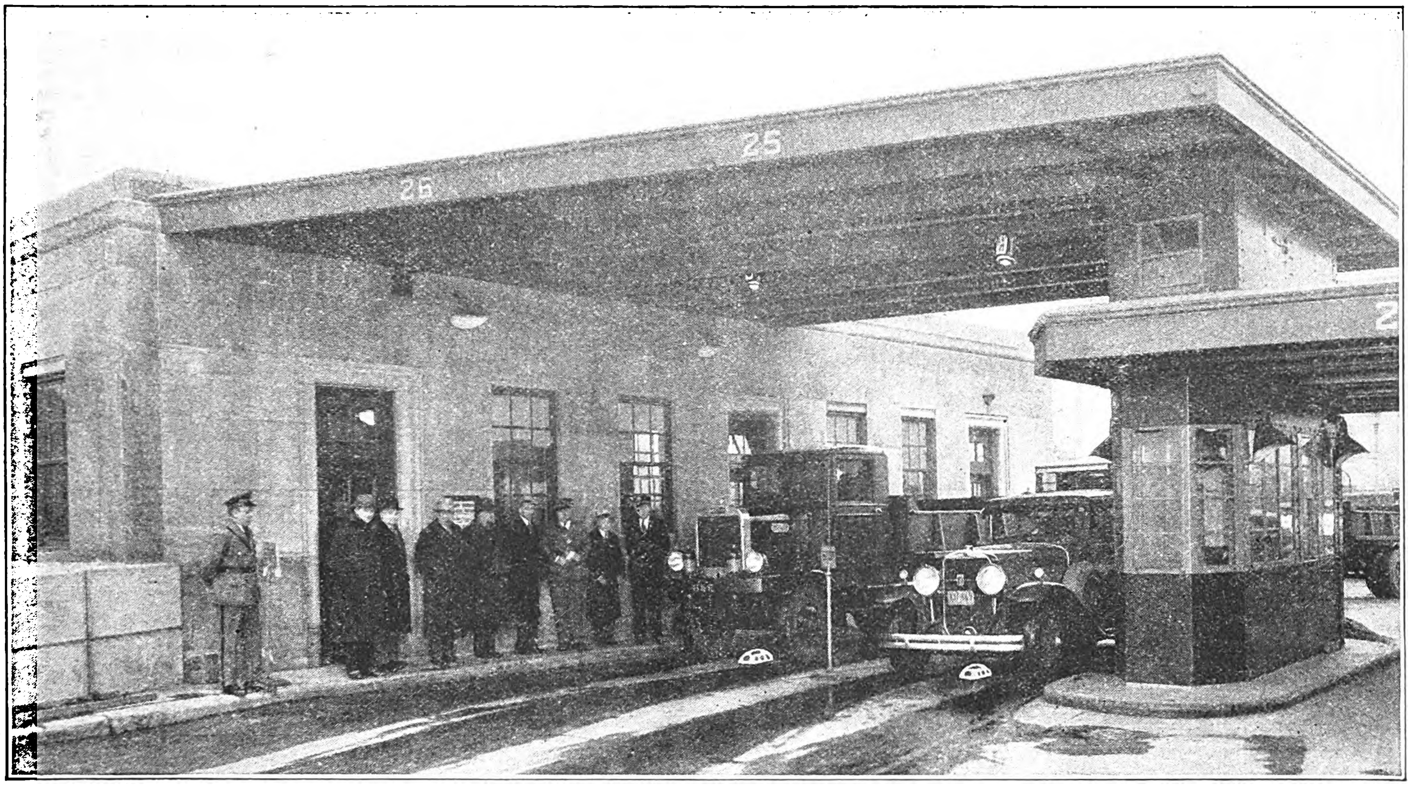
11. From the analogy of the other members of the solar family, in which excentricity and inclination are usually correlated, the inclination of its orbit to the plane of the ecliptic should be about 10°. This renders it more difficult to find.

12. Investigations on the perturbation in latitude yielded no trustworthy results. This is probably because the excentricity e' as well as the planet's other elements enter as data into the latitude observation equations.

13. The perturbative function is not discontinuous at the commensurability of period points, a fact hitherto in doubt.

14. That when an unknown is so far removed relatively from the planet it perturbs, precise prediction of its place does not seem to be possible. A general direction alone is predicable.

A photographic reproduction of the final two pages—the summary—of Lowell's original prediction, published 1914 as Memoir No. 1, Volume 1, of Lowell Observatory. Forgotten by the world, it never was forgotten by the persistent Lowell Observatory Staff. Copies of the original memoir are now very rare



A toll house showing photoelectric cells in roadbed and lights overhead

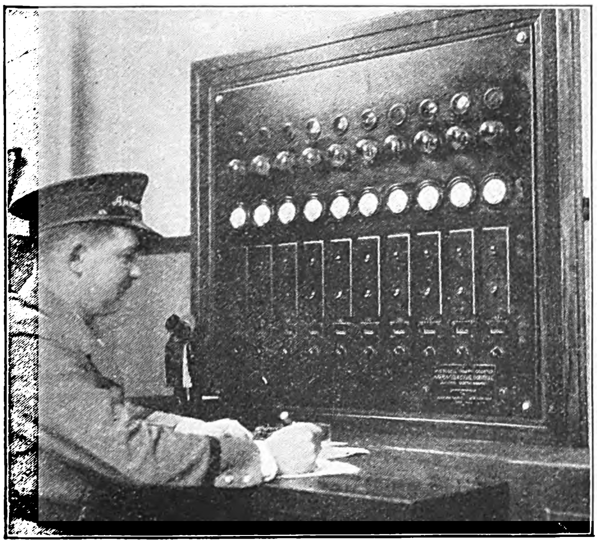
Light Counts Cars on Bridge

THE task of checking and controlling traffic over the longest span bridge in the world is being accomplished by means of photoelectric cells and light beams. The man who superintends traffic control on the new Ambassador Bridge over the Detroit River at Detroit can tell, by glancing at his control board far from the scene of operations, which traffic lanes are in operation, whether the density of traffic warrants the use of more or fewer lanes, and whether the vehicles are being cleared over the bridge efficiently. The system was devised and installed by Benjamin Cooper, a consulting engineer of New York City.

A photoelectric cell is imbedded in each of the 10 lanes provided for incoming traffic, at the point where cars must stop for payment of tolls. While the car is stopped, it intercepts a beam of light from a source in the ceiling of the toll shed. This interception causes the cell to function and it, in turn, causes a magnetic counter to register a count and also causes an indicator light to go out.

The frequency with which the indicator lamp goes on and off shows the traffic density for a particular lane. At the end of a working period, the number of tolls recorded by the cash registers must check with the count shown by the cell-operated registers.

The wires that are connected to the photoelectric cells are carefully shielded from all external electrical disturbances and carried underground to the operating panel located in the toll supervisor's office. The cells are so located in the roadbed as to minimize the effect of mechanical vibration due to passing vehicles, and so shielded as not to be interfered with by outside lights. This task of protecting the cells was particularly difficult because they are in the open and because the current through them is rated in millionths of an ampere.



The toll supervisor sits before the panel-board in his office hundreds of feet from the toll sheds and keeps close tab on the movement of traffic

Water Runs From Marathon to Athens

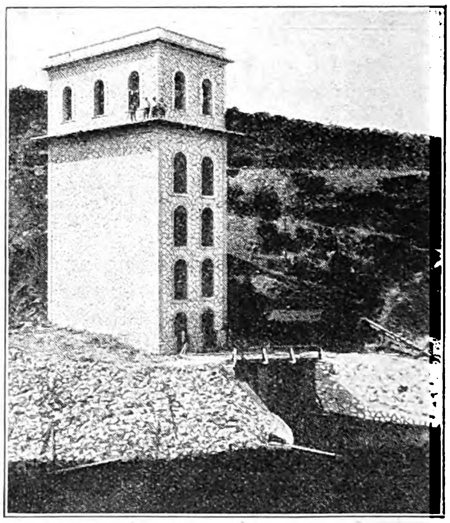
By F. D. McHugh

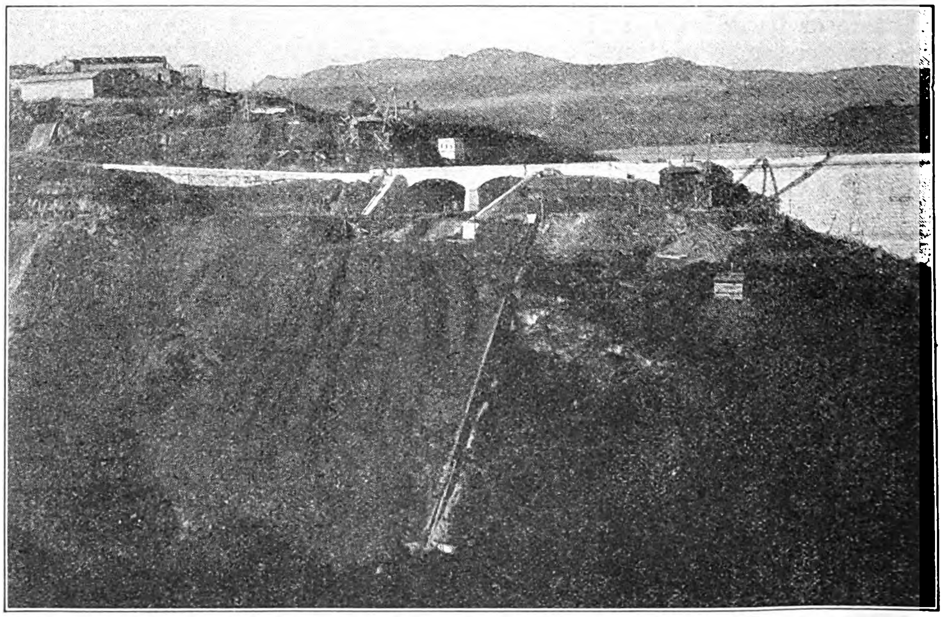
ABOUT four miles from the plains of Marathon where, in 490 B.C., the combined forces of Athenians and Plataeans numbering perhaps 10,000, won a decisive and famous victory over an invading force of approximately 50,000 Persians, a celebration of unusual importance took place last October in the presence of a large gathering including the Greek President, the Premier, and other notables. The occasion was the dedication of the Marathon Dam, construction of which had just been completed by Ulen and Company, an American engineering firm.

AS dams go, this new one presents no striking departure in construction, and in respect to size, it is far from outstanding. Its bid for fame rests upon the facts that it is practically a mass of marble, that water from it is carried through a 1900-year-old aqueduct, that it is situated in a region rich in historical associations, and that it is an important part of a very important project. Its completion marks the first big step of a plan, costing upwards of 11,000,000 dollars, to solve the age-old problem of providing an adequate supply of water for the city of Athens and environs.

One of the oldest cities of the world, Athens has been sorely pressed for water since its foundation on the sacred rock in 1259 B.C. So dry, in fact, has the Attic region always been that Aristophanes, Strabon, and Pausanias commented upon it in their writings. During Athens' early days, local springs, like the Kalirhoe with its nine spouts (Enneakrounos) and wells like the Klepsydra on the Acropolis, formed the only source of water supply. In time, the underground waters of Mount Hymettus were carried in subterranean aqueducts to the city. Yet the supply was still inadequate for, in 594 B.C., Solon found it necessary to enact strict laws regulating its use.

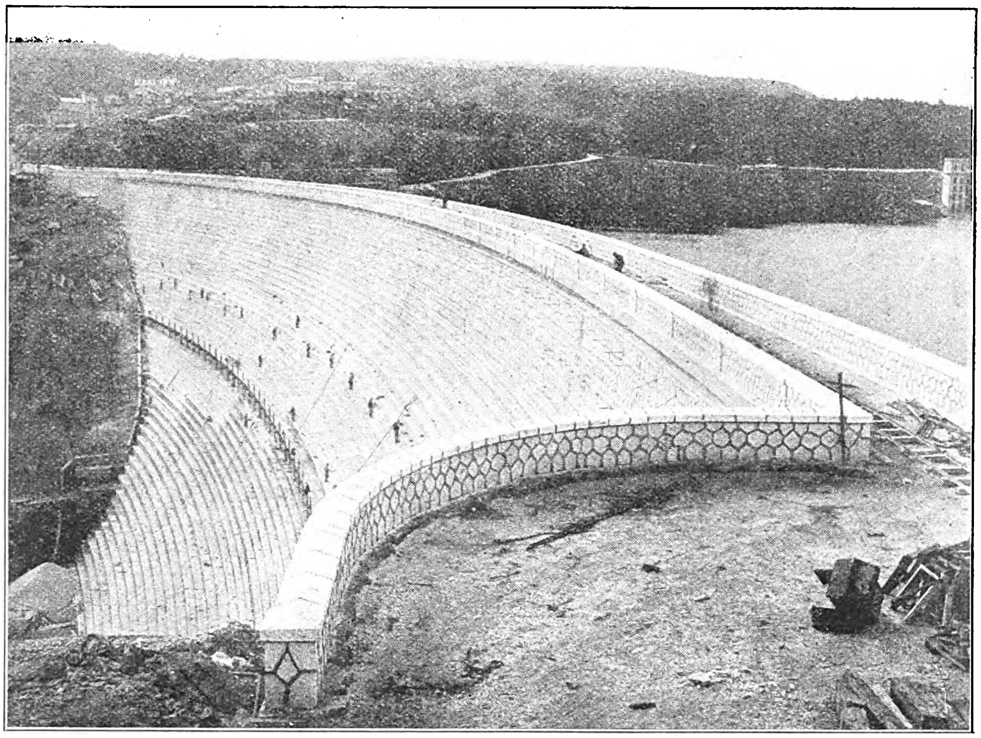
With the decline of ancient Greece, the Romans tackled the problem and solved it by constructing the famous Hadrian Aqueduct about 115-130 A.D. This





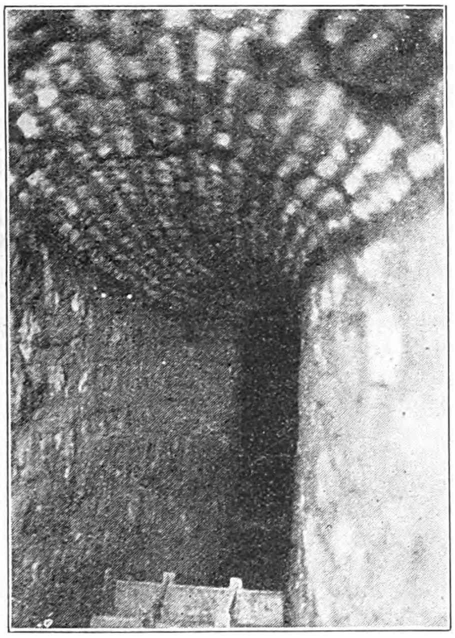
The intake tower to the water tunnel is shown in the upper illustration and in the lower one which also shows the south approach to the dam's crest

Downstream face of dam from north end showing intake tower to tunnel at extreme right and men giving the marble a final cleaning

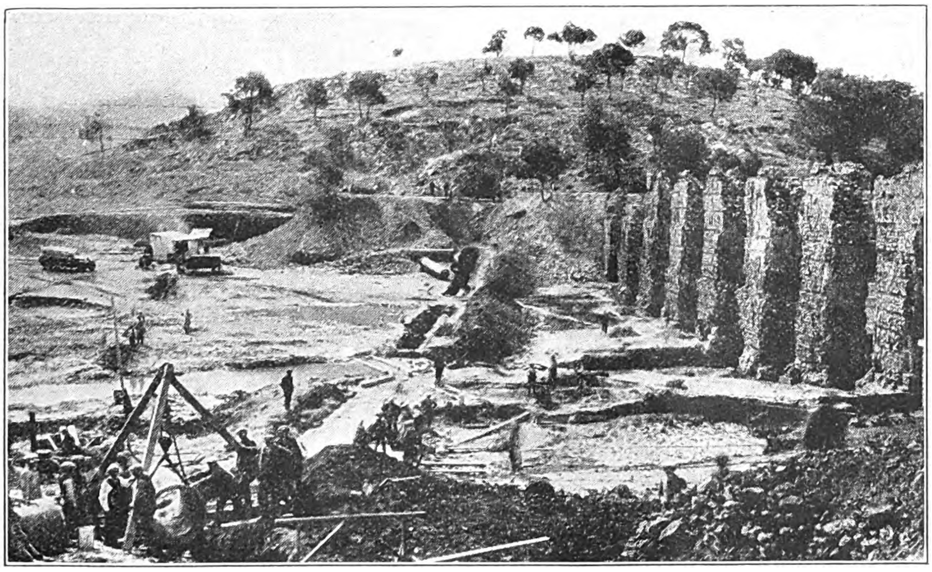


system brought water from the Pentelicon and Parnes ranges and for centuries the supply was adequate. Invasions of Goths, Vandals, and Slavs then came one after the other, and finally the country was occupied by the Turks. Amid the confusion caused by these disturbances, the aqueduct began to crumble, gradually fell into disuse, and was forgotten. Rediscovered in 1840 it was repaired and became the city's chief source of supply.

With the destruction of Smyrna in 1922 by the Turks and the driving of all Greek nationals from the territory, refugees crowded into Athens. As its population of 300,000 increased almost overnight to 800,000, the question of water supply again became acute. The government at once began consideration of various schemes and the "Marathon Project" was finally decided upon. Of this project, the Marathon Dam is the major part. Its water will flow by gravity to a storage reservoir on the Attic Plain near Athens and will be distributed from there. A secondary and separate part of the scheme is the 23½-mile pipe line through which sea water is pumped from historic Phaleron Bay for sprinkling the streets. The use of this salt water makes available more than 130,000 gallons of potable water daily—water which was formerly used for street sprinkling. Rehabilitation of existing systems was included in the provisional contract which the Hellenic Republic signed, work on which has now been completed and accepted by the government. It is expected that the entire scheme will be complete in 1931.



◂ Interior view of ancient Hadrian Aqueduct, repaired and enlarged



▾ Laying 36-inch siphon line to Athens. Ruins of the old Roman aqueduct may be seen at right

The Marathon Dam is a gravity section structure but was built on an arc radius of 1312 feet, is 174 feet high and almost 1000 feet wide along its crest. A spillway for the overflow was cut into the hill at the south end, and through its base are pipes for completely draining the lake.

WORK was begun in January, 1927, and the first concrete poured 11 months later. As has been noted, no extraordinary engineering problem was presented, but the material used in the dam is unusual. It is faced, on both the upstream and downstream sides, with Pentelic marble from the quarries nearby from which marble was taken for the famous buildings and sculptures of ancient Greece. This facing is laid in a beautiful mosaic of marble blocks in cement mortar so that the effect is very nearly that of a giant honeycomb. It is said to be the only mosaic marble-faced dam in the world. Even the sand and aggregates used in the concrete filling were ground from the same marble.

The old Hadrian Aqueduct was enlarged and repaired at several places for carrying water in this new system, and portions were extended to carry a supplemental supply.

The Pilot 'Phones His Airport Via Radio

By Harold Crary

Edmund T. Allen, who tells here of a pilot's experience with radio in an airplane

THE urgent need for radio equipment on aircraft has long been recognized by authorities in the air transportation business. With larger patronage of airmail and express, and demand for rigid adherence to schedules—and uncertain or bad weather is the chief foe of schedules—and with rapid branching out into passenger-carrying activities, the operators bend every energy to get workable radiophone equipment.

In the past, it has been necessary for the pilot to take off and fly into weather about which he knew practically nothing because it was constantly changing. Also the management was completely out of touch with the craft until it appeared at the terminal field or was forced to return due to the bad weather. If the airplane did not appear after a reasonable time had elapsed, a search had to be organized to comb the country for hundreds of miles to locate the scene of the forced landing.

Now several leading lines have authorized expenditures for necessary ground radiophone stations, hiring of operating personnel, and installation of equipment in the planes. Of these lines, the Boeing System carries passengers as well as mail, and its large-scale operations made it necessary to utilize every known aid to aircraft. Consequently it worked vigorously to perfect the radiophone. The initial use of the radiophone leads to the following positive conclusions as to its benefits:

It adds much to the safety of flying; reduces number of emergency landings due to uncertainty as to weather ahead; enables pilots on regular routes to complete a larger number of scheduled trips on time; and increases the pay load of mail, express, and passengers by reducing the amount of excess gasoline now carried to give the pilot ample cruising radius when he is uncertain as to weather. The radiophone is also of considerable value in dispatching planes and giving orders to pilots in the air.

Edmund T. Allen, whose 6000 hours in the air have included 4000 hours with the airmail, both night and day flying, on the transcontinental route, describes talking to a radio telephone station 150 miles away and several thousand feet "down" in this way:

" 'HELLO, Ed!' It is the voice of the Boeing superintendent in my ear phones. 'We have 1100-foot ceiling over the airport. Visibility five miles, barometer slightly below normal, but steady; no change in 30 minutes. Where are you?'

" 'Thirty miles out and making 115 miles per hour ground speed. How's the weather half way between here and there?'

" 'Same as here,' he answers. 'Fog begins at Summit and ceiling rises as mountains drop away. You are five miles south of the course. We will send up a yellow parachute flare when you arrive within three miles of us. What is the altitude at the top of the cloud layer?'

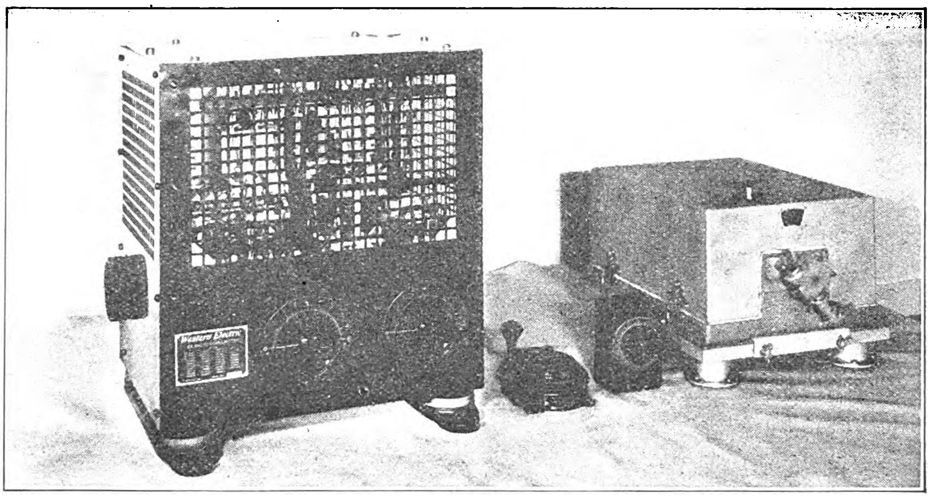
" 'Eighty-eight hundred,' I tell him. 'That gives 1500 feet thickness. Will arrive about 9:13. Shoot rocket at 9:11. Send it vertical to give me exact location. I will jazz my motor on the way down. Listen for it and tell me if I am overshooting. Where is the second section?'

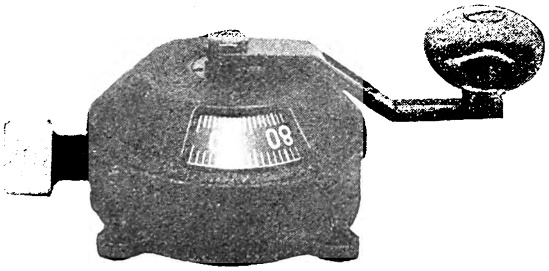
" 'John is 70 minutes behind you and is still talking with the other terminal. First section of the west-bound is due about same time as you are. Have instructed him to slow down and stay away from the airport until you are down and we tell him to come in. You are still a little south of the course. Five degrees more to the left ought to bring you right over us.' "

When asked how important he regarded the radio telephone, Allen said, "Instead of flying into the unknown and meeting shifting weather con-

Passengers who board this 18-passenger tri-motored plane, operating on a 20-hour schedule between Chicago and San Francisco, know that their pilot will have continuous radio communication with ground stations ditions single handed and without adequate information, the pilot will be maintaining uninterrupted contact with the broadcast voice of the radio.

"He may, for example, speak into the mouthpiece which unobtrusively rides in front of his lips: 'Calling Cheyenne Boeing Station—Number 12 reporting passing Elk Mountain point 106. Fog and snow coming in across course from Medicine Bow range. Fog forming along Union Pacific tracks in Rock River sector. Looks clear to north. Ceiling here 1500 feet, visibility five miles. Snow blowing on ground so badly weather station may say zero ceiling and visibility. What is weather in Laramie? Would you advise crossing Sherman Mountains north of the course and coming into Cheyenne from north?' And instantly comes a detailed answer to all his questions through his ear phones."

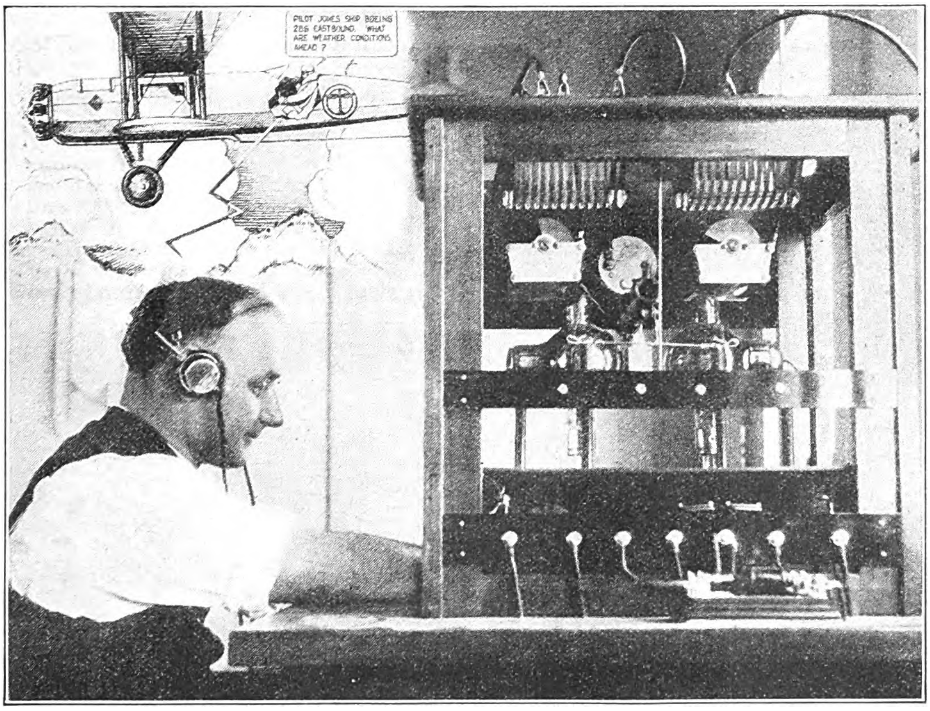




Above: The radio equipment that is installed on a plane. From left to right is the transmitter, tuning instruments, and receiver. _Left:_ The tuner. The knob can be operated even with heavy gloves on

ON one of the occasions when Lindbergh jumped from his airmail plane near Chicago after attempting to find the Chicago airport through the clouds, the field crew heard his motor overhead and knew that if they could but talk to the pilot, they could have brought him in as easily as a passenger train is threaded through the switching yards to the terminal station.

For the pilot, the operation and mechanism of the new radiophone are nearly automatic. He speaks in a normal voice and listens to the reply without the intervention of a radio operator aboard to give him the messages second hand. He can easily control the loudness of either the radio beacon signal or the voice reception as he comes nearer the station, or he can listen to both at the same time, making one or the other louder, as he desires. Boeing pilots have received clearly at 200 miles from the control station and 12,000 feet altitude, and even greater range is expected.



PILOT JONES SHIP BOEING 286 EASTBOUND. WHAT ARE WEATHER CONDITIONS AHEAD ?

There are 14 ground stations, such as this one, between Chicago and San Francisco. The pilots are never more than 100 miles distant from one of them

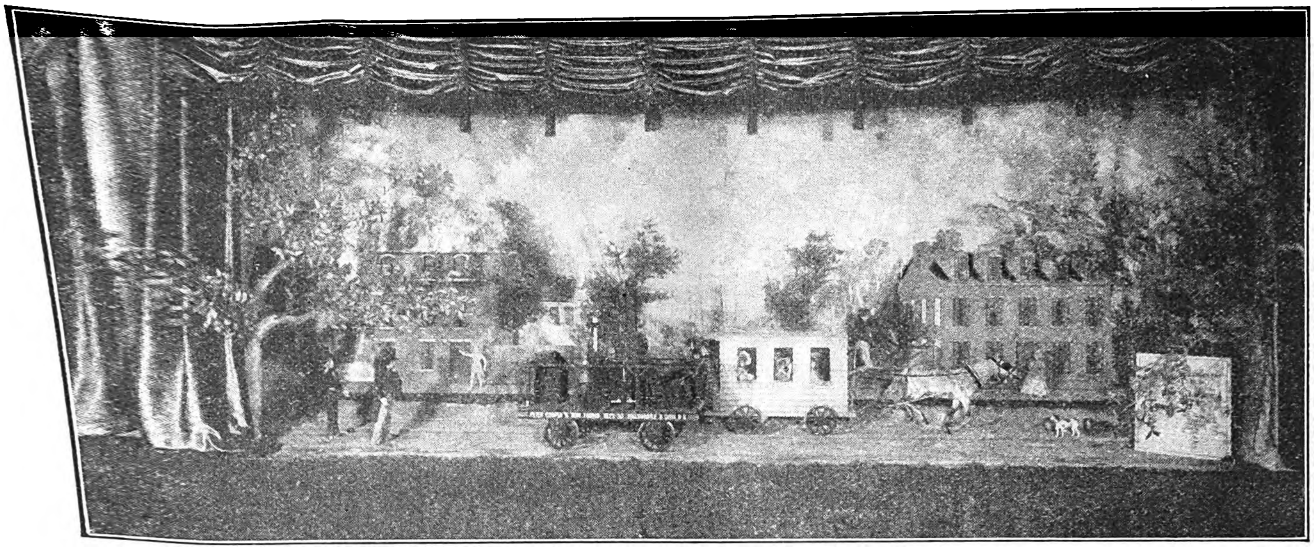
Since the equipment requires no careful adjusting on the part of the pilot, his full attention can be directed to the operation of his engine and keeping the airplane on its course. Added weight and space, which would be necessary for a special radio operator on the plane, ruled out any apparatus requiring expert manipulation in flight or the services of a special operator.

In the equipment, radio cases are mounted behind the pilot with remote controls on the instrument board. With a single throw of a switch, the pilot can change from transmission to reception. All that is required then, is for him to talk into the microphone mounted on his helmet directly in front of his lips.

TINY, soft rubber plugs, with "phonettes" attached, fit comfortably in his ears and are connected to the receiver with a fine silk cord. Thus, the pilot, if flying through a snowstorm where constant vigilance is required, will have to give no thought to the radio apparatus.

Now the United States can lay claim to the longest line in the world giving night and day passenger service, with planes having voice communication with the ground and with other planes in flight. In Europe, most of the radio sets require an operator using the Morse code. In the setup discussed here, the pilot simply talks to the nearest ground station, of which there are 14 between San Francisco and Chicago and nine between Los Angeles and Seattle. Either night or day, over plain or mountain, the pilots of the eight-ton passenger transports now place reliance on instructions 'phoned up from the ground station by men who, with the aid of reports received from weather observers on and off the line, can tell the pilot what kind of weather he will run into before he gets to the terminal port.

¶ *A coming article will describe how archeologists, under the direction of Mussolini, have found ancient Roman buildings by tearing out the walls of modern structures.*



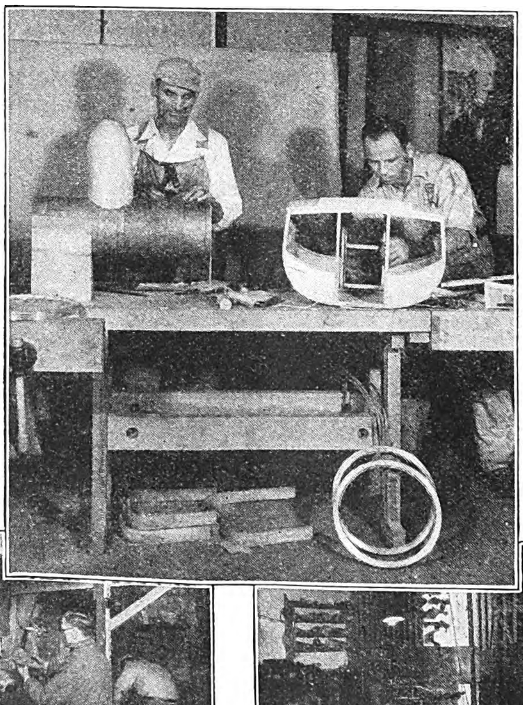
This tableau depicts the famous race between the "Tom Thumb" locomotive and the old gray mare drawing a single coach. The race took place between Baltimore and Ellicott's Mills on August 30, 1830. The rails are made of wood faced with steel. The costumes of the eight men and eight women are accurate to the last button. The horse won owing to "belt failure"

A World in Miniature

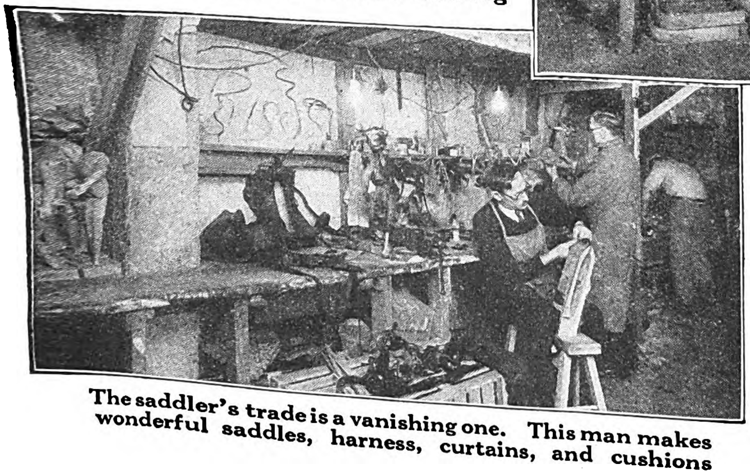
WAY down in "Chelsea Village," New York City, in an old armory is a shop which would be the delight of both the museum director and the child. Here are made camels that almost walk, monkeys that play cards—and cheat, dogs that fight for bologna links, and dolls nine feet tall. Who requires such peculiar merchandise? Department stores, pageants, fairs, children's barber shops, and dozens of others. This shop was an important factor in the "Iron Horse Fair." Here is made anything in papier mache, wood, or metal, which can be endowed with motion. We were recently invited to inspect a series of eleven miniature groups illustrating the history of transportation which were made at an expense of 150,000 dollars. The time required was one year, eight months.

We were particularly struck with the rare fidelity with which detail was handled. Think of trying to get fabrics for diminutive men's clothing and women's dresses of the period of 1830. Ancient "deposits" of textiles were uncovered and utilized. The literature of transportation and every avenue of knowledge was put under contribution, and the result is so worth while that we are presenting a series of illustrations showing how it was done.

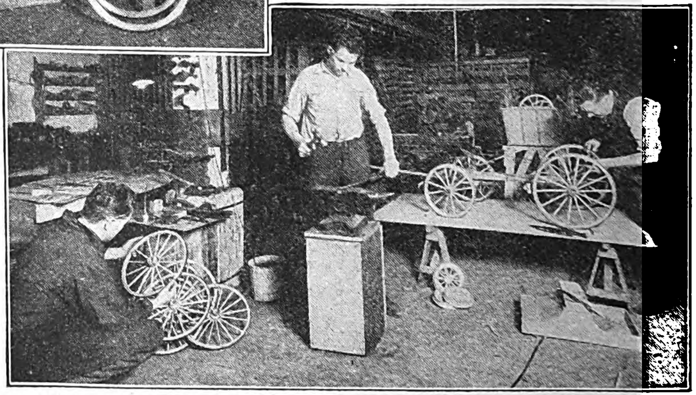
The groups are 12 feet long and six feet deep, just right size for a show window. The "ground" is a rubber composition which cannot be damaged by rolling. The whole series of groups can be packed in special water-proof cases. They can all be transported on a trailer 23½ feet long, 7 feet wide by 7 feet high, inside measurements. The groups are intended for exhibition in stores, automobile salerooms, and other places where an educational exhibit is deemed worth while. The groups are so expensive to fabricate that they could hardly be purchased, except by museums. A "Deadwood" coach would cost 5000



Coach makers and boiler makers are plying their respective trades. The coach is a marvel of skill and patience. Every cushion is beautifully fashioned and the springs are accurate reductions. Every rivet in the *DeWitt Clinton* is real

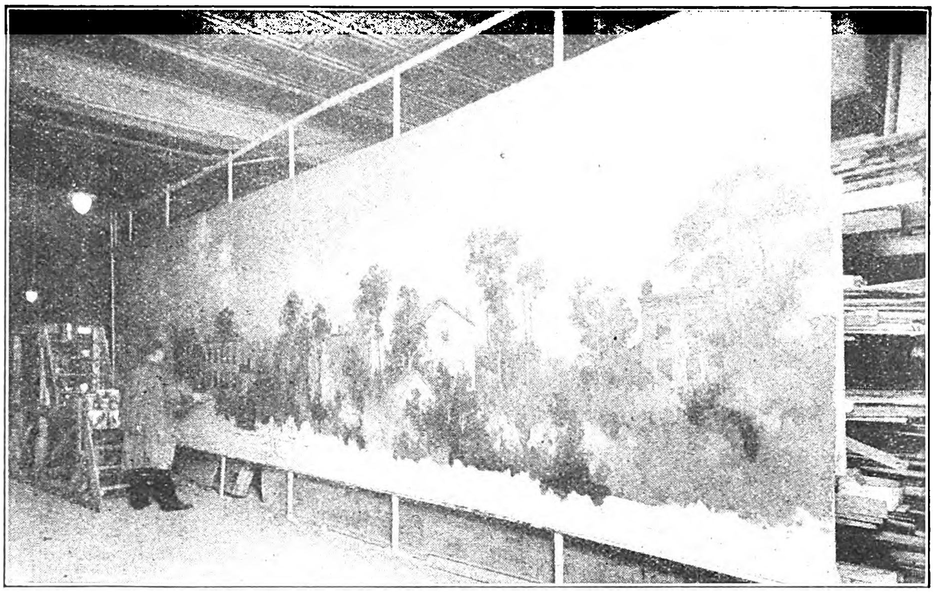


The saddler's trade is a vanishing one. This man makes wonderful saddles, harness, curtains, and cushions



The wheelwrights are on the job making miniature coach and wagon wheels as well as the running gear dollars and the *DeWitt Clinton* locomotive as much more.

The groups of this particular exhibition are as follows: The Indian Pony Drag, the Conestoga wagon (this great prairie schooner passed its 100th birthday a few weeks ago), Fulton's *Clermont*, the *Tom Thumb* locomotive on the Baltimore and Ohio Railroad, the *DeWitt Clinton* locomotive, the Deadwood Coach, the Pony Express with Buffalo Bill, Lincoln in his carriage, the race betwen the *Natchez* and the *Robert E. Lee*, the Selden automobile, the Wright airplane at Kitty Hawk.



The scenic artist is painting the background for one of the scenes. It is a compromise art between easel picture painting and scene painting. The handling of the various backgrounds helps along the illusion of reality

THE backgrounds were painted by real artists, the designs being made by Mr. Joseph Damon of Messmore and Damon, whose unique shop we are illustrating. Then began the correlation of industries and trades some of which are all but extinct. The coach maker used the care that was expended on a Brewster body. Every bolt and nut and every cushion was reproduced with absolute fidelity. The coppersmith made the boiler for the *DeWitt Clinton*, reproducing every rivet. When the tender was being made, it was found that the floor had been made with the rivets in the frame parallel instead of staggered as they should be. *Crash!* it went into the brass junk barrel and a new one was made with the rivets properly disposed. Probably only two or three persons in the United States, amateur model makers, would have noticed the difference.

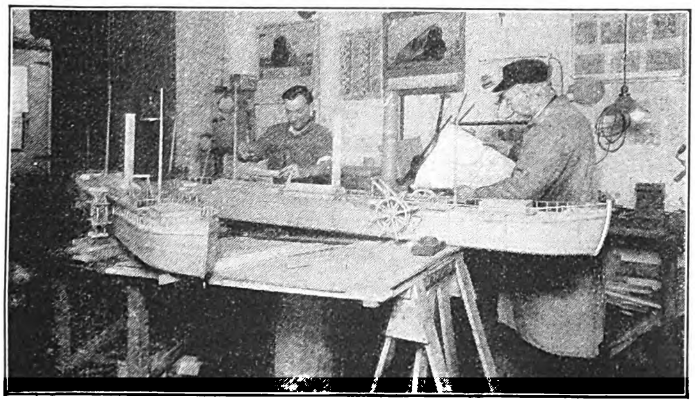
Meantime, the wheelwrights had been making the miniature wheels and the saddler had been spending days on the harness or the hood for Lincoln's state carriage. Not far away, the blacksmith had been making the springs, leaf by leaf, and the woodcarver was making the little wooden figures, for there is no composition or papier mache used here. Meantime, the wigmaker was weaving each hair into a silk foundation and the dressmaker was making poke bonnets, hoop skirts, and men's coats from material from a celebrated Chicago collection.

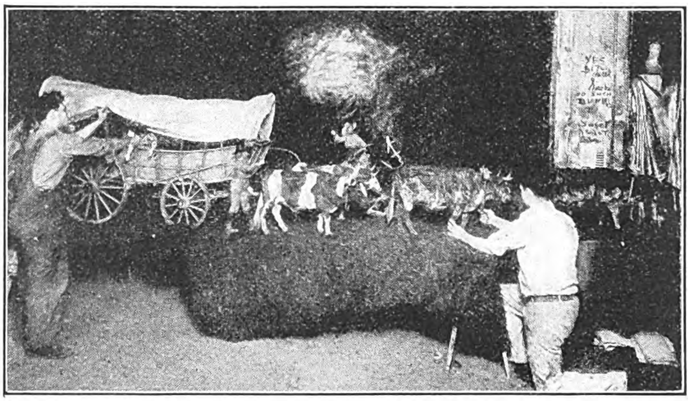
The woodcarver is also a sculptor. It took him a week to carve the head of Lincoln for the lifelike scene where the martyred President is driving. The woodcarver makes many of the accessories

The shipbuilders have been busy on their steamboats, and the sign painters are getting ready to paint the names on the paddle boxes, with the names of the company on the curve. Even such details as this required considerable search in a library where at last an early lithograph was found which gave the desired facts. Other workmen have been cutting little sticks for the fuel for the *DeWitt Clinton,* and "smoke" for the racing steamboat is supplied by mineral wool. The horses shy at the new fangled Selden automobile and it is no wonder, for it is a fearful and wonderful contraption. Nearby, the Wright Brothers are getting ready to fly 852 feet in 59 seconds. Twenty-six and one-third years later, Mr. and Mrs. Lindbergh crossed the continent, making the trip of 2100 miles in 13¾ hours at altitudes of 14,000 to 15,500 feet.

"The Story of Transportation in America," is what the show is called.

The *Clermont* will soon take the water. The model is really a monument to patience. Even the smallest detail is worked out with the greatest possible care





The Conestoga wagon was destined to carry pioneers across the continent. Its centenary has just been celebrated. Here we have the last finishing touches

The Physical Nature of Death*

By George W. Crile, M. D.,
Marie Telkes, Ph. D.,
AND
Amy F. Rowland, M. A.†

THE terms "living" and "non-living" and "dead" denote variations in energy and form. In structure the living organism is identical with the non-living—just as the live battery is identical in structure with the dead battery. But what is the essential feature in the living organism upon which structure depends? What is lost in death?

Thirty-five years ago I first attempted to approach this problem by an investigation of the basis of death. Phenomenon after phenomenon associated with death was critically examined and set aside as it was found to be a result rather than a final cause of death.

Studies of the circulation and respiration showed that the changes in these vital phenomena which are present in exhaustion and death are end effects and not primary causes of death. So, too, studies of the chemistry of the blood, while they revealed that the acid-alkali balance of the organism is of vital significance, did not reveal the cause of death.

RESUSCITATION experiments were performed in which it was found that in normal animals after complete cessation of the circulation for from five to seven and a half minutes, resuscitation followed the infusion of adrenalin into an artery; in the course of these experiments the sequence in the return of the various functions and reflexes was observed. But these experiments, important as they were, did not reveal the cause of the cessation of circulation and of the final death which would have followed had not the dose of adrenalin been administered.

By the examination of great numbers of cells under the microscope we found that certain histologic changes were invariably present in the cells of the brain and of the liver after death from any but sudden and accidental causes. The nuclear-cytoplasmic relation was disturbed and the semipermeable membranes were in process of disintegration. That life was incompatible with such a condition of the cells was obvious but was the condition of the cells in itself the actual immediate cause of death?

Later we directed our investigation to the determination of certain physical constants in various vital and lethal conditions. We found that the processes leading to death were always accompanied by a decrease in the conductivity of the brain and of other components of the central nervous system, and by an increase in the conductivity of the liver with corresponding changes in the electric capacity of the cells. But certainly a change in the conductivity and capacity could not be the immediate cause of death.

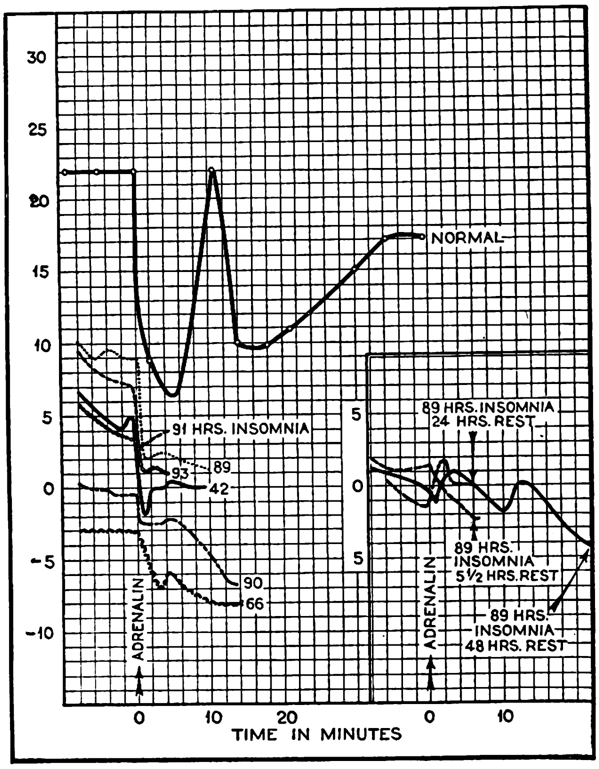


Figure 1: **Effect of insomnia on the potential of brains of rabbits. Note diminished response to adrenalin in the insomnia rabbits**

Death may result from many diverse causes: from hemorrhage, from physical injury, from infection, from insomnia, from anesthesia, from asphyxia, from surgical shock, from the excision of certain organs—any of these agents alone may produce death, or death may be due to a combination of any of these different factors. Thus in war a soldier may die not as the result of wound alone, or infection alone, or insomnia alone, or anesthesia alone but as the result of a combination of all these various factors. But whatever the cause of death the phenomena of death are identical.

In death the energy characteristic of life is lost—the dead body is in equilibrium. In death the living structures, namely, the cells, are unable to hold their form and structure and inevitably disintegrate. In death the delicate organic molecules such as the fatty-acid chains lose an organizing, binding influence and they too disintegrate.

WE propose now to offer new experimental evidence which identifies a form of energy that is lost in death—a form that is capable of constructing the films and of holding together the essential organic molecules.

These researches which have been carried out in the research laboratories of the Cleveland Clinic Foundation were directed toward finding the relation between electrical potential and oxidation; that is, toward determining whether one or the other is the primary factor in the maintenance of life and whether the loss of one or the other is the essential factor in the production of death or whether both together are primarily essential. Our researches were especially directed toward the discovery of the influence of potential on oxidation; the influence of potential

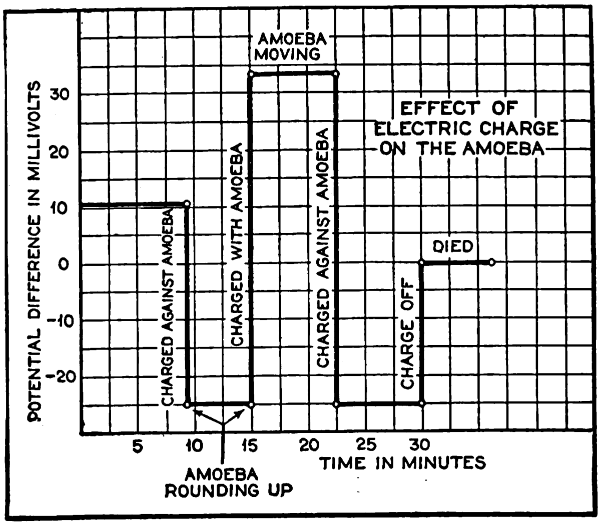

Figure 2: **Effect on the potential of an amoeba of direct and of counter electric charges**

---

*A paper presented before the American Philosophical Society and reprinted by permission, from the *Proceedings* of that society, which was founded 1727 by Benjamin Franklin.

†See "Among our Contributors," page 5.

on the form of the living, and by inference on the maintenance of the organic molecules; and to the discovery of the relation of the potential to death.

The results of these researches may be summarized as follows:

1. In animals, plants, and fruits an electric potential exists during life and disappears at death.
2. The potential is varied by insomnia, by anesthetics, by poisons, by hemorrhage, by asphyxia, by change in electrolytic solution, by adrenalin, by injury, by heat, and by cold.
3. At the moment of clinical death the potential difference between different organs drops to zero for a few moments; following this, each organ regains its potential for a short time, but finally the potential of all tissues drops to zero, the respiration of the tissues stops, and molecular disintegration sets in.

ARE we then correct in ascribing the cause of clinical death to the fall in the potential between the different tissues, and the cause of the death of single cells or of tissue cultures to the fall in the potential on the cell membrane?

Of primary importance was our finding that insomnia by itself alone produces a progressive loss of potential. In our experiments, if insomnia was sufficiently protracted, the potential declined to zero and the animal died. As the potential approached zero, recovery of potential followed a sufficiently prolonged period of sleep and of rest. Of special significance was the fact that after prolonged insomnia the animal did not respond in normal fashion to the injection of adrenalin. (Figure 1.)

If the molecular structure depends upon an electric strain or potential which also enables the organism to function and grow, we must find direct evidence therefor. Happily we found such direct evidence in observations of the potential of an amoeba. Dr. Telkes designed and constructed an electrode which could be inserted into an amoeba and with this electrode she made measurements of its potential. She found that the potential of the amoeba ranges as high as 15 millivolts and that it changes with alterations in the concentration of the electrolytic solution in which it is immersed, with changes in temperature, and when anesthetics are added to the suspending solution. Radiation, adrenalin, and sodium iodid all induce characteristic changes comparable to those seen in rabbits and in dogs.

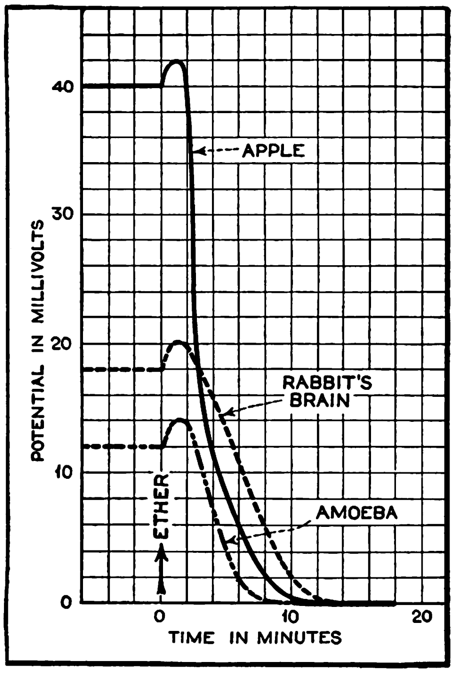

Figure 4: **Effect of ether on potential of apple, brain of rabbit, and an amoeba—again, same effect**

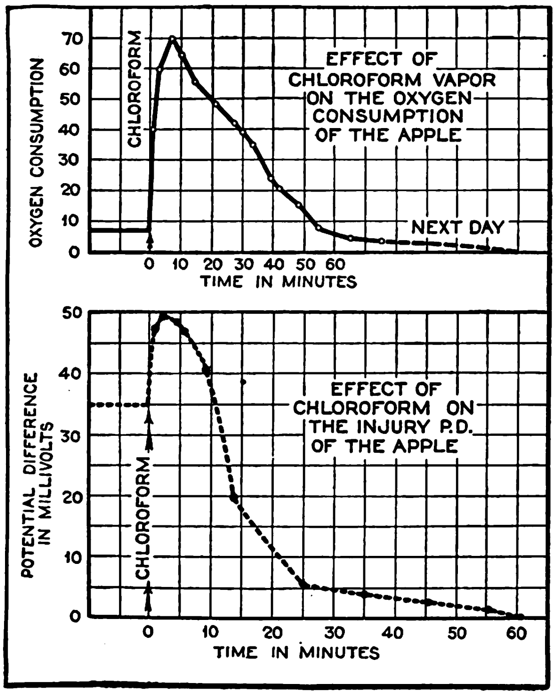

Figure 5: **How chloroform affected the potential difference of apples—again an initial rise, followed by a steady drop to zero**

The amoeba was observed under the microscope during the experiments. Here we had our first opportunity of noting under the eye the changes in structure which are produced by these various agents. Of special interest and importance were the effects of changes in potential produced by the direct application of an electric charge which could be varied at will. When the charge was increased the potential rose, and the amoeba became more active. On the other hand when the potential was diminished by introducing a current the direction of which was opposed to that in the amoeba, the amoeba progressively became less active and withdrew its pseudopodia; that is, it rounded up into a quiescent lump, until when the potential reached zero or went over to the negative side the amoeba disintegrated first into larger then into smaller granules and fragments and finally disappeared in the suspending solution. When, however, the potential was lowered by the counter-charge, and by no other factor, nearly to zero and was held there, the amoeba would round up and some granules might even disintegrate; but if at that crucial point when death and disintegration were imminent, the potential was raised by increasing the charge and by nothing else, the amoeba would pass from the resting to the active state, and would again throw out its pseudopodia. (Figure 2.)

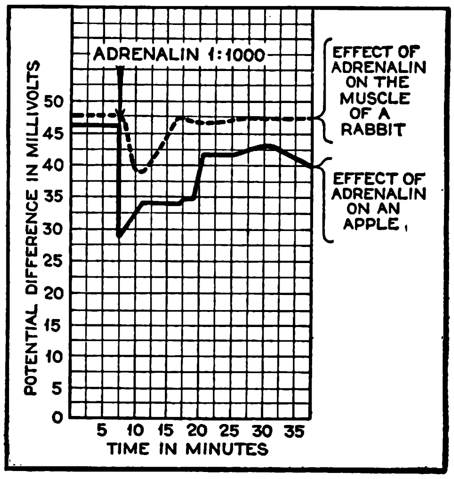

Figure 3: **Effect of adrenalin on the potential of muscle of rabbit (animal) and on potential of an apple (fruit); that is, effect was same**

This crucial experiment indicates that the fundamental control of the molecular integrity and of the activity of the amoeba—this difference between life and activity and death and dissolution—is governed by the change in the electric potential. In our experiments activity, quiescence, death, and dissolution were governed completely by the production of variations in the potential alone.

FROM this we may infer that the organic molecules that are bound together in the animal organism, the arrangement of crystalloids and colloids, the separation of nucleus and cytoplasm, the maintenance of the molecular organization—we may infer that all these phenomena are manifestations of electric force. Electrical potential is the product of chemical activity and in turn the electrical potential governs chemical activity. These electrical and chemical processes are the governing factors in the production of the phenomena which are characteristic of life. In their absence the organism is dead.

If the organic compounds, structures, and so on, in plants and in animals are created by electric potential and chemical activity, especially by

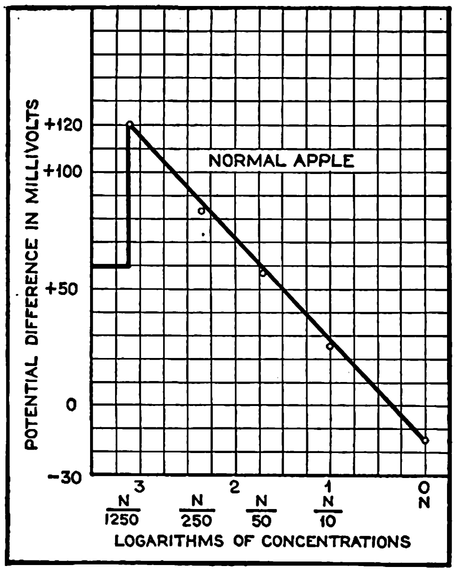

***Figure 6:* Logarithmic curve showing effect of varying concentrations of sodium chloride on the potential of a normal apple. The circles represent the five observed values**

oxidation, then in such intermediate forms of life as fruit the same law should hold.

We therefore extended our researches to an investigation of the phenomena of potential and of oxidation in fruit and we found that every kind of fruit has a potential—the potential of an apple, for example, is about 50 millivolts, and the apple has also a steady respiration—consuming from three to four cubic centimeters of oxygen every hour.

In our experiments we found that the potential and the respiration of the apple change in the same direction under the influence of anesthetics, and of changes in electrolytic concentration. The administration of adrenalin, changes in temperature, and the exclusion of oxygen affected the apple just as they affect the rabbit and the dog. (Figure 3.) Anesthetics caused first an "excitant" stage which was indicated by a rise in potential and an increased metabolism; that was followed by a continuous fall of both the potential and the metabolism to the zero point, after which neither potential nor metabolism was again manifested. (Figures 4 and 5.) Adrenalin caused a fall in potential followed by a rise and the respiration of the apple was increased. Changes in electrolytic solutions caused changes in potential which were in conformity with the Nernst formula. (Figure 6.) When the electrolytic concentration equaled the concentration of the electrolytes in the apple the potential fell to zero. Immersing the apple in oil caused the potential and respiration to fall to zero and to remain there. Increasing the temperature of the apple caused the potential and respiration to rise together and after an irregular fluctuation at a given height both fell to zero and remained there.

In all cases in which the potential was reduced to zero the apple disintegrated, just as animals and plants and the amoeba disintegrate when their potential is reduced to zero. A battery was constructed by arranging halves of apples in series and a potential of over a volt was thus created. (Figure 7.)

By this study we have demonstrated that the structure of the apple, like that of the amoeba, is dependent on potential and here again we saw the relation between electric strain and the maintenance of the organic structure.

If oxidation is due to a difference of potential and if living cells are concentration cells, then if apple juice were placed on one side of a celluloid film and distilled water on the other, oxidation and potential should be manifested just as in the apple, amoeba, or rabbit. Such an arrangement was made and as a control another artificial "concentration cell" was set up which was identical with the first, except that a hole was punched in the celluloid film in the control cell. Observations of metabolism and of potential showed that the first artificial cell functioned like the apple and the amoeba; that is, it had a potential and it showed respiration; the control cell, on the other hand, had neither oxidation nor potential.

In brief, then, in a large series of experiments we have found that in animals and in plants and in fruits there exists a potential which has a certain range during life and disappears at death. This potential is dependent on the presence of a semi-permeable film, on certain electrolytic concentrations, on water, on temperature, on oxidation, all of which together create the organizing potential. It is the charge on the films of the cells which endows the organism with its selective or adaptive property; oxidation occurs only in the presence of an electric charge and the charge is created by oxidation. Life is a phase of the organization created by electric strain or potential and death is an inert stage in which potential is lost and disintegration is inaugurated.

Or we may define life and death in the following terms: Life may be defined as a potential which is maintained and is varied adaptively according to environmental conditions, this potential being maintained by chemical activity—mainly by oxidation. The loss of this potential is death. The principal difference, then, between that potential which is life and the potential which is present in non-living systems like concentration cells is that the living potential is spontaneously and adaptively alterable.

In brief, then, life in the unicellular organism is an adaptively changing difference in potential between the cytoplasm and the medium in which it exists, and presumably between the cytoplasm and the nucleus. In the lowest forms of multi-cellular organisms life is an adaptive difference in potential between the central nervous system and the rest of the organism; in the higher multicellular organisms life is an adaptive difference in potential between the brain and the other organs and tissues, especially the liver. The life of an organ or tissue depends upon the maintenance of a difference of potential between the cells and the intercellular medium, and presumably between the nucleus and the cytoplasm of the individual cells of which it is composed. And in the unicellular and in multicellular organisms alike death is the absence of a difference of potential—final equilibrium.

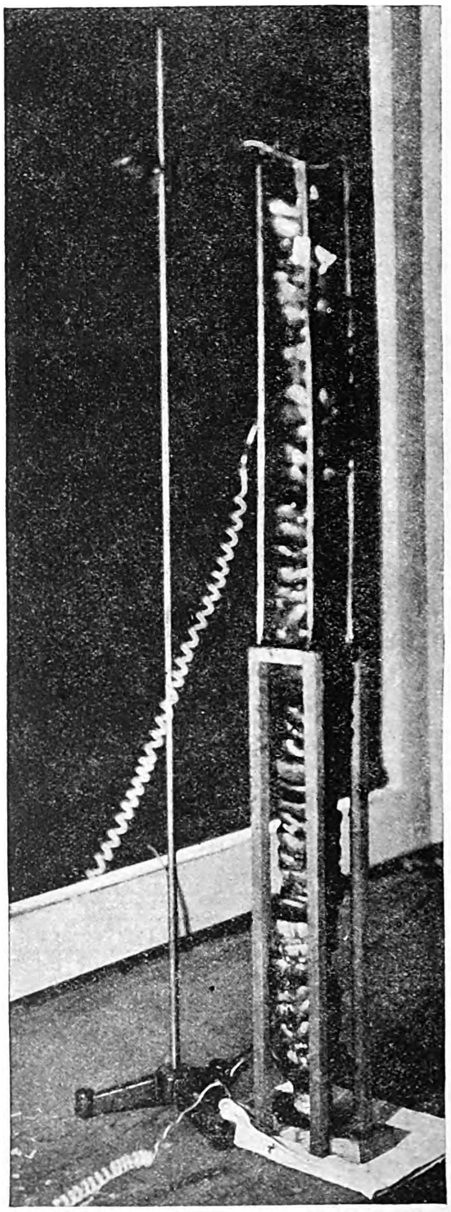

Figure 7: The apple "battery" made of 50 halves of apples arranged in series. Its potential was more than one volt. The halved apples are piled up in series and electrodes are attached to the bottom and top halves respectively

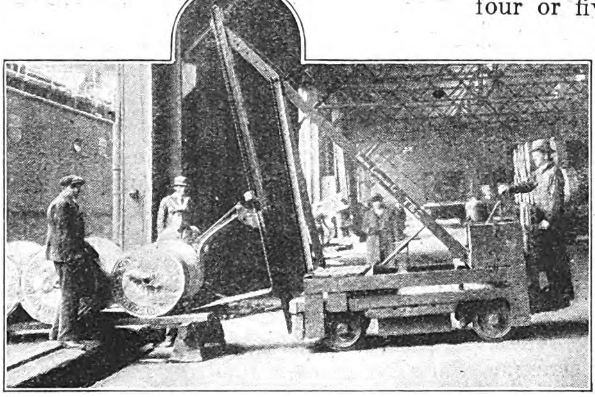
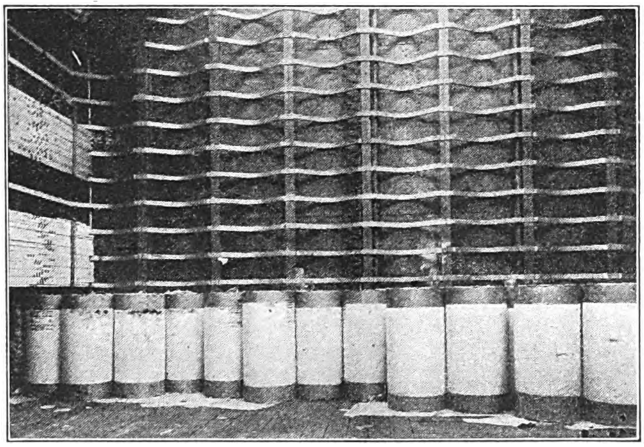
Shipping Newsprint Paper in Safety

A CURIOUS craft, the S.S. *Markland*, has been recently making trips from Liverpool, Nova Scotia, to New York at frequent intervals. She was built to perform one duty; namely, to transport 8000 rolls of newsprint paper without chafing or wetting. Of course, paper has been carried by ships from time immemorial but not in this manner. The vessel, which is 336 feet long and of 4454 gross tons, is built on the deep-frame principle. Her cargo holds are constructed with as boxlike formation as possible. All brackets, stanchions, pillars, et cetera, have been omitted and otherwise compensated for. Frames in the cargo holds are continued through the main stringer to the height of the bulwark, with the inner flange of channel removed and watertight collars fitted. The frames are bracketed to the deck. This method of construction compensates for the absence of the ordinary beam brackets usually associated with deep-frame construction, the brackets being eliminated from the hold to obtain better stowage. Frames in cargo holds have steel cargo battens covered with wood to prevent any damage to the newsprint from coming in contact with bare metal. The vertical bulkhead stiffeners support steel strips, wood covered. These strips are so curved as to allow paper rolls to be stowed snugly and firmly between the stiffeners, while the holds forward and aft are boxed vertically in the way of curvatures to allow rolls to be stowed tightly in a vertical position. Wooden battens protect the newsprint from contact with the metal.



The rolls are transferred to trucks by electric tiercing machines



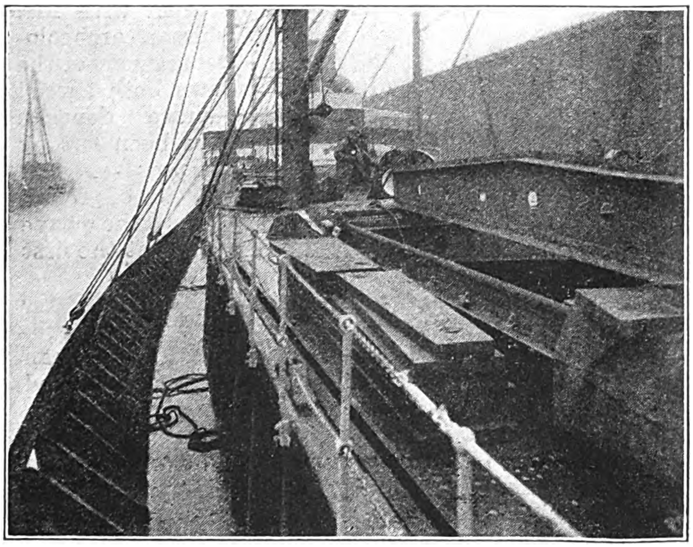
The rolls fit closely. When each tier is complete, painted boards are placed over the top, making a floor for the next tier of rolls of paper

The keel is on the duct principle forward of the machinery space to the fore peak bulkhead to allow steam lines for winches, water pipes, et cetera, to be carried forward clear of cargo holds. The *Markland* was built at Hull, England from the design of Mr. Walter Lambert of Montreal.

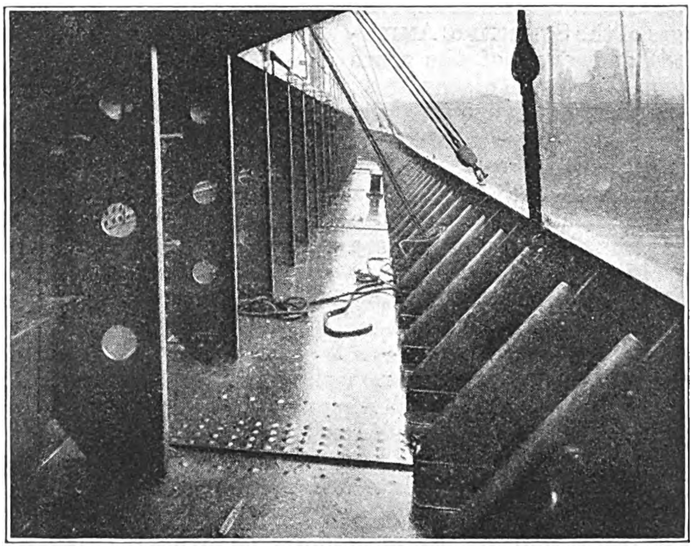
The five holds each take care of four or five tiers of paper rolls with painted wooden boards, or "dunnage" separating each tier. Every precaution is taken to avoid danger by water as well as chafing. All pipes are enclosed in other pipes to prevent dripping.

THE regular trip of the *Markland* occupies about 44 hours. Once the pier in New York is reached unloading begins at the rate of 200 tons an hour. The rolls are turned down horizontally and two are swung up through the hatch at one time, the ends of a bridle being inserted in the iron cores. Although hoisted collectively, once on the dock they are handled individually by tiercing machines or trucks which grip one roll at a time, elevating it and carrying it to the waiting truck which when fully loaded, rushes off to carry the paper to the waiting presses.

The pulp wood all comes from Nova Scotia, where the paper is made by the Mersey Paper Company of Liverpool, Nova Scotia. In this plant two paper machines each produce a ribbon of paper 222 inches wide at a speed of 1000 feet a minute.



Steel cargo battens close the five hatches; ten steam winches discharge the paper at a rate of 200 tons an hour



All stanchions, pillars, et cetera, are omitted and they are compensated for by a deep-frame construction

The Mystery of Gypsum Cave

By M. R. Harrington*
Curator, The Southwest Museum
Member, American Anthropological Association

Discoveries Near Boulder Dam Point Either to High Antiquity for Man in America, or to a Later Survival of Certain Extinct Animals Than Heretofore Has Been Believed

IN a deep, dry cavern in the mountain ranges east of Las Vegas, Nevada, overlooking a wide stretch of desert and the distant rugged gorge of Black Canyon—future site of Boulder Dam—an even dozen men and women are trying to unravel a fascinating mystery. This mystery concerns not only America's first human inhabitants, but the strange beasts of a by-gone age.

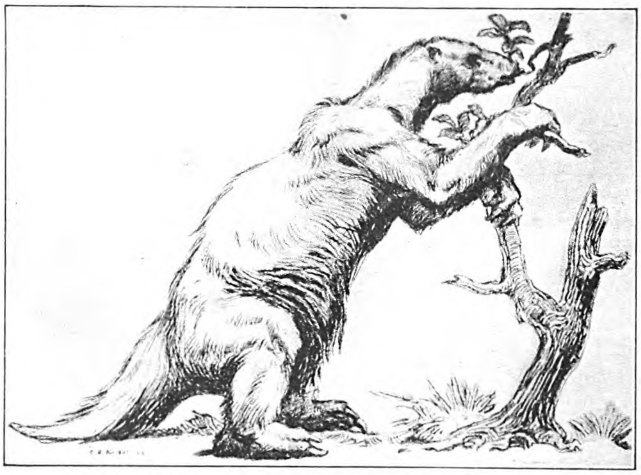
The workers represent two great institutions, the Southwest Museum of Los Angeles, and the California Institute of Technology working in co-operation, a rare example in this country of archeologists and paleontologists laboring side by side on the solution of a single problem.

I am no stranger to the exploration of caverns, but the first thing I sensed when I first entered Gypsum Cave in 1924 was the mystery of the place. Here was something different, a situation I had never found before.

A little digging near the entrance showed traces of early Pueblo Indians like those who occupied Lost City and Mesa House in the nearby Moapa Valley (both of which have been described in the pages of the SCIENTIFIC AMERICAN[1]) and even of the more recent Piutes. In the rear chambers, however—and the cavern was 300 feet long and 140 feet wide—the only human relics I could find belonged to a much more ancient people, the Basketmakers, who in fact are the oldest inhabitants of our southwest known to archeologists. Reliable authorities even estimate their date as about 1500 B.C.

The Basketmakers are remarkable for the fact that, although they had made a beginning in agriculture, they were ignorant of pottery and knew nothing whatever of the bow and arrow. In fact this weapon which we now consider so typical of the American Indian had not yet, apparently, been introduced into America at all.

Instead of the bow and arrow these ancient people used darts or small spears feathered and pointed somewhat like arrows but longer—about five feet long—and heavier. These were hurled at animals or human foes by means of the curious spear thrower known to archeologists today by its Aztec name of *atlatl*. This was a carved throwing stick about 20 inches long, with a hand hold on one end and a small hook on the other, which engaged a socket or pit drilled into the butt end of each dart. The throwing-stick or *atlatl* in effect added its 20 inches to the length of the user's arm and gave him that much more advantage in velocity when he threw his darts.



In the Pleistocene Epoch ground sloths, some as large as elephants, ranged from California and Pennsylvania to Patagonia. This one is *Nothrotherium*

One of the methods by which archeologists distinguish *atlatl* darts from large arrows is by the fact that the butts of the darts are always provided with these sockets instead of with the notches for the bow-string seen on arrows. I am describing these things here because the Basketmaker relics I found that day in the inner chambers were mainly fragments of such darts.

Now these Basketmaker remains lay on the *surface*. What might lie in the deposits below the surface was an intriguing mystery.

A few test holes revealed the fact that the deposits, upon which the dart fragments lay, consisted very largely of compact manure, reminding me strongly of some old horse corral or barnyard.

This only deepened the mystery, because I could not understand what animal might have existed before the Basketmakers that could have produced such a deposit. I knew that modern horses were introduced into America by the Spaniards, long after Basketmaker days; and that no horses could have penetrated the cave, anyway, on account of its small entrance.

IF Basketmaker dart shafts lay on its surface, the manure must certainly be older than the Basketmakers; that is to say, probably more than 3500 years old. I resolved to return some time and solve the problem, if it was solvable.

However, the Museum of the American Indian, Heye Foundation, with which I was connected at that time, abandoned its Nevada work and I was unable even to visit the cave again until January 1929, when I returned to the region in charge of an expedition from the Southwest Museum of Los Angeles, to work once more in the Moapa Valley.

During the same spring I made several visits to the cave, one of them with Mr. Jesse L. Nusbaum, archeologist for the Department of the Interior, and we both agreed that the manure deposits might well have been left by some animal now extinct, maybe some species of ground sloth, and that the cave should be explored at the first possible moment.

This opinion was strengthened after the close of the expedition when Professor Barnum Brown, of the American Museum of Natural History, examined specimens of the dung. He thought there could be little doubt that some kind of ground sloth was responsible for it, basing his deductions, I believe, on a previous find in South America.

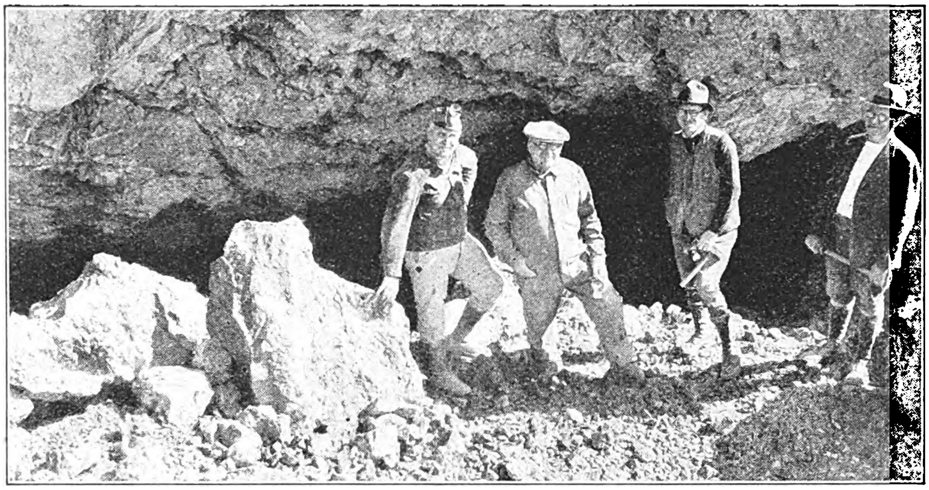
And when the long-hoped-for chance came in January, 1930, to lead out an expedition for the express purpose of solving the mystery of Gypsum Cave, I was overjoyed. However, I fondly imagined that a few weeks would bring the answer. . . . At this writing 11 weeks have passed, and while we have learned much, the mystery is still a long way from full solution.

---

*See "Among Our Contributors," page 5.

[1] "The Lost City of Nevada," M. R. Harrington, July, 1925, pages 14-16; "The Last Stand of the Nevada Pueblos," Irwin Hayden, February, 1930, pages 132-135.

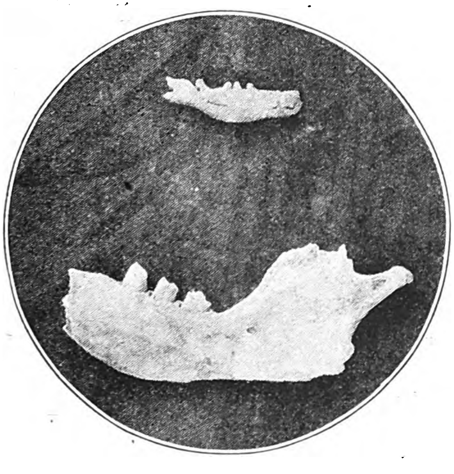
Our first task was to examine the surface of the cave floor and all its crannies and crevices as carefully as we could. This resulted in finding, scattered everywhere in the inner rooms of the cavern, hundreds of fragments of wooden and cane dart shafts broken and splintered. Most of them, as were the first ones found in 1924, seemed to be the work of the Basketmakers. There were also countless burnt sticks—the remains of torches.

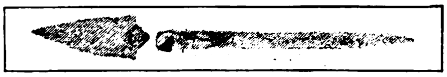


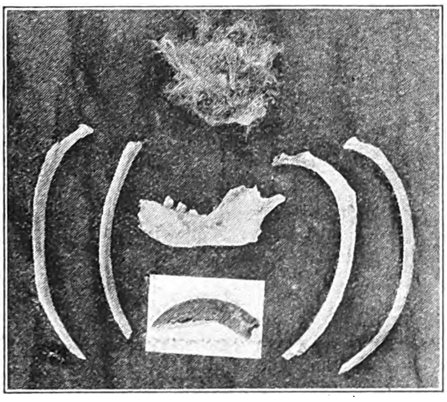
Right to left: **Dr. E. L. Furlong and Dr. Chester Stock of California Institute of Technology; Dr. Scherer, Director of Southwest Museum; the author**

TWO ancient wooden flutes, some curious bits of archaic basketry, and occasional other relics turned up, including even a few fragments of more modern arrows, but these were as nothing compared to the hundreds of splintered primeval weapons which littered the place. Why were there so many, and why so splintered? The mystery deepened.

Then we found upon the surface among the dart fragments some strange-looking bones, and then my niece, Bertha Parker Pallan, found the unmistakable skull of a ground sloth! We learned later that it belonged to the ungainly species known as *Nothrotherium*, not the largest of the ground sloths by any means, but a creature about the size of a husky brown bear. The skull was not buried; it lay upon the surface protected from view only by an uptilted slab of rock.







Jaws of baby and adult sloths; spear point found near a sloth skull; relics of *Nothrotherium*—hair, ribs, jawbone, and a claw

Was this really a clue? Our suspicions as to the origin of the manure deposits were strengthened, of course, for we now knew with certainty that the cave had been a sloth den, but what of the darts? Had they been thrown to slay the odd, misshapen beasts of the cave?

Only digging could reveal the answer, and dig we did, starting a trench in the main chamber. Here we found bones—a few of them—some of the mountain sheep, some of a small variety of horse, even a piece of a sloth claw, but nothing made by man.

It seemed a cruel fate that it was not the hard-working trench diggers who made the next big find, but an outsider, or almost an outsider. It was Mrs. Myrtle Evans, wife of one of our Indian helpers, and herself an Indian of the Washoe tribe, who was visiting the cave one afternoon with her little nephew. Scratching with a trowel in a distant end of the cavern she unexpectedly turned out a big bone. It was a sloth vertebra! Soon we had uncovered a large part of the skeleton of a *Nothrotherium*, so well preserved in parts that one great claw still retained it horny covering. Bunches of the long, coarse, tawny hair, with its dark shading, were in perfectly good condition.

In rock crevices near the bones appeared a bit of native string made of yucca fiber and some small feathers wrapped with sinew, possibly part of the decoration of a head dress or perhaps part of a votive prayer stick.

The situation seemed too much for a mere archeologist to handle and I wired for help—paleontological help. In answer, our Museum's director, Dr. James A. B. Scherer, brought to our camp Dr. Chester Stock of the California Institute of Technology, a leading authority on ground sloths, and his associate, Dr. E. L. Furlong. As a result of their visit this institution joined us, and now a joint expedition is laboring in Gypsum Cave. A paleontologist, Mr. J. F. Thurston, is continually on the ground and frequent visits are made by the others.

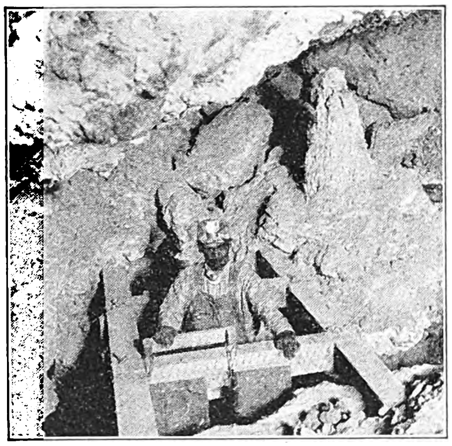
We have a capable and interested force, including Mr. Charles Amsden of the Southwest Museum, and Mr. Willis Evans, my Pit River Indian friend who worked with me at the Lost City and Lovelock Cave and is now foreman of our laboring crew.

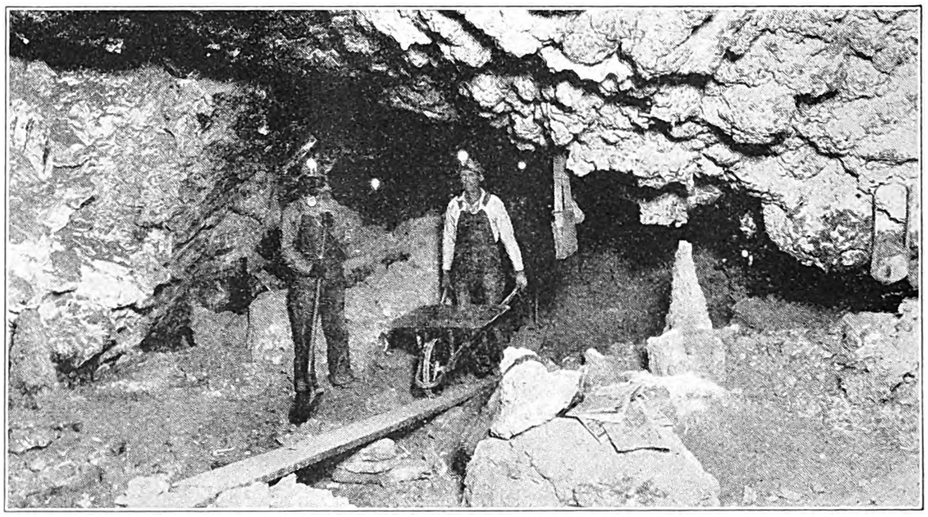
GYPSUM CAVE (named, by the way, for its beautiful crystals of gypsum or selenite) is not easy to explore. This is not only because practically every chamber is cluttered with rock falls, large and small, but principally because the lowest level is 64 feet below the entrance, and the passage from the entrance to the inner chambers is so steep and in places so narrow and tortuous that to carry our tailings or "back dirt" completely out of the cave, as we desire to do, would require a mechanical hoist such as is used in mines, and a lot of blasting. To build such a hoist would require so much outlay of time and money that it would not be justified at present. In consequence, our Zuni Indian workmen are obliged to build huge bins with stone retaining walls, in which to pile the earth and rocks dug from the trenches. Some of these bins will doubtless have to be moved and their contents rehandled when we get ready to explore the cave floor beneath them.

As in a mine, we have found it necessary to timber the roof where it seemed crumbly and in danger of falling; to build cribbing for holding back rockslides that threatened to slip down and engulf us; and even to timber like a mine shaft any pit that must be driven down into the ground to a depth of more than six or eight feet. All of these operations were new to me, after all my 30 years of archeological delving.

Some days are better than others, but almost every day is adding its bit to our knowledge of the men and the animals of the cave.

On the archeological side we are forming a picture of a people who seem to have visited the cave, long before the Basketmakers, but the portrait so far is little more than an impression. At least we know that the Basketmakers were not the first humans; for, far below the level containing their relics, we have found pieces of dart shafts differing from theirs and cruder. However, these shafts are painted with quite elaborate patterns in red and black, blue and green. We think that the points used on this type of dart were lozenge-shaped rather than notched like the Basketmakers', and were fastened in place with pitch.





Above: Mouth of shaft, 12 feet deep. At bottom were found bones of extinct American horses and camels. Near the surface to the right lay most of the ground sloth's skeleton. ***Right:*** Here were found sloth bones and various evidences suggesting that man and sloth existed at the same time

From the tiny drilled pit on the butt of the dart we surmise that the missile was hurled like those of the Basketmakers, with an *atlatl* or throwing stick, the pin of which fitted into the pit of the dart. We also know that the mysterious "first comers" made these darts of arrow brush stalks and feathered them with whole feathers, instead of the split feathers used by the Basketmakers. From the painted patterns we have some idea of their decorative art, but so far these facts are all we know about them.

If the Basketmaker was not the first human being to leave a record of his presence in the cave, neither was the sloth the first animal. Deep down in the bedded rockfalls and silt of the cave floor, at least ten feet below the level which has yielded most of the traces of the sloth, we have found bones of American horses and camels. In the upper layers other sloth bones have appeared; also more well preserved claws and hair—even the remains of a tiny baby sloth, not much larger than a cat.

But, as for the mystery, which after all may be boiled down to the question, "Did man visit the cave while it was still a den of sloths?" we have no absolutely positive answer as yet. Little by little, however, evidence is accumulating that may some day, we hope, clear away the shadows. For example in Room 1, which is near the entrance and seems to be the only chamber in which the ancients really made their home, we have found a layer, buried under more than eight feet of other deposits, containing large pieces of sloth dung, scattered specks of charcoal telling of ancient fires, and an occasional object made by man. Another bit of evidence is the discovery of some painted *atlatl* darts at depths ranging from eight to 10 feet *beneath* a layer which has yielded dung and hair of the sloth. Still another is the discovery of the lozenge-shaped dart points under the base of the rockslide upon the surface of which lay the sloth skull, only a few feet distant; while in the back chambers in the layers of sloth manure a piece of polished *atlatl* dart imbedded in the manure itself, an occasional burnt stick in the manure and sometimes even below it, are certainly interesting in the same connection.

Any one of these bits of evidence might be explained away. One can say that the ancients might have carried the pieces of manure up from the depths of the cave to Room 1 to use as fuel, or that the deposit with the hair and dung covering the painted darts was really older than they, but had slipped down upon them from some point higher up the slope of the cave floor. Or one might say that the skull of the sloth had rolled out of some other hiding place after the lozenge-shaped dart points had been buried. One might even say that the dart shaft found in the manure had worked its way in through some hole which was afterwards closed again with manure, and that the burned sticks, in spite of their resemblance to the torch sticks found all over the cave, were the result of spontaneous combustion in the manure, some of which is really burned in patches.

BUT so many bits of evidence in so many parts of the cave are rather hard to explain away *in toto*, and it now looks as if, when the mystery is finally cleared, we may find that the sloth, grotesque survivor of an age of monsters, was really seen in the cave by human eyes, and even possibly that the last of his race were slaughtered for food by some of the first "discoverers of America."

But even if the original mystery is cleared up finally and to the satisfaction of all, there will remain, I fear, still another one which is the outgrowth of the first.

If we prove that man and the ground sloths really existed in America at the same time, does that mean that man lived here twenty thousand or thirty thousand years ago—which is the age usually given to the strange society of animals to which the sloth belonged, the mammoth, the dire wolf, the giant lion, and the saber-toothed tiger of Pleistocene days—or does it mean that some of these animals lived on after the glaciers had receded, until comparatively recent times, say up to within ten thousand or fifteen thousand years of our times? The future alone can supply the answer, if any.

¶ *While this article was in press Dr. Frank Leverett, the widely known glaciologist, described before the National Academy of Sciences the discovery in Equador of human remains, associated with those of a mastodon. This supplies another bit of evidence on the question stated in the above paragraph.*

The fuselage of the "Waterplane" rises from the water after a run of 150 feet

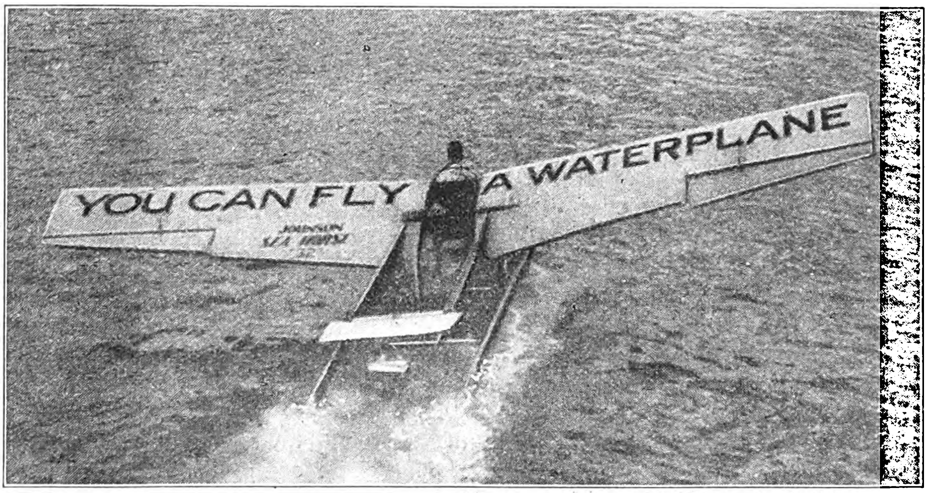
A "Flying" Outboard Motor Boat

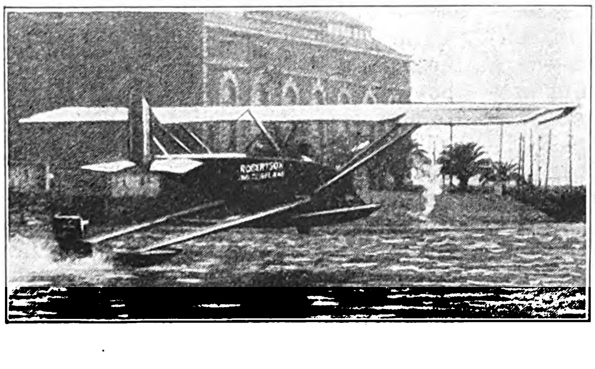
The pilot's right hand is grasping the joy stick, his left the gas control; his feet are on the rudder bar

A NEW water sport that combines the safety of outboard motor boating and the thrills of flying is made possible by the "Waterplane," designed by Russell and Milton Robertson of Alameda, California, after they had repeatedly watched tiny outboard powered racing craft rear their bows out of water. The thought occurred to them: Why not put wings on the boat and lift it completely out of the water?

Essentially the "Waterplane" consists of two units connected together by hinged arms. The rear unit is composed of two pontoons which support a standard four-cylinder outboard motor. The front unit is nothing more nor less than a glider, but in this case it is a glider that does not require a ground crew, being entirely controlled by the pilot. The fuselage of the glider is so constructed that it will float on the water, and can be pushed by the outboard motor. When the proper speed is reached, the pilot manipulates the controls and up in the air goes the glider. The motor stays in the water and continues to furnish the motive power as long as the pilot desires to stay aloft. The glider can reach a height of from 10 to 15 feet above the surface of the water.

Milton Robertson tells of flying a "Waterplane" as follows: "Seated at the controls, the pilot starts the motor by means of the electric self-starter. From a standing start to full flying speed requires a 150-foot run. At first it is best to plane over the surface, getting used to the controls. At about 35 miles per hour, the stick is pulled gently back and the 'Waterplane' leaves the water. At first it took all my attention to navigate but after the first few times aloft, the movements of the stick became automatic. Slowing the motor to a little below flying speed allows the plane to settle gently to the surface."





Above: **A rear view of an open model "Waterplane" about to take off**

At left: **All the thrills of flying in a "Waterplane" built with an enclosed pilot's cockpit**

The glider unit of the "Waterplane" is equipped with the usual controls for ailerons, rudder, and elevators. By proper manipulation of them the pilot can bank on the turns, swoop gracefully from higher to lower altitudes, and get a taste of all of the thrills of actual flight, at the same time literally "keeping one foot on the ground."

Waves and Particles[*]

Professor of Natural Philosophy in the University of Aberdeen, Scotland
Non-resident Lecturer at Cornell University

The New Concept of the Nature of Matter

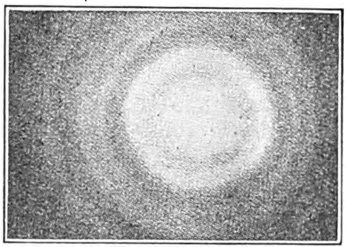
IF I break a piece of chalk, then take each of the bits and break them, and so on, is there any theoretical limit to the progress other than that imposed by the coarseness of mechanical appliances? This is a question which has occupied science since the twilight of its earliest dawn.

In the last three or four years opinions have altered as to the best answer to this question. During the first quarter of this century the answer to the question was quite definite. If the piece of chalk is continually broken and rebroken a time comes when the pieces are no longer merely smaller but become different in kind. This stage can not be reached by mechanical breaking, but it can be reached by heat and suitable chemical action. The chalk has been broken into its atoms. In chalk there are three kinds; other substances would yield other kinds, and, in all, chemists have distinguished 90 kinds from which all matter is made.

THESE atoms are small. They bear about the same relation to a drop of water that a drop of water bears to the earth. But even here the limit had not been reached. Towards the end of the 19th Century it had been found possible to break pieces off these atoms: for example, by the violent collision of other atoms. These pieces were always the same. They are called electrons and have now become almost an article of commerce, for they are the working material of the radio valve. The hot filament of the valve gives off electrons as water gives off steam, and the electric forces in the oscillating circuit control the motions of the electrons.

The older view of the electron is best expressed by regarding it as a tiny lump of electricity which had a little mass—less than a thousandth of that of a light atom—as a kind of secondary property of its charge. It was supposed to have a certain extremely minute size, but as a matter of fact the estimate of this size rested on purely theoretical arguments and no one had ever measured it. However, it soon became apparent that each atom contained electrons varying in number from one each to nearly 250 each for different kinds of atoms. Thus it was reasonable to suppose that an electron was a good deal smaller than an atom.

Later on—it is difficult to give an exact date—it became clear that there was a second universal constituent and that this was the residue of a hydrogen atom when one electron—the only one—was removed. It has been called the proton. Every atom contains, in its normal state, an equal number of electrons and protons. The protons are much the heavier of the two, but they occupy only a very small region in the center of the atom called the nucleus. This region is so small that the combined nuclei of a man's body would form a barely visible speck. Since the nucleus also contains some electrons these apparently must be at least equally small, and we are left with a picture of matter as mostly emptiness. That such a view is not purely figurative has been shown in a striking manner recently. It seems certain that some stars known as "white dwarfs" are so dense that a cubic inch would weigh a ton. This is still nothing like the density of a nucleus but it shows at least that an ordinary solid must have plenty of gaps if it can be compressed to such an extent.



Courtesy of *Nature* (London)

In the author's experiment rings were produced on a photographic plate by electrons scattered systematically in passing through a gold film. The pattern is interpreted as due to electron waves. See the text, page 40

The picture of matter was thus essentially one of discontinuity. It consisted of a number of specks—of a whole number, for an electron or proton can not be split. It is a return to the earliest philosophy, for it was Pythagoras who taught that "all is number."

But there was another side of physics in which continuity was supreme. If you had asked the question "How does one electron act on another," the answer would have been "through stresses in the ether." Now the ether has had a long and checkered history. Ethers of a sort were common in early physics—rather too common. But the ether first acquired an assured status in the scientific world when it became clear that light had to be explained as *waves*. As this introduces the other half of the title of my paper you will perhaps allow me to dwell on it in some detail.

The obvious thing about light is that it goes in straight lines—as can be seen if you watch light passing into a darkened room through a small hole and tracing out a path as it lights up the motes of dust. Now Newton said that a particle free from force goes in a straight line. It was natural to suppose that light consisted of a stream of particles shot out by the luminous object. Light can be reflected by mirrors and refracted by glass but, superficially at least, these effects can be explained as a rebounding of the light particles, or their deflection by forces at the surface of the glass, as the case may be. Nevertheless, influential men such as the Dutch physicist Huygens suggested in the 17th Century that light was a form of wave motion. Now sound is wave motion and every one knows that sound will go around corners. So will water waves. How can you explain the rectilinear propagation of light on this view?

It is all a question of the wavelength. Even in sound a high-pitched note is not heard well round a corner. If the wavelength of light is small enough rectilinear propagation is all right. Also light does bend very slightly. The really crucial test is what is called interference, the property by which two lights can produce darkness. A special form of this is to take a number of regular spaced wavelets, all derived from one wave. This gives a peculiarly marked effect. The effects of the combined wavelets are strongly concentrated in a few privileged directions and cancel everywhere else.

LIGHT shows this phenomenon to a very marked extent. For example, in the case of the diffraction grating, light scattered from a large number of regularly spaced scratches on a glass or metal surface is found to be concentrated in a few directions, and this effect can be used to measure the wavelength of light with very great accuracy.

The ether was required to carry these light waves. At first it was thought of as a kind of jelly, and Lord Kelvin used immense mathematical skill in finding the very peculiar type of jelly which alone gives exact agreement with the experimental laws of light. Now Faraday long before had regarded electric and magnetic effects as stresses in a medium, and Maxwell showed that the same medium could do double duty—carry electric effects and transmit light. Hertz crowned the theory by actually producing waves by purely electromagnetic processes which had the velocity of light, and in fact were invisible light: "light" whose wavelengths were to be measured in meters instead of thousandths of a millimeter as are those of the visible kind. I need hardly say that these waves are those now used in radio.

[†] See "Among Our Contributors," page 5

Later it was shown—not until 1913 indeed, but logically it comes in here—that X rays are invisible light, on the other side, as it were. Their wavelength is about 10,000 times shorter than that of ordinary light instead of millions of times longer. The way in which this was proved is of interest. To show interference well, one needs an apparatus so exactly shaped that the errors are smaller than the wavelength to be tested. Now X-ray wavelengths are smaller than most atoms. It is impossible to shape an apparatus exact to an atom. Von Laue got over the difficulty in a very ingenious way. He remembered that in a crystal the atoms are arranged in regular order like soldiers drawn up in close formation.

The result is a series of lines like a diffraction grating and about the right distance apart. Actually it is a little more complicated because the atoms are arranged in a solid array, while an ordinary grating is on a plane, but this does not really matter. The result of sending X rays through a crystal is a diffraction pattern, and in this way the wavelengths can be found.

So far, then, we have matter made of discontinuous particles, while the interaction is due to a continuous medium which can transmit waves. But now came the difficulties. I will take two selected ones which are enough to show their nature. When light is allowed to fall on a polished metal surface, electrons are thrown out from the metal. Since light is electromagnetic waves and electrons are electrical, it is not surprising that there should be an action of this kind, but the details are all wrong. The speed with which the electrons come out does not depend on the intensity of the light. They come out with just the same speed for the feeblest light as for the strongest, only there are fewer of them. Now if, for example, sea waves are breaking on the beach and rolling the pebbles about, the more violent the waves the farther the pebbles are thrown. If the water waves behaved like light, an almost calm sea would throw a few selected pebbles as violently as a great storm throws them all. This is obviously contrary to one's ordinary conception of waves, and it is equally at variance with the results of a complete mathematical treatment. Moreover, the energy with which the selected electrons appear is so great that they would take hours to absorb it from feeble light, while even with the feeblest light there is no detectable lag between switching on the light and the appearance of the electrons. Obviously something is wrong.

Einstein suggested that the light contained units of energy or quanta which behaved practically like particles. When one collides with an electron it gives up its energy to the electron which then can escape from the metal. All the quanta in a given kind of light are the same, but the stronger the light the more numerous they are. The energy of each quantum is the frequency of the light multiplied by a quantity "h," which can be found by measuring the energy of electrons emitted by light of known frequencies. This has been done by Professor Millikan. He finds $h = 6.55 \times 10^{-27}$.

In measuring electron scattering, the "electron gun" at upper left corner sends a steady stream of electrons to the crystal, which scatters them in various directions. The collector (marked "to galvanometer") catches more or fewer electrons according to its position. In the case at right, for example, the maximum number of electrons caught was at 60 degrees angle. This is the principle of the method used by the physicists Davisson and Germer of the Bell Telephone Laboratories

Now this is all very well for the photoelectric effect, as the above is called, but what about the diffraction grating? We have just decided that light must be waves and now it turns out to be particles instead, for it is essential for the explanation that the quanta should be so concentrated that one electron can catch a whole quantum. This is the famous photoelectric paradox.

Before I try to answer it, I will describe the other difficulty. Atoms can be made to emit light, and each atom emits its own characteristic wavelengths. These are clearly a consequence of the structure of the particular atom, presumably of the arrangement of its electrons. Now one theory, and one only, was found capable of explaining these wavelengths even in general terms. This was the theory due to Neils Bohr according to which the electrons were supposed to move in orbits 'round the nucleus rather like planets 'round the sun. But in order to make the theory fit the facts, Bohr had to assume a behavior of the electrons which is quite contrary to ordinary dynamics, and curiously enough the same quantity "h" came in, though in quite a different way.

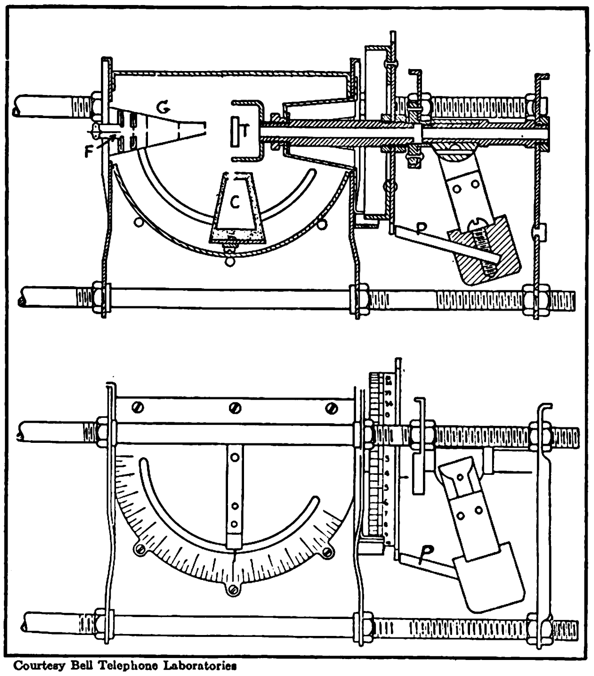
The real trouble was not so much that the electrons obeyed different laws from those of Maxwell and Newton, but that they were not consistent about it. Some of the things they did required the old laws to explain them; others required a new and inconsistent set. Sometimes both had to be used in different parts of the same calculation. The position of a physicist investigating an atom was rather like that of a man trying to make sense of an account of a game which started as golf and suddenly for no apparent reason turned into tennis and then back to golf again. Worse still, as time went on it became clear that the electrons did not play fair even at the game they had for the moment chosen. The results were nearly right but not quite. The only hint was that the quantity "h" came in whenever the atom chose to break the old rules, and this suggested a connection with the photoelectric paradox.

The first really successful attempt to solve these difficulties is due to Prince L. de Broglie. [See SCIENTIFIC AMERICAN, March, 1930, page 183.—*The Editor*.] He realized that the reason why the electron in the atom seemed to follow two different sets of rules at once was that it was behaving much more like a wave than a particle.

Now if you think that you are reading an account of a game played with a ball, when really the reporter was writing about a swimming match, it is not to be wondered at if the report does not make good sense. It is perhaps surprising that the physicists made as much of it as they did. De Broglie's theory was a mathematical one based on relativity. He reached the conclusion that any moving particle would be accompanied by a wave, and he postulated that this wave controlled the motion of the particle. Instead of Newton's laws of motion (motion in a straight line, acceleration proportional to the force, and so on) this view gives a motion governed by waves. Of course Newton's laws are true in every-day life. This is because a very short wave is indistinguishable in behavior from a particle, and the scale of de Broglie's waves is given by "h," which is a very small quantity.

But according to his theory the smaller the particle the longer the wave. For an electron in an atom the wave is quite comparable with the size of the atom, and the behavior of the electron is greatly different from what you would expect of a particle. It has been found in fact that this theory, when fully applied mathematically as it has been by Schrödinger and others, brings order out of chaos in the explanation of the properties of atoms.

Further, it is capable of dealing with the photoelectric paradox. Granting that there are in fact quanta, or particles, in radiation, they will inevitably be accompanied by waves which will guide them. The quota will appear where the waves are strong; where there are many quanta the light will be intense.



Courtesy Bell Telephone Laboratories

The actual apparatus devised by Davisson and Germer for exploring in three dimensions the space surrounding the target *T* of electron gun *G*. Angle of electron collector *C*, may be varied by means of curved slide; also target can be rotated (see dial on lower section drawing of same apparatus). Galvanometer connected to collector *C* registers the number of electrons

In other words, the regions of brightness and darkness will be just those predicted on the wave theory. This way out had indeed been suggested before. It turns the flank of the difficulty by saying that it is the natural way for a particle to behave. But if you accept this you must be prepared to take the consequences. A free electron, such as a cathode ray, should also be guided by waves and should also show diffraction. How could we hope to detect it if it did? Calculation shows that the wavelength of a free electron of manageable energy is of the same order as that of X rays. Can not we use a method similar to that by which the waves of X rays have been measured and take advantage of the regular structure of crystals?

Successful experiments on these lines have in fact been made by Dr. Davisson and Dr. Germer[1] in this country and by myself and others in Scotland. In my own experiments a narrow beam of fast electrons, cathode rays, in fact, pass through a very thin film of metal. The metal scatters the electrons, and since metals consist of a number of minute crystals, the scattering occurs predominantly in certain privileged directions, just as is the case with X rays. Accordingly, if the electron strikes a photographic plate placed somewhere behind the thin film we should expect to get a pattern similar to that produced by X rays of the same wavelength.

This expectation is in fact realized. I have obtained these diffraction patterns from a considerable number of metals. In all cases the patterns are in exact agreement with what is to be expected if they are regarded as the result of diffraction of waves by the known crystal structure of the particular metal used. The patterns are in general formed of concentric rings just like the familiar Debye-Scheerer X-ray powder photographs. From the sizes of the rings it is possible to deduce the wavelength of the waves causing them, and I find in all cases absolute agreement with the theoretical expression due to de Broglie, $\lambda = h/mv$. Thus instead of being scattered irregularly by the metal, it appears that if the film is thin enough it will guide the electrons into the direction which would be taken up by waves diffracted from the crystal structure of the metal.

If you accept the experiments as showing that electrons behave as if guided by a train of waves, you will agree that de Broglie's idea brings a remarkable simplification. Both electrons and light quanta are on the same footing as particles guided by waves.

The difficulties of physics in the earlier years of this century were due to ignorance of this dual character. For some reason we had got hold of the wave aspect of light and the particle aspect of electrons, and were running each to the exclusion of the complementary view. It also explains the curiously confusing nature of the difficulties. If we had neglected, say, the wave aspect in each case, all the new facts would have pointed to waves. As it was, some pointed to particles, and some, as we now know, to waves.

This dual aspect of things as waves and particles must be very fundamental in the world. There is little doubt that protons would show it also, though experimental proof has so far not been possible[2]. There is even strong, though indirect, evidence that a completed atom has a wave as a whole as well as component waves for its individual electrons. One reason for regarding the duality as really fundamental is that it holds for such different things as electrons and quanta. For in spite of this one point of resemblance they are essentially different. The electron has electric charge and hence is influenced by electric and magnetic forces in a way that the quantum is not. The quantum always goes (*in vacuo*) with a speed of 300,000 kilometers a second. The electron can go with any speed, provided it is less than this. For equal wavelengths the penetrating power is quite different.

These differences make it all the more significant they should both show the same curious duality. The new view is not by any means free from difficulties. To take the most obvious, many electrons form part of each of the atoms of a crystal, yet the experiments I have described essentially involve the idea that the wave of the moving electron is spread over a number of the atoms in the crystal. Have we proved that the part is greater than the whole? I think that even modern physics is not so paradoxical as this. It depends on what you mean by the size of an electron. We can measure the size of atoms in a fairly definite way by finding how many can be packed into a given space of solid. It is rather like measuring the size of shot by counting how many will fill a cartridge case of known volume. Of course we have to allow for possible empty spaces between, but this can be done if we know how they are piled together, and in many cases we do. The sizes are not quite definite; they vary a little with circumstances, but this is not surprising.

Suppose that you want to know the size of a tennis ball. It is easy enough to measure it to an accuracy which will satisfy the authorities at Wimbledon that it is legal, but if you were asked to give its diameter to a hundredth of an inch there would be difficulty. Are you going to measure it to the farthest-out hair of the felt? Obviously that is not a very important measurement, but where are you going to stop? There is no sharp edge. Here a rough measurement has a real and useful meaning, but if you try to make it precise beyond a certain point it can be done only by making some arbitrary convention, such as how hard the measuring instrument is to press.

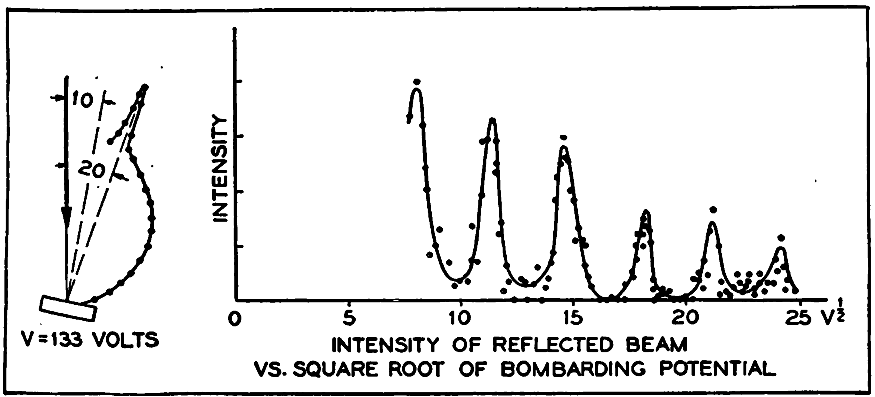
---

[1] See page 7.

[2] Soon after Dr. Thomson made this prediction it was made good by Professor A. J. Dempster of Ryerson Laboratory, University of Chicago. See our April number, pages 263 and 264.—*The Editor.*

This is the case of the atom, but for the electron the size is even less definite. It has not got even an approximate boundary, as far as our present knowledge goes. It is more like a gas which can expand to "fill" (in a sense) any vessel into which it is put, and yet can be compressed into a very small space. When an electron is part of an atom, its waves curl round, as it were, on themselves until it occupies only the atom, and perhaps only a part of that. When it gets free from the atom as a cathode ray, or escapes from the filament of a valve or vacuum tube, its waves can uncurl and expand indefinitely. I think, however, that in all cases one must consider it as also having a sort of center, even if this is only a mathematical point. Whenever an electron produces any detectable effect it does so as a particle, and it seems easiest to suppose that even when it is not producing an effect the particle is somewhere 'round. The best analogy I have been able to find for this view is a gossamer spider.

WHEN this little animal is clinging to the stalk of a plant, it is a small solid object. When it wants to move it shoots out long filaments many times its own length. The wind catches these and wafts it away. I regard the filaments as analogous to the waves which surround the electron, while the body of the spider is analogous to the central point. One can press the analogy further. If the wind carries the spider so that one of its filaments is caught in an obstacle, the spider will be swung around and its path deflected although its body has not hit anything solid.



Courtesy Bell Telephone Laboratories

Davisson and Germer also measured the selective intensity of the reflected beam of electrons as a function of speed (potential) of bombardment of target. "We find," says Dr. Davisson, "that it passes through one maximum after another as the speed is increased." (Note curve.) These classic experiments are comprehensible on the hypothesis that electrons are "trains of waves of wavelengths comparable to distances between atoms in solids." All these famous experiments were performed in 1928

In just the same way with the electron, if its waves pass over an obstacle, say an atom, the direction is modified and this modification is transmitted back through the wave system to the electron itself. If we suppose that the electron is constrained always to move in a way determined by the waves in its immediate neighborhood, the motion of the electron itself will thus be modified. The waves thus act as a kind of intermediary between the disturbing objects and the electron itself. The electron goes where the waves in its immediate neighborhood carry it, just as the spider is pulled by the parts of the filaments which are actually attached to it. But the form of the waves, near the electron, is determined by events at a distance, whose effects are propagated through space in the form of waves.

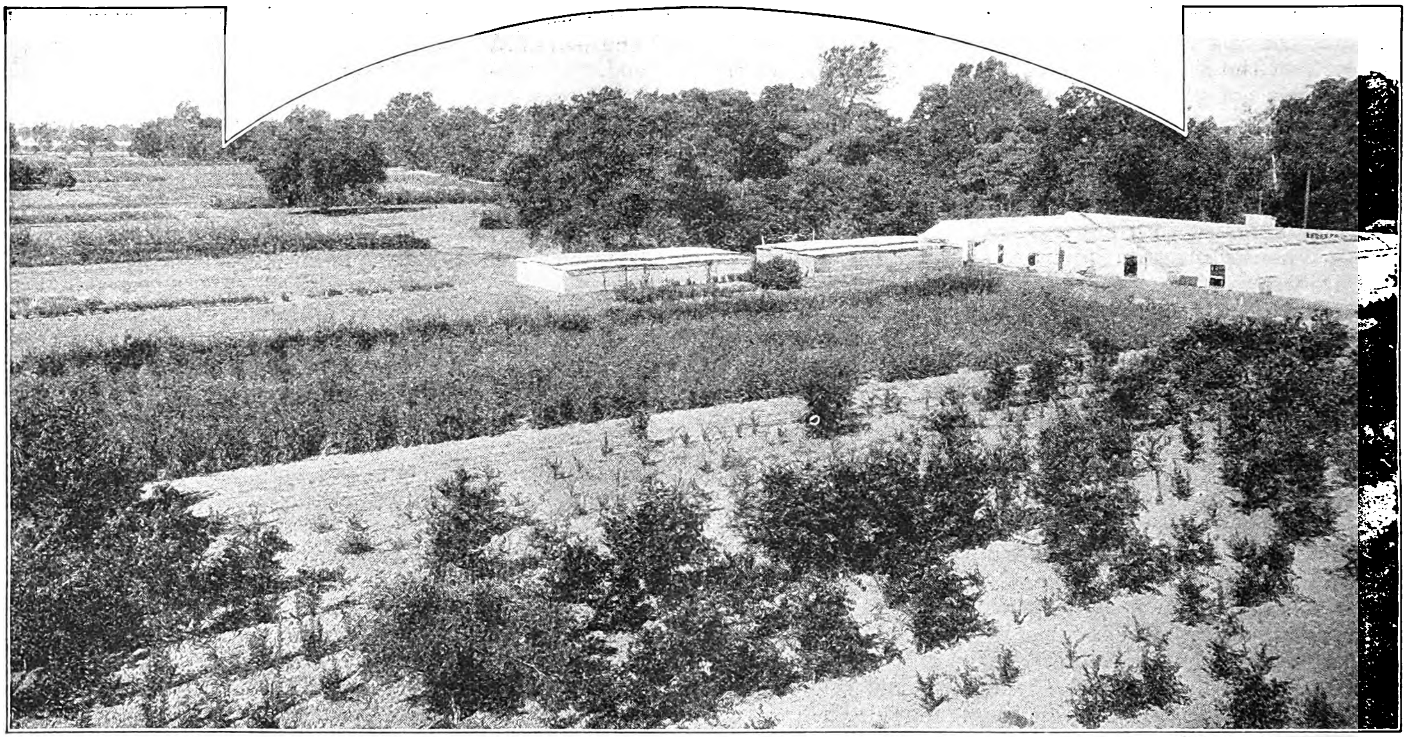
A question that inevitably arises is—what is the medium which transmits electron waves? I am sorry that I can give no entirely satisfactory answer. For the first time, physics is faced with waves in empty space which do not fit into the ordinary series of ether vibrations. All the ether vibrations differ only in wavelength; if the wavelength is given, the kind of "light" is fixed. The electron waves have varying wavelengths, depending on the speed of the electron, but they usually fall in a region of wavelengths which is already appropriated by X rays. As we have seen, they are certainly not the same as X rays. One must suppose some other medium, or at least that the ordinary ether is in some way profoundly modified by the presence of the electron. It is possible that they are waves in a "subether." But it is not a very attractive idea to have two ethers filling space, especially as the waves of protons, if they exist, would demand yet a third. Space is getting overcrowded.

Other suggestions are to regard the waves as a kind of mathematical abstraction, a sort of ghost waves. The whole question is getting very metaphysical. Perhaps a simple physicist may be content as long as the waves do their job of guiding the electron, and it is possible that, after all, the question will ultimately be seen to be meaningless. Whatever the medium is, the new wave conception has altered the view we take of the best answers to the question with which I began this lecture. Matter is still supposed made of discrete units, but instead of these units moving by laws which concern them alone as did the laws of Newtonian dynamics, we have had to introduce laws based on waves. Now a wave is essentially a continuous thing, even if the continuity is only mathematical. It is spread through space, not divided into little lumps. So although the older belief in the discontinuity of matter still holds, it has lost some of its rigidity; continuity has crept in by the back door.

The idea of the ether has also changed. The sole function left it is to guide the quanta; they do the work. The picture of light as waves breaking on a shore of matter, and thus disturbing it, is replaced by one of a stream of bullets which affect only the particular objects which they hit. The bullets, it is true, do not move quite as ordinary bullets would; they are directed by the waves, but all the effects are bullet effects, not wave effects.

WE have seen that Newtonian mechanics needs modification; that it is a simplification which is permissible only when the wavelength is very small. This of course does not detract from its practical value in every-day life and in astronomy, nor from our estimate of the genius which gave it a form which has satisfied two and a half centuries. On the contrary, the new developments, as far as they concern light, which I have tried to explain to you at such length, are much better expressed in the words of Newton's Optics. "Those that are averse from assenting to any new discoveries but such as they can explain by an hypothesis, may for the present suppose, that as stones by falling upon water put the water into an undulatory motion, and all bodies by percussion excite vibrations in the Air; so the Rays of Light excite vibrations in the refracting Medium or Substance . . . that the vibrations thus excited are propagated in the refracting or reflecting Medium or Substance, much after the manner that vibrations are propagated in the Air for causing Sound, and move faster than the Rays so as to overtake them . . . and that every Ray is successively disposed to be easily reflected or easily transmitted by every vibration which overtakes it. But whether this Hypothesis be true or false I do not here consider."

After being regarded for generations as an artificial attempt to save a dying theory, we have proved this guess of Newton's to be a supreme example of the intuition of genius.



Jujube trees are being propagated in the foreground of this scene which shows the greenhouse and nursery at the Chico station

An Immigrant Plant Proving Ground

By Charles W. Geiger

FEW Americans realize that plant introduction has given to the United States practically all of its commercial crops. Thousands of the new plant immigrants that enter the country each year find their first home in the plant introduction field stations, or gardens, of the Department of Agriculture. These are the "Ellis Islands" of the plant immigrants, but they also are the workshops, field laboratories, and plant propagation factories of the Office of Foreign Plant Introduction.

The United States Plant Introduction Garden near Chico, California, is the largest government-owned and operated garden of its kind in the United States. This station serves the State of California primarily, and other regions on the Pacific coast generally. It is located in one of the leading deciduous-fruit, nut, and citrus sections in northern California. The high summer temperature, abundance of water for irrigation, long growing season, and mild winters of this region make possible the propagation and testing of such widely different species of plants as alfalfa from the steppes of Siberia, hardy apples, pears, and cherries from Russia, chestnuts, jujubes, and persimmons from northern China, and citrus fruits from the tropics.

The Chico station consists of 210 acres of land, three hot-houses, and office and residence buildings. The entire garden is under irrigation, the greater part of it under a pressure system. For the entire garden there is an electrical installation of approximately 30 horsepower for pumping service.

CHICO is primarily a propagating and testing station. The plants are tried out there and if they seem promising, they are then distributed for experimental purposes, on order from Washington, to state experiment stations, botanic gardens, arboreta, and similar institutions. There is, in addition, a list of qualified experimenters to whom material is sent when there is more than that required by the regular research institutions.

The thousands of new plant immigrants annually received in Washington in the form of seeds, plants, cuttings, and so forth, from the agricultural explorers and correspondents of the office, are unpacked and given an identification number in the specially equipped plant-inspection laboratory of the office. If a plant immigrant is found to be affected with insects or other pests or with diseases, it is ordered into quarantine, and the necessary treatment is prescribed and administered. If found to be free from insects and diseases, it is given a clean bill of health. It may then be forwarded to the experimenters within the department for whom it was especially secured, or to the plant introduction garden at Chico, California; Coconut Grove, Florida; Bell, Maryland; or Savannah, Georgia. The selection of any particular one of these four gardens depends largely on the character of the plant.

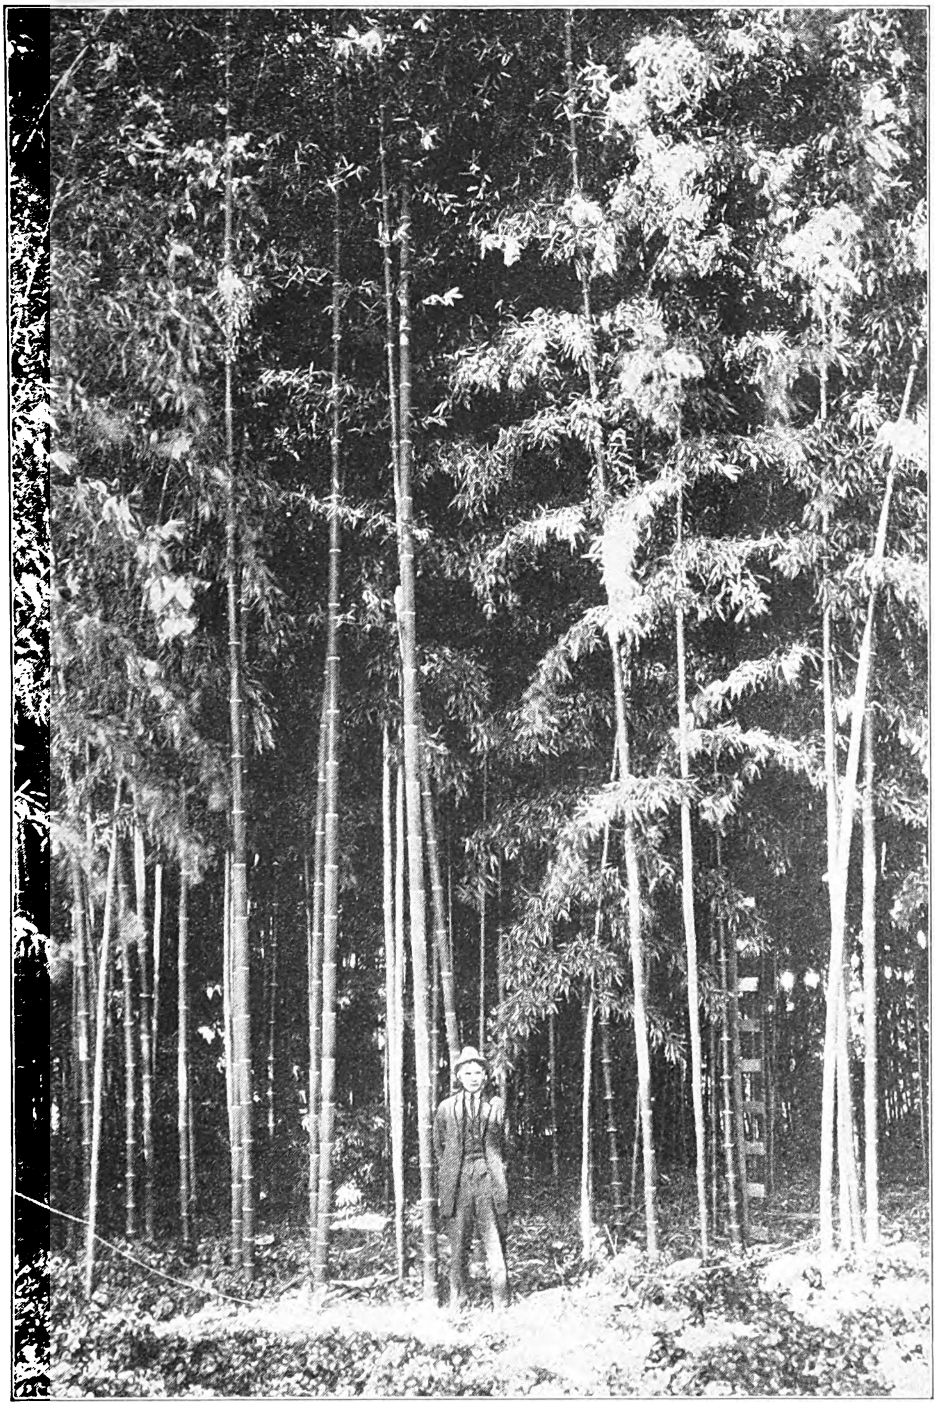
THE plant propagators at these gardens have frequently to resort to every known practice of the craft to save an introduction which arrives out of season or in a critical condition; and in some instances, when the plant introduced is unknown and no information regarding its identity can be secured, they must rely upon their own ingenuity in developing methods of handling such material in order to save what may eventually develop into an important new plant industry.

The propagation houses, cold-frames, lath sheds, greenhouses, and other equipment at the plant introduction gardens of the department, together with trained superintendents, experienced plant propagators, and a corps of capable gardeners and laborers afford excellent facilities for the propagation and preliminary testing of the thousands of new plants annually introduced. They also make possible the efficient distribution of new plant material to specialists of this department, state experiment stations, botanic gardens, and to a limited number of private experimenters.

Among the host of interesting new plant introductions which have been propagated at the Chico station, a few selected examples will give some idea of the range of species handled and the variety of the problems presented.

The jujube, or so-called Chinese date, is a promising plant for California and the semi-arid south and southwest. The experimental tests made with this alkali-resistant and drought-resistant fruit at Chico, to determine the possible value of the strains and varieties that have been introduced, have been very satisfactory. The fruit of the better varieties is fully as large as a large prune, and reddish or mahogany brown in color when ripe. While the jujube is a very good fresh fruit, it is undoubtedly of greatest value when processed with cane sugar or honey. Prepared jujubes are as delicate in flavor as many dates.

From the seed of the tung oil trees (See page 355, May, 1930, SCIENTIFIC AMERICAN) is made an oil which the paint manufacturers of this country consider one of the best drying oils known to the trade. Trees of this plant immigrant distributed from the Chico garden in 1906-07 are doing well and bearing fruit in many places in the region extending from northern California to and throughout the Gulf States, but appear to be doing best in northwestern Florida and the southern parts of Georgia and Alabama.



It has been well said that there is no other plant which is so intimately bound up with the life of man as the bamboo. Here is a forest of it at Chico

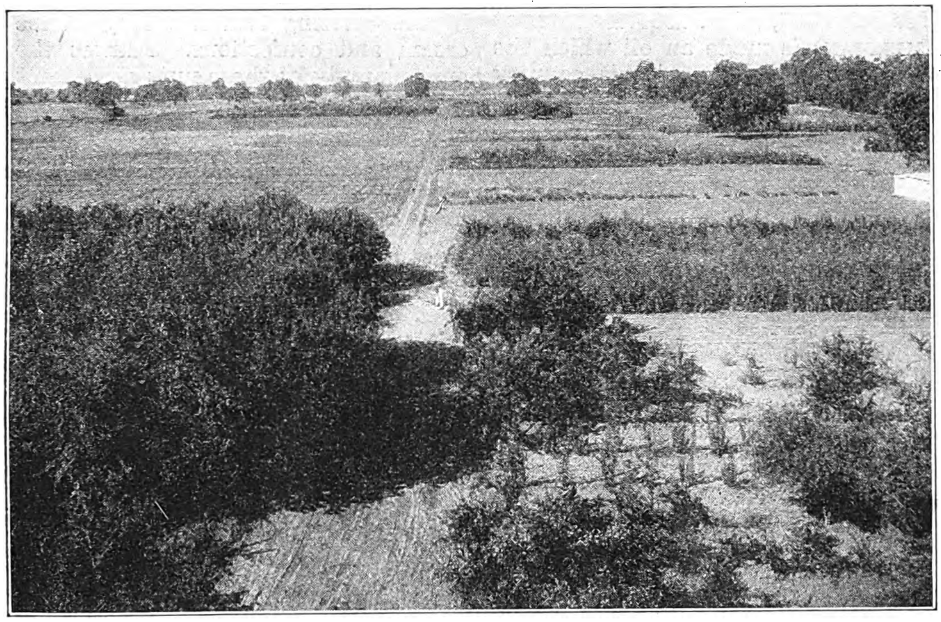
The pistache tree, a promising introduction from central western Asia, presages another new industry for the United States. The small, green-fleshed nuts are delicious when roasted and salted, and are extensively used in the coloring and flavoring of ice cream and confections. Almost the entire supply of these nuts at present comes from abroad. The trees do exceedingly well in the Sacramento and San Joaquin Valleys in California. Seedling trees near Fresno, California, have borne large crops of nuts for some years.

Budded and grafted plants of some of the best commercial varieties have been distributed to experimenters interested in testing out this introduction to determine the possibilities for its cultivation as a new plant industry. The peculiar beauty of the Chinese pistache tree and the great age to which it lives have suggested its trial as an avenue tree, and thousands of young trees have been distributed to parks throughout the country. A trial avenue, a quarter of a mile long, planted at the Chico garden in 1910, has already made an excellent appearance.

THE Chinese varieties of persimmon vie with those of Japan in size, quality, beauty, and hardiness. Many varieties have been propagated at Chico and the special Chinese stocks upon which they are grown in China have been used. The region in which the oriental persimmon can be successfully grown commercially includes California and the South, where the temperature does not fall much below freezing. The culture of this excellent fruit is destined, sooner or later, to develop into an important industry. Dried persimmons form a staple food product of China and Japan.

The Chinese dry-land elm is a promising new plant immigrant. This elm is found throughout northern China and Manchuria and is known to be very resistant to drought, neglect, and extremes of heat and cold. Seedling plants of this elm secured at Fengtsi, near Peking, Chihli, China, in 1908, were grown and distributed from the Chico station. These early distributions proved sufficiently promising to justify its propagation in quantity for distribution throughout the United States. The stock at the Chico garden being limited to a few small trees retained for permanent planting, it was necessary to resort to propagation by dormant hardwood cuttings. Tests with this elm indicate that it is likely to be of very great value for windbreaks, shelter belts, and other plantings in the Great Plains region.

A promising, small, early, sweet cherry introduced from Tanghsi, China, in 1906, was saved to the country by a chance graft. When this introduction was received at the Chico station, the gardener, after working practically all of the scions received upon nursery stock in the usual way, conceived the idea of running the remainder into the small limbs of an old seedling cherry tree. The scion worked upon commercial stocks all perished, but two of those worked upon the old seedling tree survived. In the following spring these grafts were in full flower before the buds of the seedling tree began to swell, and they ripened their fruit by the time the old tree was in flower, or several days earlier than the earliest commercial cherries of that region. From the scions thus saved, a large number of plants have been propagated and distributed throughout the country for experimental tests. At Yuba City and Vacaville, California, this introduction gives promise of being of considerable commercial importance as an early cherry for the eastern markets.

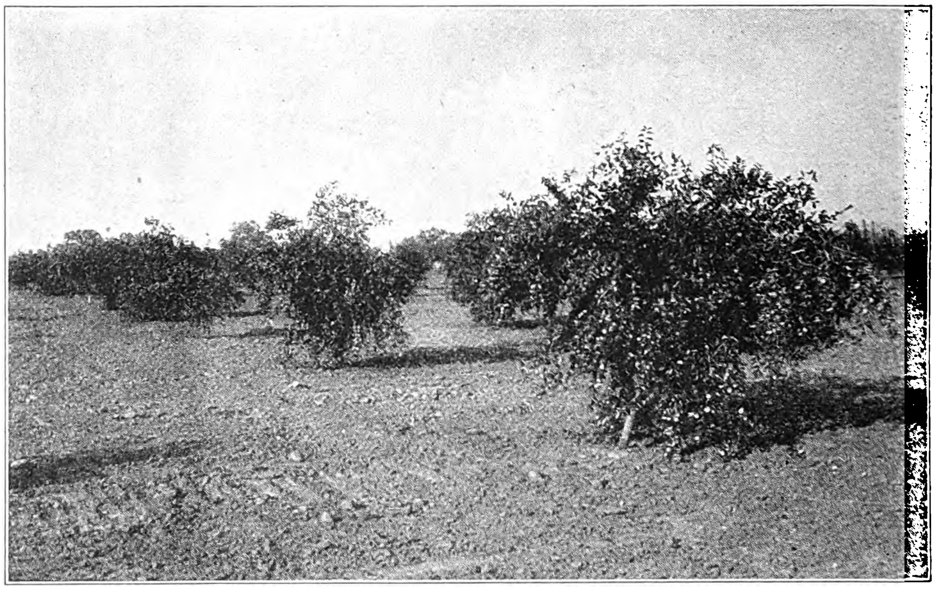


A section of the nursery at the Chico Plant Introduction Gardens

THE Davidiana peach appears to be quite resistant to alkali and drought and well adapted to the deep alluvial soils of California. It is also succeeding at San Antonio and other places in Texas and has stood a temperature of —40 degrees at the State Agricultural Experiment Station, Ames, Iowa, with little or no injury when 50 other varieties, tested in comparison, were either killed outright or seriously injured.

The fruit of this wild peach is small and inedible, but the introduction may, because of its extreme hardiness, prove valuable in hybridization experiments for the production of much hardier types of commercial peaches.

Interest has been maintained in bamboos and their probable uses in this country for several decades. We have no native bamboos worthy of the name, our nearest approach to the many varied and useful forms of other countries being the arundinarias of the southern states. During the past 30 years the Office of Foreign Plant Introduction has imported into this country more than 60 inventoried numbers of bamboos.



An orchard of the better variety of jujube tree at Chico Gardens

Long before the Department of Agriculture inaugurated its systematic work on agricultural explorations, some 30 years ago, bamboos were being brought into the United States in various ways. These unusual and often strikingly beautiful plants naturally attracted the attention of travelers, who found they could be lifted in clumps and kept alive for several weeks. Isolated plantings were thus early established along the southern seacoasts and some of these have developed splendidly.

EARLY in 1908, David Fairchild, in charge of the plant introduction work of the Department, inaugurated some extensive measures for bamboo introduction. The services of W. D. Hills were obtained in Japan, and he was authorized to get together, grow, and ship to the United States a large collection of three or four varieties of the most important economic bamboos. When Mr. Hills had completed his plans he returned to the United States in the autumn of 1909, on an Army transport, bringing 3500 bamboo clumps with him. The plants were divided into two lots, one being sent to William Tevis, Bakersfield, California, and the other to the Plant Introduction Garden at Chico, California.

The clumps sent to the Tevis place were planted in the open ground in January, when it was cold, and although the best of care was given them, most of the plants died. The Chico shipment was put in a greenhouse and carefully nursed. Heat was supplied and plenty of water given. These plants came through in fair shape, and most of them were shipped to a garden at Brooksville, Florida.

It is impossible to foresee what the future has in store for the bamboo in the United States. That this group is worthy of study and effort is beyond question. Who knows that some day these giant grasses may play an important rôle in our welfare. As our forests disappear and the need is more and more felt for quick-growing and easily worked wood material the bamboo may find an important place here as it has found a vital niche in the scheme of things in many countries of the world.

A Clearing House for Inventions

AMONG the many things which have contributed to the development of American business, two infrequently stressed factors stand out significantly. One of these has been the remarkable ingenuity of American inventive genius; the other has been the flair of American business men for commercializing inventions. And yet until quite recently no organized facilities have existed for the promotion of new ideas. American finance, highly organized in all other branches, has left this important field to unorganized or casual direction.

It is common knowledge that the typical free-lance inventor is a lone worker who pursues his own ideas in his own way, often under obscure conditions; and it is rather a strange circumstance that the American inventor today is as much at a loss to know where to turn for the commercialization of his ideas as he was 50 years ago. In the meantime practical and profitable contact between industry and inventors is urgently needed. Every industrial concern today is in danger of having its product or products not only equaled but in some cases bettered or entirely supplanted. Obviously the one effective means of anticipating this serious competition, with its resultant slowing up of production, is to have adequate and systematic access to the wide and growing field of free-lance invention.

EVERY year inventive genius produces thousands of new inventions and numerous new industrial processes. Sometimes they justify the incorporation of separate companies but more often they call for absorption by established industries; that is, if they are properly brought to the attention of those that need them. The inventor, as has been implied, is too often an impractical business man.

Now, however, there is being assembled a group of manufacturers in an organization which will persistently search out new inventions and endeavor to place them in the hands of manufacturers most likely to be interested in their production. This corporation is Campbell, Peterson & Co., Inc., who have had seven years of specialized experience in the examination, selection, and development of new things, and have now evolved a collateral service which provides, on an organized basis, an experienced clearing agency for inventions.

Directed by men of prominence in industry and finance, who are also officers and directors of companies the combined assets of which total over five billion dollars, this corporation is an organized agency to which inventors may submit their ideas for study, classification, utilization, and financing. Fortunately the organization which undertakes this task has already been able to demonstrate in its own experience the practicability of its procedure. Since its inception in 1923 the company has developed through private development syndicates five interesting businesses based on new inventions.

As a clearing house for inventions and the utilization thereof, this organization is setting up an industrial intelligence service which will consist of an investigating and research department and an industrial service department with widespread domestic and foreign affiliations.

THE industrial service bureau will solicit, through advertising and contact, newly invented machines, devices, processes, and so forth, from various sources. It appears conservative that the number of inventions which should thus be made available will range from 10,000 to 20,000 per year, based upon the fact that without advertising or other solicitation the company has received in the past well over 1000 inventions annually. Among the sources which will be canvassed are free-lance inventors, research laboratories of technical institutions, patent attorneys, industrial advisers who have inventions submitted to them, reports of technical societies, et cetera.

In regard to foreign affiliations, the organizers have knowledge of one foreign agency which is now successfully operating and which, it is reported, has access to new inventions of central Europe. This agency, which is headed by prominent European industrialists, has expressed its interest in effecting a working agreement with the American company. Already affiliations have been established for the purpose of attracting new inventions from most of the countries of Europe. It is planned to secure through these foreign affiliations representation in all of the principal industrial cities of the countries concerned.

The present investigating department will be expanded so that its facilities will be adequate for investigating all proposals meriting more than preliminary examination. The staff of this department, trained for this purpose and experienced, will assemble and study products and inventions submitted, and satisfy themselves as to their elements of originality and commercial possibilities. It is expected that this department will provide a steady stream of analyses of new and unappropriated inventions suitable for the consideration of American manufacturers.

THE information service will be made available to suscribing members in the form of printed bulletins, and drawings or photographs if these are available. Any subscriber desiring further information on any invention may arrange for a further discussion of details. When the matter progresses to a point where purchase or license of a device or patent is contemplated, the subscribing member may either negotiate the matter direct or he may retain the service of the organization. The list of subscribing manufacturers will be limited in number to 200, including one company in each field of industry as those fields have been distinguished in a careful survey. Inventions will be placed outside this selected group when they are not wanted within the group.

Contact will be maintained with subscribing members not only through the distribution of information in printed form but also by special letters or other communications calling attention to the possible use of certain inventions to meet the particular needs of subscribing members. Regular visits to plants or offices of subscribing members will be made in order to ascertain their needs and increase co-operation. Inventors will be notified of manufacturers' needs and encouraged to co-operate in the solution of their problems.

As occasion arises for the financing of such inventions or processes as are deemed suitable for building into individual industries, the company will form underwriting syndicates.

The inventor who wishes to capitalize his "brain child" but admits a lack of the necessary knowledge of financing problems, who has not the industrial contacts, or who cannot or does not wish to spare the time attempting to sell it to some manufacturer, may thus have all the details attended to by this new well-supported organization. Its liaison service promises a solution to the inventor's problems. With his invention in their hands, the inventor stands a better chance of having it commercialized than if he attempted to do the job himself—and at a nominal cost; and he may then turn his thoughts to other inventions or projects.

ON THE OPPOSITE PAGE

1. Here we see the pioneer staff in the early nineties. These men were osteologists, geologists, zoologists, microscopists, mineralogists, ichthyologists, and anatomists or preparators. Many of them became prominent figures in the educational world. One of them has worked for this institution for 56 years

2. Preparing a rock specimen. The rocks are first broken in the mineral trimmer and then are finished with the hammer

3. Articulating a human skeleton. The osteologist is adjusting the arm so as to permit of the proper movement. Note the picturesque specimens and tools

4. A step in the production of a contour map. Mr. Blackstone is shown enlarging with a pantograph. Relief maps are largely used for educational purposes

5. The artist's corner. Here the expert, Miss Waters, is putting the finishing touches on a scientifically accurate model of an extinct animal, the *Archisaurus*

Mr. Oscar Kirchoff, head of the Department of Biology, is shown examining gorilla skulls which have just been received. The fine collection is unique

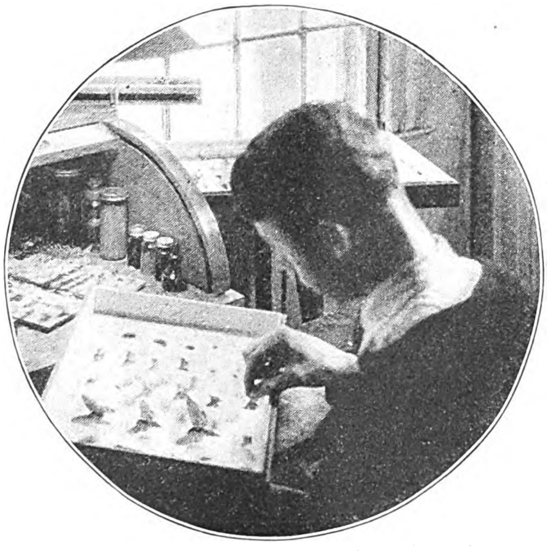
America's Cradle of Natural Science

A Curious Industry Owned by a University to Supply the Needs of Colleges

NESTLING near the University buildings at Rochester, New York, is an interesting group of old buildings where natural science in America may be said to have been cradled. Here was the incubator where many of the leading museum directors and curators of today served their apprenticeship. Among the great names are Carl E. Akeley, Dr. F. A. Lucas, Dr. Wm. T. Hornaday, Prof. James Orton, Dr. Chas. H. Townsend, Dr. Henry E. Crampton, Dr. C. E. Cummings, and a dozen others. The group of buildings are very unpretentious but the interiors are highly picturesque, as will be seen by the illustrations. In the early days taxidermy was in its "upholstery" period. This means that you stuffed an animal the way you would a chair. Akeley changed all this and here is where he learned the art which he was to regenerate.

It might be asked "What is a natural science establishment?" This can be answered best by a quotation from an old circular of the nineties. "This is a serious scientific institution; a great clearing house to which are brought and from which are distributed objects in all departments of nature. These objects we first collect, then prepare, determine, label, and gather into classified series, compiled to suit the needs of museums and educational institutions of all kinds. The general public knows of the establishment as the little village on College Avenue with the whale jaws over the main gateway—where Jumbo was mounted—and where can be seen curios from every clime. To the small boy this is a benevolent institution, where cats, turtles, birds' eggs, snakes and other vermin can be converted into cash. To the naturalist we are a place of terrible temptation, where rare and beautiful specimens of all kinds unite to awaken covetous cravings."

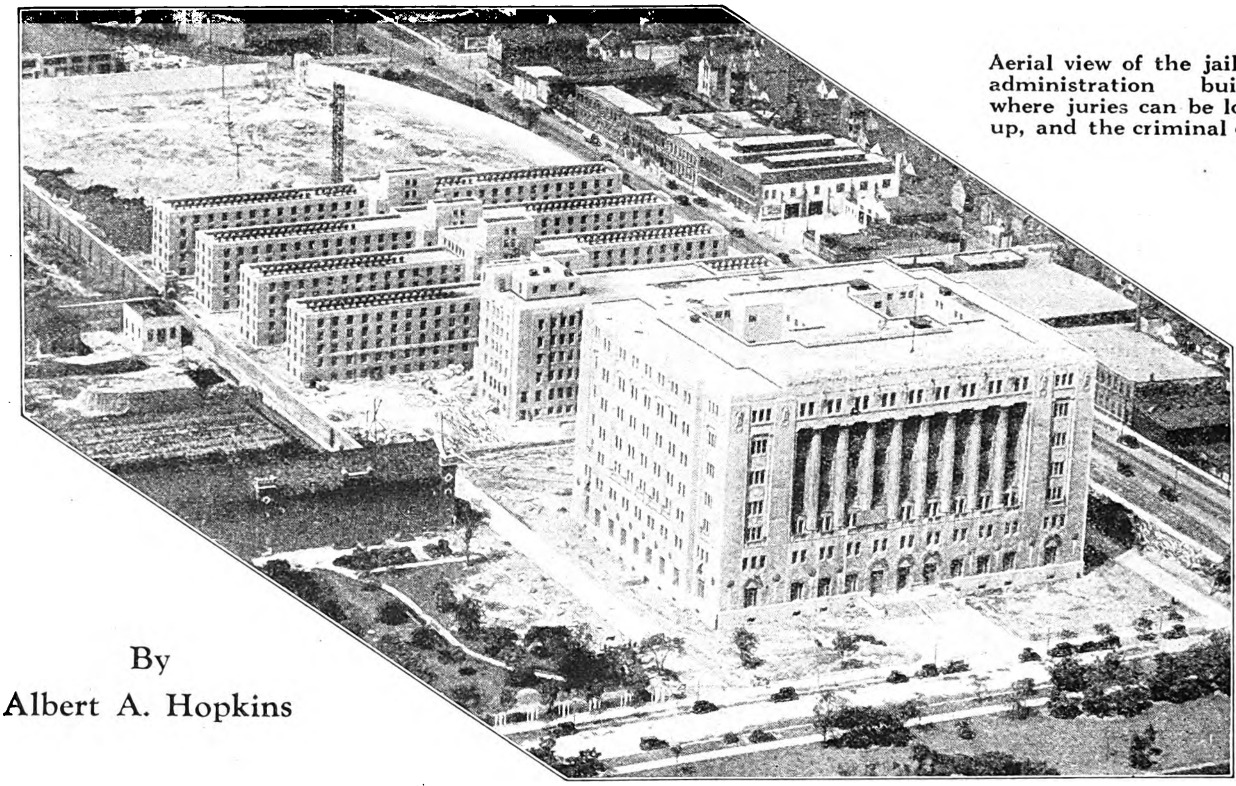
From 1862 this unique establishment, founded by Henry A. Ward, has had no rival. When colleges were indifferent to natural science Mr. Ward held the lamp aloft and kept up interest in the subject. In the period of its existence it has issued 295 circulars and 43 catalogues; the last one (issued only recently) is a valuable reference work of over 200 pages. Among the subjects listed are scientific models, charts, skeletons, zoological material for exhibition and demonstration, entomological specimens and supplies, zoological material for dissection, microscope slides, paleontological specimens, relief maps, geological models, and mineralogical specimens of all kinds.



Mr. Ocorr is transferring to a case specimens of insects which have been expanded

ON January 1, 1928, the ownership of Ward's Natural Science Establishment passed to the University of Rochester, the transfer being made as a gift for a memorial to Mr. Frank A. Ward who for over 50 years directed the affairs of the establishment. In taking over the ownership it is not the intention of the University to conduct the establishment as a money-making institution, but rather to make available all such material as can be supplied at the lowest possible prices.

The writer has visited this institution twice and was reminded very much of Mr. Venus's shop in Dickens' "Our Mutual Friend." Here are boxes of shells, boxes of minerals, boxes of bones, all in great mental order but extremely picturesque to look at. Through the co-operation of Mr. F. H. Ward these pictures were secured.



Aerial view of the jail, the administration building where juries can be locked up, and the criminal court

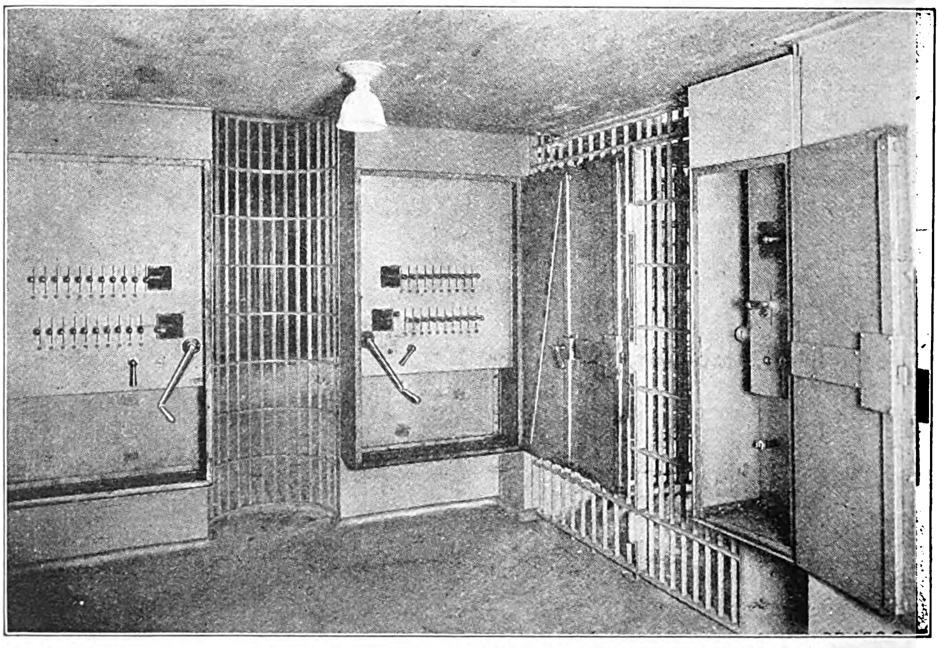
Albert A. Hopkins

Chicago Gets a New Jail

CERTAINLY Chicago was entitled to a new jail and when she got one she got a good one, the cost being 7,500,000 dollars. They tried to build for the future but they can put out the "Standing Room Only" sign right now. Of course we know all about Chicago's crime wave but the new jail seems to be about the only answer that can be made to the gangster, the yegg, and the racketeer. The Cook County jail is the largest jail in the United States, and it is one of the most humane ever constructed. The writer is indebted to Mr. Eric C. Hall, County Architect, of the firm of Hall, Lawrence and Ratcliffe, Inc., who designed the structure and to the engineers of the Van Dorn Iron Works for much assistance in the preparation of the present article.

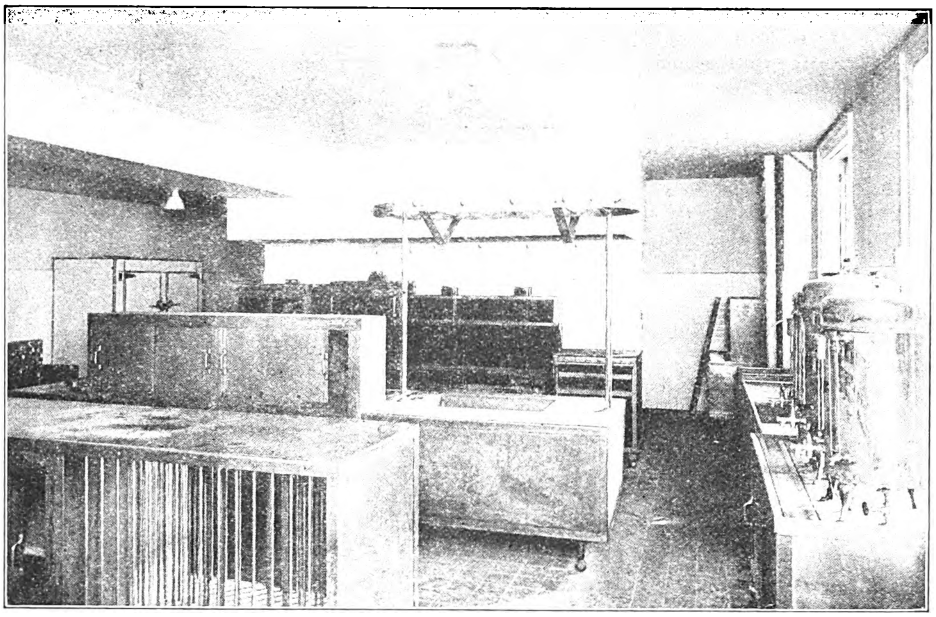
THE site comprises about ten acres and was formerly occupied by a school. It is next to the house of correction, or Bridewell. The group of buildings includes a stately court house, an extremely efficient administration building, and four units of cell buildings. They are all connected by a prisoners' tunnel and prisoners' corridor so that there can be no attempt at rescue. The criminal court building is a beautiful structure 239 feet long, 181 feet wide, and 139 feet high. It contains 14 regular court rooms besides the manifold rooms necessary for the orderly and rapid administration of criminal justice in a large city.

The second building is of considerable interest as it embodies many new features. This administration building also is of considerable size, being 150 feet long and 62 feet wide. It is divided into independent parts between which there is no connection. One is for the accommodation of 12 juries at the same time. Each jury is provided with a three-room suite, two baths, and a separate dining room. There are three rooms in each suite because, although not yet, of the possibility of juries consisting of both sexes. You never can tell when such innovations will take place. There is also a general recreation room for jurors, quarters for jury bailiffs, separate dining rooms, and the jurors' kitchen. The other part of the administration building is for the superin-



Control compartment enables a guard to direct the movements of 39 detained persons. Doors to cells are opened and closed mechanically from this station tendent of the jail and his assistants and contains facilities for receiving inmates. Looking down from the air a "telegraph pole" is suggested by the disposition of the structure.

The remaining four structures are cell buildings, each consisting of four stories and English basement, 343 feet by 32 feet by 37 feet high. These buildings contain a total of 1302 cells. Additional units can be built as required. The cells are classified as receiving, general, hospital, isolation, and debtors'. They are divided among 36 units. Thirty-two of these are typical, two of them being on each of the four floors of each of the four cell buildings. Each of these typical units is complete in itself, permitting of group classification and segregation of inmates.



In the jurors' kitchen in the administration building hot meals are served to jurors who are locked up to deliberate. Twelve juries can be accommodated

THE typical unit contains 39 cells, each five feet by eight feet by eight feet four inches, made purposely so small that it will not provide for more than one inmate at a time, thereby insuring individual segregation. Each of the cells contains a bed, a bench, a drinking fountain, and a push button, with which to signal the guard in the control compartment.

From the administration building access is given to the four cell blocks at the first floor level, and elevators serve to convey inmates, guards, and visitors to the various floors. At each floor there are two guards' rooms facing each other with the public corridor between. Surrounding each of the blocks of 39 cells and separated from it by a grating is the guards' corridor which enables them to walk completely around the cell area. The windows in the outside wall are located opposite every other cell, thus insuring plenty of light and air.

Adjoining the control department inmates can see and talk through glass which prevents passing contraband

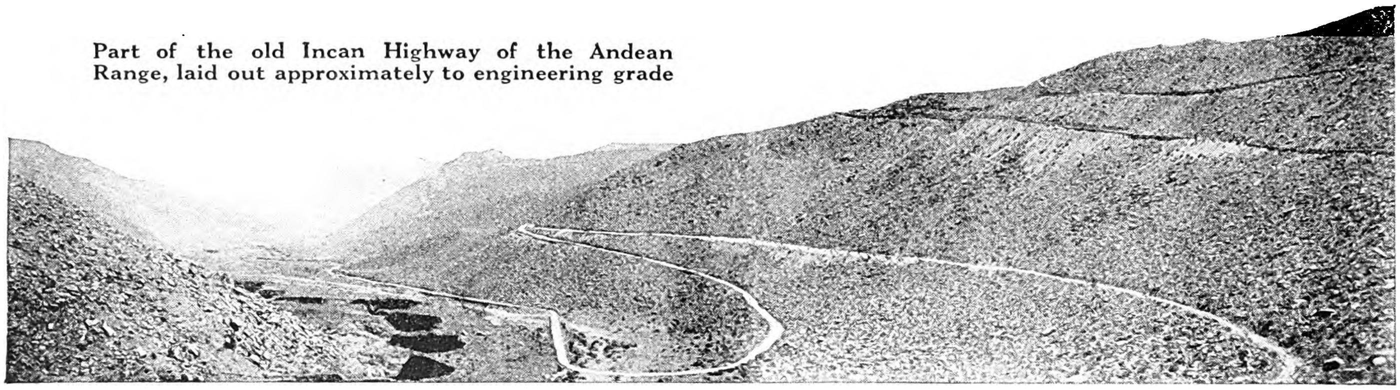
In a cell block 39 cells open into a central cell corridor. One guard controls all doors

The 39 cells open into a central cell corridor and are provided with doors which are unlocked, closed, and locked by means of a mechanically operated locking device. The control is vested in a control box situated in the isolated guards' room. The central corridor on each floor of each cell block leads into the inmates' recreation room, 20 by 31 feet, where the detained persons eat and spend their time when not in their cells. Adjoining is a serving kitchen, the food being supplied by a dumb-waiter from the central kitchen in the basement. In connection with the recreation room, otherwise known as the "day" room, there are toilets and a shower room.

Adjoining the guards' control room is a space where persons who are detained may see and talk with their friends through shatter-proof glass, which enables a conversation to be carried on without danger of smuggling weapons, drugs, or other contraband. Adjoining the guards' control room is a compartment for inmates to consult with their attorneys.

Each cell door is controlled by the guard from his practically armored room. A semi-circular tool-resisting grill enables him to view the entire prisoners' corridor through the recreation room. When a detained prisoner wishes to leave his cell for any legitimate purpose he pushes a button and his call is indicated on an annunciator in the guard's room. The guard then goes to the proper control box (right or left) and by dropping a small lever he unlocks the cell door in question and permits the prisoner to leave his cell. The guard can then lock the door in an open position, if he so desires, so that it cannot be closed without his sanction.

WHEN the prisoner returns to his cell the guard then closes the cell door by means of the large crank shown at each side of the semi-circular grill. The entire operation of opening and closing the door can be accomplished without disturbing any other cell door. All the cell doors in a single row can be opened at one operation at meal time or in an emergency. The steel in the cell blocks is tool-resisting which means that bars cannot be mutilated by the inmates, under prison conditions. The cells are fireproof.



Part of the old Incan Highway of the Andean Range, laid out approximately to engineering grade

America's First International Highway

By A. Hyatt Verrill

Pre-Incan Aborigines Engineered a "Modern" Highway 4000 Miles Through the South American Andes

IN these days of transportation and traffic problems, of the universal automobile, and of the constantly increasing trend of travel to South and Central America, the proposed International Highway is of the greatest interest to the public. But how many of us know that centuries before the first European set foot on American soil an international highway had been constructed and was in daily use?

To be sure, this highway did not link the two continents, but it linked several great nations; it was over 4000 miles in length. Many of the facts regarding it seem incredible, even with our present-day knowledge of road-building and modern engineering, our massive machinery and labor-saving devices.

THE International Highway to which I refer was the "King's Road" of the Incas; a road built by the ancient aborigines of South America; by men who, so far as we know, were entirely ignorant of the use of iron or steel; who possessed no true mathematical instruments, no transits, no compasses, no comprehension of engineering as we understand it. Yet they built their marvelous road through country that presents some of the greatest obstacles. Even the Romans never succeeded in building such a roadway and, compared to the Incan road, the famed Appian Way was scarcely more than a trail.

From Quito in Ecuador, to beyond Tucuman in Chile, the Incan Highway followed the general line of the Andes. At intervals, side roads branched off. A second road 25 feet in width, and almost as remarkable as the first, followed the shore line from Ecuador to Chile.

No one knows when this remarkable road system was started, how much time was required for its construction, what it cost in labor and riches, when it was completed or what man first conceived the idea. Although called the Incan Road, and while unquestionably extended, improved, and maintained by the Incas, yet much of the main highway antedates the Incan Empire by hundreds of years. It is the work of the pre-Incan races. The pre-Incans are shrouded by mystery which no one has yet been able to pierce, and we really know nothing about them, aside from the fact that they were a highly civilized race, were wonderful engineers and builders, and left remains in the form of walls, roads, and buildings that are among the greatest of the world's wonders.

The most outstanding feature of their works are their structures of the so-called "cyclopean type," most of which center in and about Cuzco which, later, became the capital of the Incan Empire. No cement nor mortar was used, the walls and buildings being formed of immense stone blocks, often weighing as much as 20 to 30 tons each, and frequently with many angles—cut, faced, and fitted with such amazing perfection that even today it is quite impossible to insert a knife blade between the stones.

That the same people who erected these titanic structures, by means that have never satisfactorily been explained, built much of the great highway is certain. In many places we find the same type of stone work employed in the road construction, and we know from incontrovertible evidence that much of the material, in the form of giant stone blocks, used in building forts and other edifices near Cuzco,

The old and the new. A motor car and Aimerá Indians, descendants of the ancient, powerful Incans, on the Incan Highway on the Peru-Bolivia border

were transported long distances over the ancient highway.

The road was carried up the stupendous heights of the Andes by accurate, easy grades, by wonderfully calculated hair-pin turns, S-curves and zig-zags. It was carried along the faces of precipices on shelves hewn from the solid rock, or upon masonry abutments built up from far beneath. Ravines and chasms were often filled with solid masonry to form causeways over which the road crossed. Where the canyons were too deep for this the abysses were spanned by suspension bridges supported by immense cables of wool, cotton, or fiber rope. Where the way was barred by insurmountable cliffs tunnels were cut through them.

A bit of the old road where it passes through an Indian village in Peru. Note that it is well paved

FOR a great portion of its length, this wonderful King's Road was paved, much of it was surfaced with asphalt or bitumen, and so thoroughly well built was the highway that long stretches of it are still in use at the present time. Throughout the entire 4000 miles and more of the road, there were rest-houses for the benefit of travelers, and which served also as relay stations for the couriers of the Inca. There were "Imperial Inns" every 40 miles. These served as storehouses for food, supplies, and equipment for the army or for the relief of neighboring villages in case of famine or war; and as eating places for the army when on the march.

There was also a continuous series of sentry stations, forts, and watch-towers. A very complete system of signal-fires or lights was maintained, by means of which the men who were constantly on watch could transmit messages from one terminus of the highway to the other. At the time of the uprising of the *Caras* tribe near Quito, Ecuador, news of the revolt was thus received by the Incans at Cuzco, Peru, within four hours after the trouble broke out. To transmit a message from the Chilean terminus of the road to Quito, 4000 miles away, ordinarily required scarcely more than six hours.

Although of great importance for peaceful purposes, yet to the Incans, their highway was primarily a military road. Over it their well-trained, well-equipped armies marched to their innumerable conquests. Over it, according to Incan records, trudged 250 carriers, each bending under a burden of gold, the whole weighing more than ten tons, to be used in making the immense gold chain that Inca Huayna Kapac ordered made to commemorate the birth of his eldest son, Huascar. Over it, too, was transported that marvelous, inconceivable store of gold, amounting to 7000 loads of 75 pounds each, that was sent from Chuquis to ransom the captive Atahaulpa, but which never reached its destination. Somewhere along the ancient Incan road, that vast accumulation of precious metal lies hidden to this day, for when word of Pizarro's treachery and Atahualpa's death was brought to the toiling, gold-laden Indians, they concealed the treasure in some secret spot near Piscobamba.

But the great highway that served the Incans so well in times of peace and war, the international road that connected the far-flung limits of their Empire, proved of inestimable value to their enemies as well. Over the Incan road the mail-clad Dons marched to Cuzco and their wanton destruction of the Incan civilization. And over it, following it across the vast Atacama desert, marched Pedro de Valdivia to his bloody conquest of Chile.

A wonderful, a fascinating, a romantic tale could this old highway tell if it could speak. A tale of riches, of conquests, of murder, bloodshed, and pillage such as the world has seldom seen equaled. If ghosts walk, then, surely, there should be an endless procession of ghosts over this highway.

An Indian village on the old Incan road, in Peru. The hut in the foreground is built on the remains of one of the Incan rest houses mentioned in the text

BUT even ghosts would find much of it hard going. Long stretches of it have completely disappeared. Many of the bridges have long since rotted and fallen away. Retaining walls have crumbled, letting the road disintegrate. Landslides have bodily destroyed miles of it, and modern roads and railways have cut through it. Still, portions remain in as good condition as ever. Llama trains still plod along it and patter over suspension bridges whose cables were stretched from shore to shore in Incan days. Portions of it also have been improved and incorporated in the splendid system of motor highways being pushed energetically forward. No country in South America has progressed so rapidly in its road work as has Peru. More roads is the watchword, the slogan, of that nation and the system of roads completed is remarkable.

If ever the proposed International Highway reaches South America, we may be sure that Peru will be ready and waiting to do her part of it, if indeed it is not completed through the land of the Incas long before it extends southward to the Peruvian boundary. Unquestionably, much of the great International Highway, where it crosses Peruvian territory, will be laid over the same bed, through the same tunnels made by the forgotten, prehistoric, mysterious pre-Incans. The time may yet come when one may drive a motor car from New York to Lima, or even to Valparaiso.

The Difference Between

The Majority of the Discoveries of Practical the Scientist's Penchant for Prying Into

By F. K. RICHTMYER
Professor of Physics, Cornell University

"TWEEDLE-DEE and Tweedle-dum agreed to have a battle,
For Tweedle-dum said Tweedle-dee had spoiled his nice new rattle."

Louis Carroll, in his famous Alice in Wonderland, has immortalized these celebrated characters and has given a very real meaning to the popular statement that, "the difference between Tweedle-dum and Tweedle-dee is something so trivial as to be entirely unworthy of further notice." When, however, we come to consider the way, if at all, in which this famous phrase is applicable to scientific research, either pure or applied, we realize that the phrase loses much of its popular meaning. Indeed, a glance over the history of physical sciences shows that, so far from being unimportant, "the difference between Tweedle-dum and Tweedle-dee," when carefully observed, has been responsible for a very large number of the striking advances which have taken place in science during the past four or five centuries.

Without discussing this matter in a general way, let us proceed at once to examine certain well known instances in which "the difference between Tweedle-dum and Tweedle-dee" has played an all-important rôle.

WE go back in history to the days of Copernicus, a younger contemporary of Columbus. You will recall that Copernicus, after making a thorough study of the apparent motion of the planets through the heavens, came to the conclusion that the Ptolomaic system of the universe was entirely wrong and that the heliocentric theory proposed by the Greek Aristarchus 15 centuries before was the more nearly correct. According to this latter theory, the planets—Mercury, Venus, Earth, Mars and the others—revolve around the sun in circular orbits. Perhaps the one good reason why Copernicus decided that the orbits were circular was that there was no good reason to suppose them anything else.

Then came the all-important question: What makes the planets move around the sun? The question was not to be answered for many decades, but in the meantime two astronomers made very substantial contributions to the subject. Tycho, the Dane, in the days before telescopes and with only a "sight-tube" containing cross hairs—a telescope without lenses—observed very carefully the positions of the various planets in their apparent motion among the stars. In particular, he made very careful measurements of the planet Mars. A young associate of Tycho was the astronomer Kepler. He was, as we would say today, a theorist and made very careful studies of Tycho's observations on the positions of the planet Mars at various times of the year. He noted that the motion of the planet, as determined from the very careful observations of Tycho, did not quite coincide with the hypothesis of Copernicus that the planets moved in circles. At certain times the planet Mars was not quite in the position which it should be were its orbit circular, the difference being some eight minutes of arc, or roughly one fourth of the apparent angular diameter of the sun. The difference between this predicted position, based on the supposition of a circular orbit, and the observed position was not very much—much less than "the difference between Tweedle-dee and Tweedle-dum." Kepler, however, knew that on the one hand the observations of Tycho could not be in error by even so small an amount as eight minutes of arc and on the other, that his own computations must be correct. *When observation and theory disagree, ever so slightly, theory must be modified.* The orbit of the planet Mars could not be a circle. After much long and tedious computation, Kepler hit upon the happy solution that the orbit of the planet is an ellipse with the sun at one of the foci of the ellipse.

Even so, however, the difference between the two paths, the apparent circular and the actual elliptical, was not very much but it was enough to play a very important rôle in subsequent developments. For, a century later, the fact that the orbits of the planets around the sun are ellipses gave to that great genius Newton, one of the strongest arguments in support of the now famous "inverse square law" of gravitation, a law which every school boy knows by heart and which states, "*Every* particle of matter in the universe attracts every other particle of matter in the universe with a force . . . inversely proportional to the square of the distance between the two particles."

WE who are concerned primarily with physical science, have come to take this law of gravitation for granted. It is an important law applicable in many branches of science—astronomy, physics, chemistry, and so on. But we sometimes forget the even greater philosophical importance of the discovery of this law. Newton saw its terrestrial operation in the falling of the apple. He saw its operation in the solar system in answer to the question: "What keeps the planets in their orbits?" And astronomers came to regard the law as applicable to the most distant stellar universes. For the first time in the history of the world, man came, with the announcement of this law of gravitation, to realize that at least in this one particular there is a common natural law extending and operating throughout the entire universe, a law which governs the motions of terrestrial objects, planets, and stars alike.

Without doubt, we are in large measure indebted for this law to the careful work of Kepler and Tycho in observing *and then interpreting* this small "difference between Tweedle-dee and Tweedle-dum," out of which difference grew the far-reaching law of gravitation as propounded in quantitative form by Newton.

WE pass over something more than a century and come down to about 1825, when many of the best known scientists of Europe were attempting to answer the question which that genius, Michael Faraday, put to himself: Is it possible to "convert magnetism into electricity"? A few years before this, in 1819, Oersted, the Danish scientist, had accidentally found that a magnetic field is produced by an electric current flowing through a wire; or, in the rather loose language of the time, electricity was itself "converted into magnetism."

Numerous observers were attempting the converse: namely, making an electric current by means of a magnetic field. In spite of numerous attempts, by 1830 most scientists had given up the problem as hopeless.

In the summer of 1831, Faraday was working in his laboratory at the Royal Institution of London in one more attempt to solve the problem. He had a hollow helix of many turns of wire, the ends of which were connected to a crude galvanometer; that is, a device for measuring an electric current. Into this helix he was going to introduce a bar magnet, hoping that the presence of the bar magnet would cause a current to flow continuously through the wire of which the helix was made. When, however, he tried the experiment the galvanometer showed no deflection when the magnet was in place.

Tweedle-Dum and Tweedle-Dee

Value to the World Have Been the Result of "Little Things" of Apparent Unimportance

He noted, however, that when the magnet was thrust into place in the helix, there was a very slight, hardly noticeable, motion of his galvanometer; and that when he removed the magnet from the helix there was again a similar slight motion. This slight motion was not what he was seeking and it was exceedingly minute —let us say only 1 percent of "the difference between Tweedle-dee and Tweedle-dum." But Faraday had never heard the couplet at the beginning of this article and to his discerning mind every bit of evidence, however, slight, must be taken into account. He, therefore, made a further study of these slight motions.

In an incredibly short time Faraday had shown that these slight motions of his galvanometer indicated unmistakably "the conversion of magnetism into electricity"; and after further study he evolved the physical laws governing the process.

Some four decades later students of applied science began to understand that these laws had a very important practical bearing. An understanding of them led to the development of electric motors and dynamos for the production of electric power. Out of this development in the seventies grew our whole electrical age of today. Within a year or two we shall be celebrating the centenary of Faraday's discovery and perhaps some eulogizer of this great scientist will again point out the very important fact that "The difference between Tweedle-dee and Tweedle-dum" has played a very important part in making this the age of electricity and thereby in revolutionizing present-day civilization.

WHY should Michelson have spent so much time in making new and ever more accurate measurements of the velocity of light? The discovery of argon answers the question.

In 1894 two English scientists, Rayleigh and Ramsay, were interested in making a more precise measurement of the density of the well-known gas nitrogen. Whatever may have been their reasons for making this measurement, we might at the present time look upon their motives as based upon idle curiosity, if you will. When, however, they had determined this density with a higher precision than had ever been attained before, they observed that samples of nitrogen from different sources and prepared under different conditions had slightly different densities. They may have been suspicious of the unimportance of the "difference between Tweedle-dum and Tweedle-dee," and they sought to find the reason for the difference in densities of these samples of nitrogen. The result of this search was most profound. They discovered that the reason for the differences was due to the presence, in varying amounts, of the hitherto unknown gas argon, which, because of its chemical inactivity, had previously escaped detection although it makes up well toward 1 percent of the atmosphere.

Now, one might say that a gas which makes no chemical compounds, can not be seen or smelt, and makes up only 1 percent of the atmosphere is of no great importance. Nevertheless, the discovery of this gas soon led to the discovery of other similar gases and today we recognize a whole series of them, known as the inert gases: helium, neon, argon, krypton, and xenon. These gases are somewhat similar to each other but differ from each other in certain of their physical properties.

Seldom has a discovery been productive of greater results. In recent years we read much about the question of atomic structure; how the atom is like a miniature solar system with a nucleus containing a positive charge of electricity around which are swarming electrons in various states of orbital motion. It is not too much to say that the starting point of the various modern theories of atomic structure is to be found in certain properties possessed by this series of inert gases and it is doubtful whether, had those gases not been discovered, our concept of the atom would be anything like as definite as it is now.

But we need not confine our discussion of the importance of the discovery of argon to matters pertaining to physics and chemistry. We all know that helium is being used as a much safer gas than hydrogen in dirigible balloons; that neon, as well as some of the other gases, is finding important practical uses in electric signs; and that argon has played a very important rôle in the development of the gas-filled incandescent lamp (by its introduction, the efficiency of artificial light sources was almost doubled). Those who are interested, may compute the value in dollars and cents of this particular use of argon and thereby can place a monetary value on "the difference between Tweedle-dee and Tweedle-dum."

But why elaborate the thought further? Everyone will be able to call to mind numerous illustrations of the fact that minute differences such as those which have been mentioned, play a very fundamental rôle in all branches of human activity. Indeed, machines have been taught to recognize "the difference between Tweedle-dum and Tweedle-dee." For example, one of the important revolutions in modern machinery has been the introduction of the ball bearing and the roller bearing. The very success of the ball bearing depends upon making steel spheres which differ from each other in diameter by not more than one ten-thousandth of an inch. Two Fords—at least as they leave the factory—are much more nearly alike than the proverbial "two peas." The ability thus to duplicate parts is one of the striking successes of our modern industrial life.

ONE catch-phrase definition of a genius states that, "a genius is one who has an infinite capacity for taking pains." Like many another of its kind, this definition contains just enough of truth to make it somewhat dangerous. Many a man has an infinite capacity for taking pains, but he will never be a genius.

I propose an alternative definition: A genius is a man who can observe *and interpret* "the difference between Tweedle-dee and Tweedle-dum." And let us emphasize "interpret." It was not so much Kepler's discovery of the slight discrepancy between theory and observation in the motion of Mars; it was his ability to interpret this difference that brought him fame. It is quite probable that other investigators before Faraday had observed similar "kicks" in galvanometers, but Faraday regarded the minute disturbances as worthy of further study. Had Ramsay and Rayleigh been content merely to point out that different samples of nitrogen seemed to have different density, we might have waited a long time for the discovery of the noble gases, with their important uses in both science and industry.

A very large part of present-day research in science depends on devising instruments and methods for making more and more accurate measurements, for observing minute differences hitherto beyond detection. So frequently has it happened that new phenomena have been discovered when such measurements have become possible, that it is now almost an axiom that "a new discovery is to be found in the next decimal place." Michelson's motive in repeating, each time more precisely, his determination of the velocity of light thus is obvious.

The Scientific American Digest

Conducted by F. D. McHugh

Direct-Reading Light Intensity Meter

ONE of the latest uses of the photoelectric cell is in connection with a meter to measure light intensity, now being built at Newark by the Westinghouse Electric and Manufacturing Company.

This cell, in various special constructions, has already found many uses in industry and is finding new ones almost continually. The present meter, embodying a new application of the photoelectric cell, should render unnecessary the question in a picture studio, "Is it light enough in here?" A photographer need not wonder whether the north light today is as strong as it was yesterday, for the meter always gives the same values for the same intensities. Used in connection with a printing frame it makes possible accurate adjustment of lights when certain special printing is to be done.

The photoelectric cell is an important part of this light meter

The instrument is complete in a case 12 1/2 by 10 by 6 5/16 inches, and consists of a special cell of broad response covering the visible spectrum, in series with the smallest size "B" battery and a microammeter calibrated directly in foot-candles. The light "pickup" or cell, something like a radio tube in appearance, is connected to the meter by a cord and may be moved about a six-foot radius outside the case. Normally directional, so that light from given points may be studied, it may be made non-directional as well.

The sensitivity of the meter is pronounced; used in tests at a motion picture studio, it showed the change in illumination of an actor's face when he lighted a cigarette.

Further suggestion of its value is seen in the studio where Mazda lamps are used with panchromatic film, in color photography where intensity of special colors is desirable, and in cinema houses to measure the screen illumination. It may also be used to determine illumination in factories.

The New Digest

WITH the express purpose of improving the quality—as to selection, preparation, and appearance—of the material heretofore presented in SCIENTIFIC AMERICAN following the major articles, we inaugurate this month what might aptly be called a *super* SCIENTIFIC AMERICAN Digest. This enlarged section of the magazine will contain items formerly segregated and published under various specific heads, but their authorship will remain as before.

Professor Alexander Klemin, in charge of the Daniel Guggenheim School of Aeronautics and Associate Editor of SCIENTIFIC AMERICAN; A. E. Buchanan, Jr., Lehigh University, Corresponding Editor of SCIENTIFIC AMERICAN; and Morris Fishbein, M. D., Editor of the *Journal of the American Medical Association* and of *Hygeia*, and Corresponding Editor of SCIENTIFIC AMERICAN, will be responsible for the articles, signed by their initials, in their respective fields of aviation, chemistry, and medical science.

Fireproof Houses in France

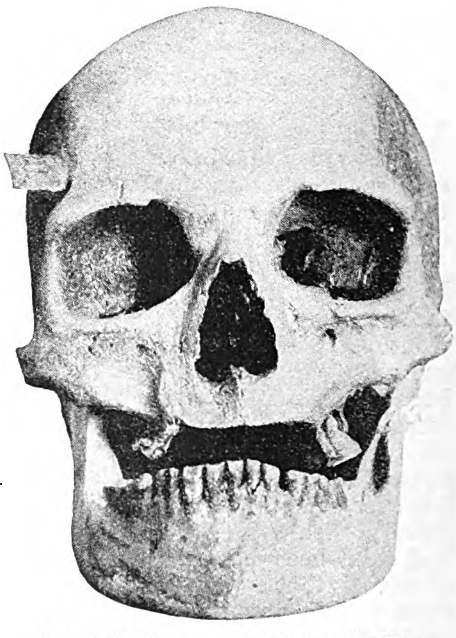
DWELLINGS of fireproof wood are being erected in France by a German concern as part of the reparation payment. Each month 100 five-room houses of this type are being erected at a fixed price of 1500 dollars each.—*Engineering News-Record.*

Arrow Point Injuries

ALTHOUGH the stone arrow-points used by prehistoric Indians are fairly common, yet it is rarely that they are found imbedded in human skulls or other bones. Collectors of Indian relics regard such a find as is pictured on this page as a great prize. Numerous instances of such finds are known among the Indians of the eastern and middle North America, but the one shown here is the first to be recorded from the southwest. It was found on San Nicolas Island, one of the channel islands off the coast of California. The skull was associated with another cranium containing a small, black obsidian point. The present case shows the point firmly fixed in the right temple where its situation shows that a large artery inside the head was cut, and the Indian died of cerebral hemorrhage.

Angleworm Big as Snake

IF you happen to be in the Philippine mountains some day, and see an angleworm as big as a small snake, colored bright blue with pale yellow spots and bandings, don't blame it on something you may have eaten (or drunk) in the last village. It's real, and it's there, although it is a zoological rarity. Dr. M. Michaelsen, of Hamburg, Germany, has just reported to the *Philippine Journal of Science* on specimens collected in Luzon some time ago and forwarded to him by a fellow-countryman, W. Schultze, formerly an entomologist at the Bureau of Science in Manila. The specimens, when living, were over a foot in length and nearly an inch in



A relatively rare find: An Indian **skull retaining the arrow head which killed the Indian ages ago** greatest diameter. They are of a species new to science and have been named *Pheretima ophioides.—Science Service.*

Chemical Warfare Turns to Peaceful Victories

WHILE the chief duty of the United States Chemical Warfare Service is military, it has made numerous contributions to chemical science and industry in peace time. The widespread activities and accomplishments of this branch of the service are described by Lt. Robert E. Sadtler in a recent issue of *Chemical and Metallurgical Engineering.*

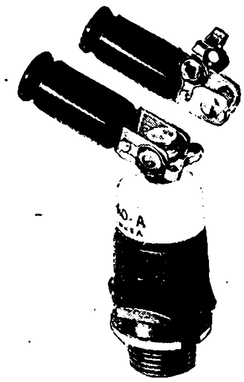
"Among the more important of these," says Lt. Sadtler, "is the development of compounds that will destroy the boll weevil more effectively than the calcium arsenate generally used; it (the Chemical Warfare Service) has demonstrated the use of tear gas in controlling mobs; it has developed gas masks for protection against industrial poisoning and ammonia fumes, and for the use of the public health service in its work of fumigating buildings. It also has assisted the shipping industry by three commercially valuable developments: toxic ship-bottom paints, protection of marine piling, and a safer and more effective method of ship fumigation."

"Anti-fouling paint, according to the estimate of competent authorities, will save the shipping industry from 125,000,000 to 150,000,000 dollars annually in reduced fuel and maintenance costs. The need of a poisonous paint for the exterior of hulls of ocean-going vessels is due to the accumulation of marine organisms, which increases fuel consumption and reduces the ship's working time by the amount spent in dry dock to clean the bottom. Barnacles are the principal marine organism attaching themselves to the ship's bottom. Not only commercial but naval vessels are affected by this growth."

Another interesting discovery made by the Chemical Warfare Service is that of the use of tear gas in controlling crowds and individuals. The effectiveness of this method in comparison with the old one of subduing the mob by the free use of bullets has been demonstrated frequently. A simple tear gas, chloracetophenone, in harmless, non-explosive tear-gas grenades, may be used effectually without permanently injuring anyone who may encounter it. This tear gas is a non-poison in the concentrations obtainable in the open air, and yet is effective even with one part of tear gas to three million parts of air. Its only reaction is to cause smarting of the eyes and the stimulation of the lachrymal gland causing a copious flow of tears.

Attacking the boll weevil from the air. Dusting cotton with chemicals

Still another service which the Chemical Warfare Service has rendered to peacetime America is the development of various kinds of gas masks as protection against the deadly gases employed in many industries, and the detailed study of methods to prevent the fatalities resulting from other forms of poison. Since all of these poisons have at one time or another been brought to the attention of the Service as possible chemical warfare agents, the Service has necessarily made a close study of them and of methods of protection against them, and has been able to offer freely to industry the knowledge thus gained.—*A.E.B.*



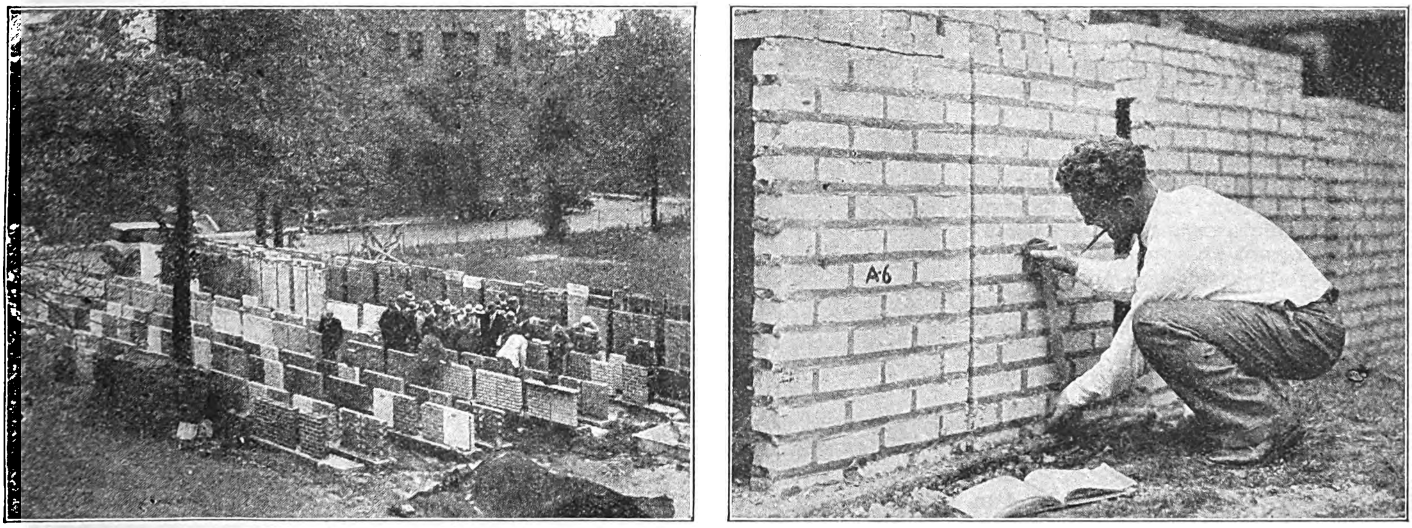
Two views of the new locking terminal for engine spark plug cables

A Locking Cable Terminal

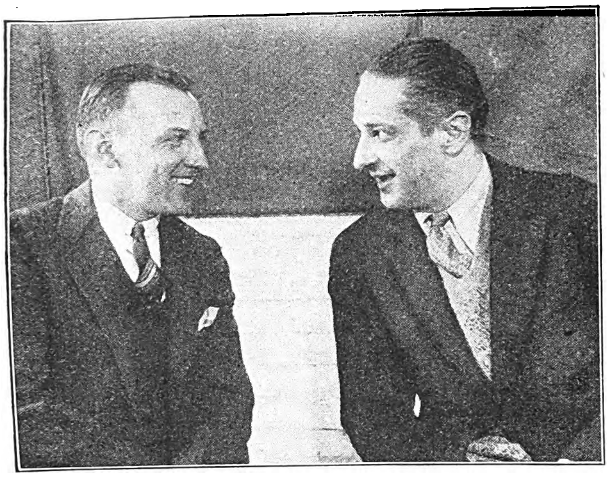
THE accompanying photograph shows an interesting locking spark-plug cable terminal which has been approved by the Army Air Corps for airplane use. Powerful phosphor bronze jaws of this new terminal make firm contact with the spark plug. Then the contact is locked by a hinged bale that swings down across the end of the terminal. Violent air maneuvers, rough landings, sudden propeller blasts, engine vibration, or bumpy roads cannot loosen its firm grip. Yet, in service, the terminal may be removed as quickly as the ordinary kind.—*A. K.*

Scientific Research on Bricklaying

AN interesting example of collaboration between scientist and artisan is found in the broad scientific study of bricklaying recently inaugurated by Mellon Institute of Industrial Research and the Eastern Face Brick Manufacturers' Association. The experiments are being carried out by Dr. F. O. Anderegg, Senior Industrial Fellow of the Institute's Multiple Industrial Fellowship on Portland Cement, and his assistants; architects, building contractors, and masons are aiding the work



Above is shown the group of experimental brick walls that has been built on the grounds of the Mellon Institute. *At right,* an assistant makes use of the strain gage, sensitive to 0.002 inch, for measuring shrinkage



Friendly enemies exchanging reminiscences. Major George A. Vaughan, Jr., second American ace now actively engaged in the aircraft industry, and Captain Franz Carl Schlieff, former war pilot of the German air force. Major Vaughan was credited with 13 enemy planes during the war while Captain Schlieff accounted for 22 before the British shot him down on the Somme. Here he lost his left hand in the crash

by contributing opinions and advice based upon experience.

So many varying factors are involved in the construction of a brick wall that it has been necessary to limit the experimental study to combinations of variables representing the probable range of practical application. Hundreds of thousands of experiments would be required if all possible combinations were to be studied. For this reason the research program has been under discussion for a considerable period of time, and the actual investigation was begun only when a satisfactory plan had been elaborated. Up to the present time some several hundred experimental walls or panels have been erected.

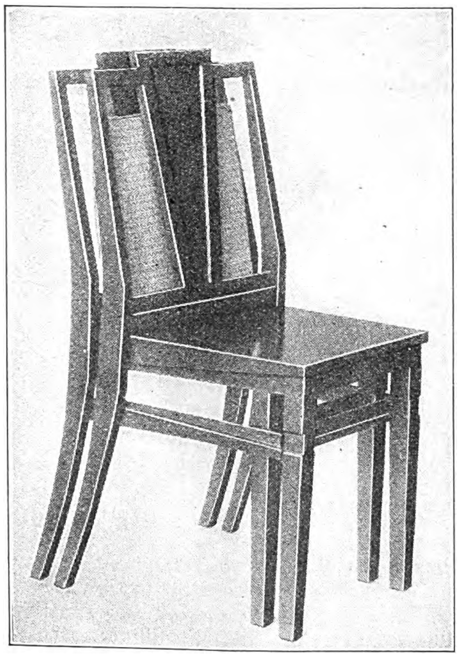
In brief, the investigation will cover certain aspects of all the factors involved in bricklaying. The most obvious points of attack are studies of the characteristics of different kinds of brick and mortar. Problems of special appeal to the practical man are those concerned with different methods of backing and with differences in workmanship. The design of walls and their relative elasticity are subjects which will be of considerable interest to contractors and architects.

Brick and mortar problems under investigation include the absorption and surface characteristics of brick, and differences in mortars due to varying the cementing materials, sand, and pigments. Properties of the mortars which are being studied carefully are workability, compressive and transverse strength, absorption and permeability, shrinkage, durability, staining and efflorescence, and elasticity. Information is being collected to determine whether the 10 percent of lime often specified by architects or the 25 percent or more usually employed by brick masons gives better all-around results.

The problems in backing include a study of hollow tile of different sizes, of brick, of cinder or concrete block, of brick tile, and of metal or other lath on steel frame. Variations in workmanship are most apparent in regard to tapping, pointing, and the filling of head-joints. The first mentioned subject is being studied, not only in regard to the effect of excessive downward tapping into place, but also in regard to plumbing both before and after initial set.

Nested Rigid Chairs Easily Stored

SINCE the time of the Pharaohs of ancient Egypt, there has been but little, if any, improvement in folding chairs. The same scissors-like legs that were used on chairs found in tombs of the Pharaohs are still used in making chairs that are collapsible for storing purposes, for ease in moving them in numbers, and so forth. And they are still as roundly sworn at for pinching fingers and tearing clothes as we assume they were in those olden days.



Two chairs of the type recently invented. They telescope one into the other for storage purposes

A patent has recently been granted, however, to Mr. Louis Dellert, of Brooklyn, New York, on a chair of conventional appearance but of novel design and construction. These chairs are made of sturdy pressed metal, and although they are rigid and non-collapsible, they effectively serve the purpose of folding chairs since they telescope one into the other.

All chairs of a set made according to this design are identical in all respects. Telescoping is possible because the seat frame is open in the rear and the sides of the seat frame, which is formed of metal, converge toward the front legs while the rear legs are securely mounted at the rear of the seat frame on the outer side. The thin metal seat slopes slightly forward. Any number of the chairs may, therefore, be nested, each additional one occupying only two or three inches more space.

They may be made in any period style, may have arms if desirable, and their seats and backs may be upholstered by means of thin removable cushions which may be stored between the backs when chairs are nested. A chair of this new type is well adapted for use in homes, banquet halls, or other places requiring strong, durable, attractive chairs that can be easily stored when not in use.

Tractor Efficiency on the Farm

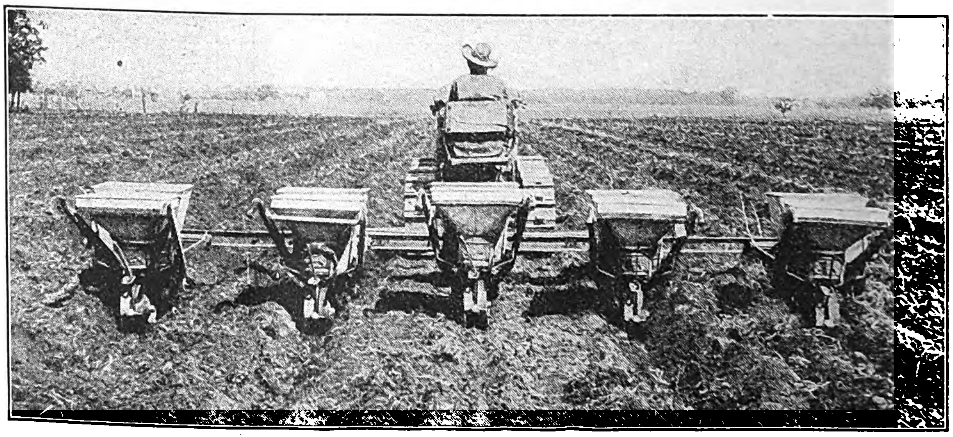
AS the horse is gradually supplanted by the tractor, the American farmer evidences a rapidly developing native ingenuity in the use of this modern time-saving aid to greater efficiency and profits.

On this page we show a tractor of the articulated tread type, equipped with five planters for fertilizing and planting four rows of corn and one row of peanuts. The planters are attached to the beam with a flexible hitch that allows a free up-and-down movement but prevents side movement. Three-inch spacing on the beams allows for any desired variation in the row width.

Chemical Prevents "Fatigue" of Rubber

EVERYONE knows that a piece of rubber can be stretched to several times its original length and will return almost completely to its original form as soon as the force is released. However, when rubber is stretched, released, and stretched again hundreds of thousands of times, it undergoes a form of deterioration which, for lack of a better name, we call "fatigue." When ordinary rubber "gets tired" it cracks; witness, for example, the cracks that develop on a pair of rubber boots where they are folded.

Rubber chemists of E. I. DuPont de

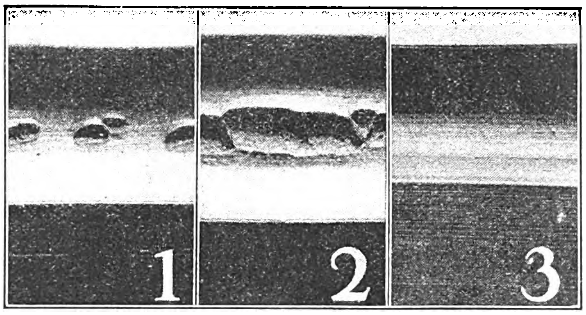


The ever-useful tractor leads to greater farm efficiency

Nemours Company have discovered that a very small amount of certain organic chemicals, introduced into the rubber before vulcanization, prevent "that tired feeling" and the resultant cracks in the rubber. The remarkable action of these chemicals, marketed under the name "Neozone" is described by E. R. Bridgewater in a recent issue of the *DuPont Magazine*. Referring to the use of Neozone in tires, he says:

"Carbon black made from natural gas is used by practically all tire manufacturers to toughen the tread rubber, thereby making it more resistant to abrasion. Most manufacturers use approximately two parts of carbon black to five parts of crude rubber, in high-grade tire treads. Greater amounts would be used if it were not for the fact that when more of this black pigment is used, there is a tendency for the rubber to crack at the points where it undergoes the most severe flexing when the car is in motion. It has been found that when small amounts of Neozone are added to the tread formula, considerably greater quantities of carbon black can be used without causing the rubber to crack at the points of flexing."

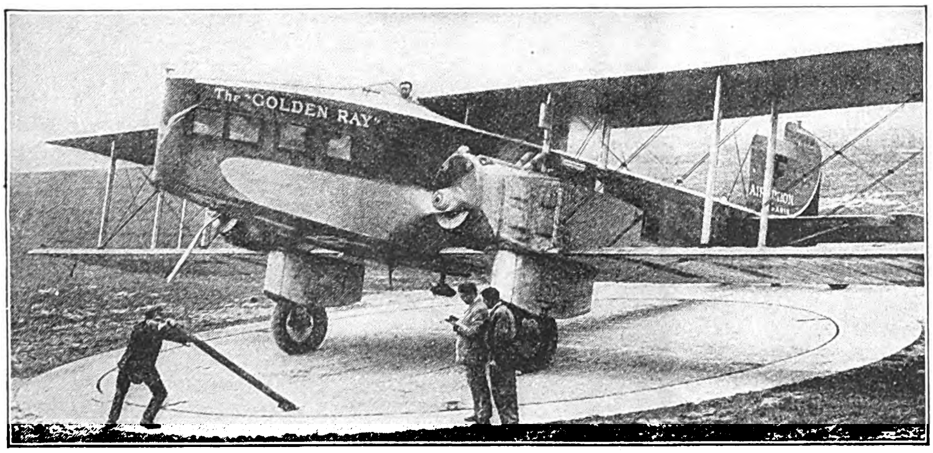
Many other rubber products, such as parts for hydraulic brakes, rubber belts for transmitting power, rubber wire-insulation, and many rubber articles whose purpose is to absorb shocks and vibration, have been improved in this manner.—*A. E. B.*



No Neozone is in sample No. 1 which shows the effect of bending a piece of rubber around a small pulley 1,500,000 times. Number 2 is identical and has gone through the same tests. Number 3 is identical except that it contains 1 percent of Neozone. It has undergone the test 3,750,000 times without cracking

A Compass Turn-Table

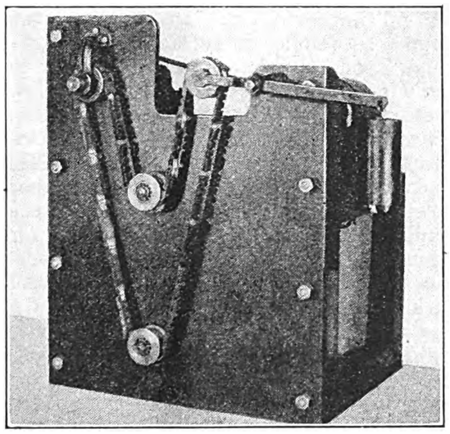
SERIOUS errors in the aircraft compass often occur owing to the magnetic fields of the airplane's steel parts. The process of compensation is termed swinging the compass. For "swinging the compass," Army flying fields are equipped with circular concrete platforms. The platforms are placed not less than 100 yards from any steel structure, such as a hangar. Starting with the magnetic north, radii are laid out every 30 degrees. A dolly is used to elevate the tail so that the airplane is in approximately flying position with the engine running. The airplane is headed to various points of the true compass and deviations are noted and corrected by special compensating magnets, until the errors are reduced to a minimum. A table of corrections is then compiled. A useful wrinkle for expediting this process has been devised at the Croydon Airport in London. A special turn-table is provided on which the airplane is placed. It can then be swung to various directions in a fraction of the time required when the airplane is slowly turned by man power. The turn-table is easily turned by one man.—*A. K.*



At the Croydon Airport, a turn-table for "swinging the compass"

X rays and the Tonsils

THERE are various methods of controlling enlarged tonsils—they may be removed by surgery; they may be destroyed by heat through an electric cautery or through electric heat; or they may be X rayed. As far back as 1913 it was suggested that X rays be used for the control of enlarged and infected tonsils, and since that time numerous papers have been written as to the effects of X rays on these tissues.



The flexing machine developed by the DuPont laboratories for fatiguing rubber. The weight at the right regulates the tension on the V-shaped sample "belt" of rubber

In the last quarter century hundreds of thousands of people have had their tonsils removed and it is now generally understood that removal of the tonsils is advisable in the presence of infection or of extreme enlargement. However, there is also considerable conservatism concerning the removal of apparently normal tonsils.

In St. Luke's Hospital, New York, Dr. Leila Charlton Knox has given special attention to the possibility of treating tonsils with X rays. She does not advise the use of X rays in children, particularly those with rheumatic symptoms. She does feel, however, that X rays provide a useful method in all cases in which operation is not advisable because of some secondary complication, particularly heart disease. Neither do X rays seem to be indicated in cases in which there is acute infection or a complicating disease such as diphtheria or scarlet fever.

X rays seem to be useful in the control of the secondary growth of lymphoid tissue in the form of stumps after the tonsils have been removed surgically. The method is also useful in elderly people who are troubled with chronic or repeated sore throats.—*M. F.*

Man Linked With Ground Sloth

WHILE the part of this magazine containing the article "The Mystery of Gypsum Cave," by Dr. M. R. Harrington of the Southwest Museum (page 34) was in press, the following telegram was received:

"Have found what seems to be the campfire of our sloth hunters: a patch of real charcoal under a layer of unbroken sloth dung capped by more than seven feet of undisturbed strata in the topmost of which are found Basketmaker and early Pueblo artifacts. This find to my mind establishes beyond question the association of man and the sloth.—M. R. Harrington."

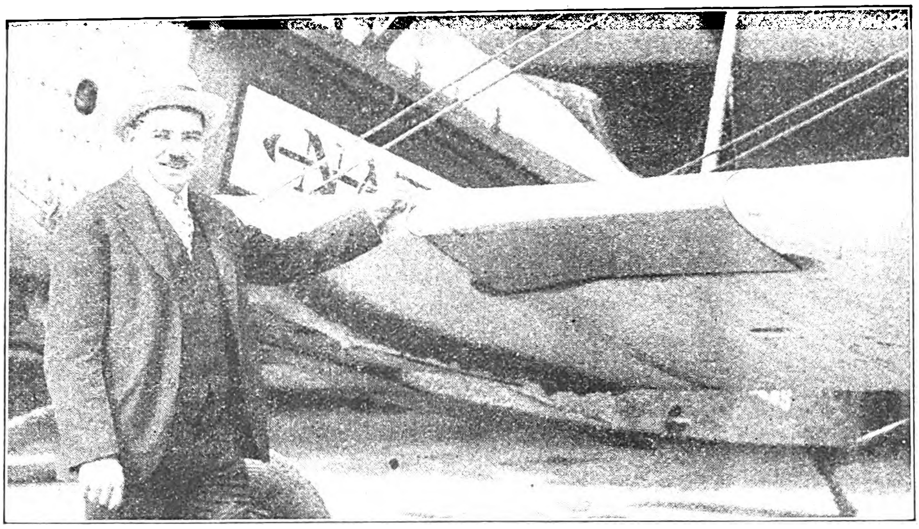
Dr. Harrington's beliefs, as expressed in his article, apparently have been vindicated.

Carbon Remover

IT is a well-known fact that if a gasoline engine of the poppet valve type can be kept relatively free of carbon, the intervals between necessary removals of the cylinder head can be increased greatly. In the article "Your 1930 Car," published in our January 1930 issue, we mentioned a product of the Alemite Corporation, called Carbosolve, which has been installed as standard equipment on Chrysler cars.

This carbon removal system is now available for use on all cars, having recently appeared on the market in "kit" form. Essentially, it involves the use of a valve permanently mounted on the dash, and with a connection to the center of the intake manifold. The valve is so arranged that a can of the special carbon-removing liquid can be attached when it is desired to treat the explosion chambers. The makers recommend that this be done every 500 miles.

When the device is to be used, a can of



Leslie L. Smith of the N. A. T., exhibiting the airplane "overshoe"

the liquid is attached to the valve, the motor is warmed up to running temperature, and the valve knob is pulled out and the motor shut off simultaneously. The liquid is sucked out of the can and is equally distributed to the cylinders. The engine is then allowed to stand undisturbed for at least three hours, or overnight. It is then started and the carbon, loosened by the action of the liquid, is blown out with the exhaust.

Airplane Overshoes

DR. WILLIAM C. GEER'S "airplane overshoes," developed with the aid of a subvention from the Daniel Guggenheim Fund for the Promotion of Aeronautics and with the co-operation of N.A.T. and the B. F. Goodrich Company, give promise of conquering one of the most serious hazards of flying.

The adhesion of ice to metal—polished aluminum for example—is high. The adhesion of ice to other substances varies greatly, and to some it is remarkably low. In previous attempts to solve the problem, the surface of the airplane wing has been covered with oil. The oils used have generally become viscous and sticky at their freezing temperatures, and moreover the wind forces have scrubbed off the layers of oil.

Profiting by these early mistakes, Dr. Geer selected a group of oils the freezing points of which fall below 20 degrees Fahrenheit, and the boiling points of which are high. Such oils would possess mobility at ice-forming temperatures and would be non-drying over long periods of time.

The second difficulty was to prevent the scrubbing off of the oil by the wind. To render this scrubbing off impossible, the oils were absorbed into thin sheets of vulcanized rubber, which can absorb a large volume of oil. To avoid the weakening and deteriorating effects of oil upon rubber, the effects of over 100 oils and oil mixtures were investigated. Finally an oil mixture was found which gave to the vulcanized rubber practically zero adhesion to ice and which left its physical properties unaltered. Moreover, the rubber thus treated showed the property of exuding oil at the freezing temperature. During the course of the intensive research work conducted in connection with this problem, it was found that the volume of ice formed on an untreated rubber sheet is somewhat less than upon other substances.

There then remained the problem of removing ice should this be formed despite the oil impregnation. Ice formed even upon a zero adhesion surface does not remove itself. It shapes itself perfectly to the wing and at the leading edge the low pressure over the wing helps to keep it on. To meet this third difficulty, Dr. Geer invented a simple mechanical device. This took the form of a light-weight thin rubber "overshoe," or pneumatic nose, for the leading edge, with a fabric backing for strength. In the leading edge of this overshoe was placed an air tube strengthened with extensible fabric. This inner tube was connected to a pump, either motor or hand driven. The tube lay flat when collapsed and so altered the curvature of the wing very little. If ice forms in spite of the impregnated rubber, the pilot turns the air into the tube, thus slightly expanding it. This moves the ice and breaks the vacuum. The only precaution to be observed when flying under ice-forming condition is that the pilot should "break the ice" when the layer is still thin. These overshoes are designed to be applied only when bad weather is expected, just like the overshoes of our everyday life.

In a test run in Cleveland in March, an overshoe was attached to a radio mast behind the cockpit. During the flight, ice formed to a thickness of about one half inch over the leading edge. A hand pump was used to expand the tube. When a pressure of two pounds per square inch was applied, the ice suddenly left the overshoes, flying off in chunks. Experiments on a wing and on a strut were similarly successful.

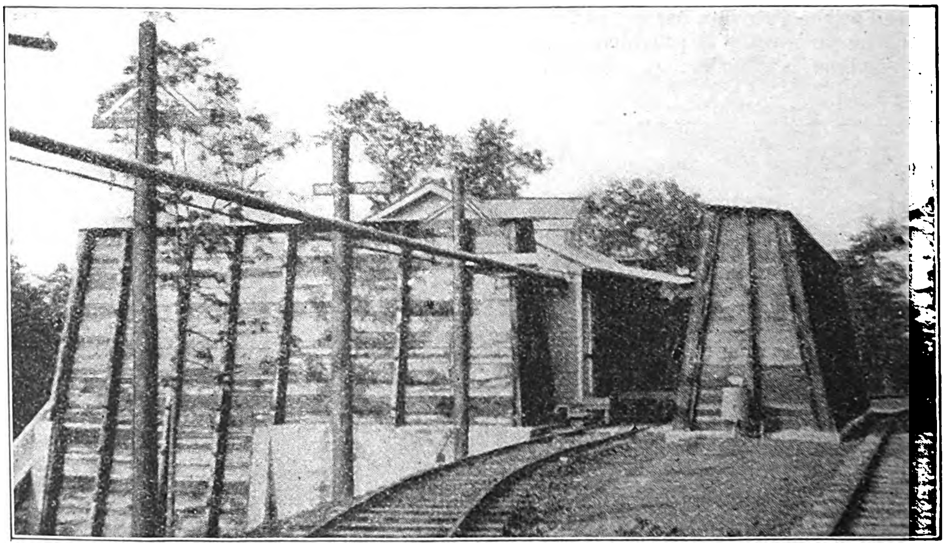
These experiments made in full flight are very encouraging. While pilots and operators always object to the addition of "gadgets" to aircraft, this gadget at least seems well worth while and we shall await further developments with keen interest.—*A. K.*

Measure the Speed of Dynamite Explosion

ONE of the most rapid chemical reactions known takes place when a stick of dynamite is detonated. It has been found that the detonation wave travels along a cartridge of dynamite at speeds as high as four miles a second. These speeds were measured at the Explosives Experiment Station of the U. S. Bureau of Mines, Bruceton, Pennsylvania, in connection with research and testing of mining explosives.

In one type of apparatus, known as the Nettegang recorder, the time elapsing between the breaking of two wires threaded through the explosive is recorded on a rapidly revolving smoked drum. In a method recently developed, the explosive is placed behind a narrow slot cut in a sheet of armor plate and the detonation process is photographed by its own light on a rapidly moving film. This method has the advantage that it records the speed of the detonation wave at every point along the column of explosive. It has been found that the speed of gelatin dynamites is affected by the degree of confinement under which the charge is fired. A charge of gelatin dynamite confined in a steel tube may detonate at a speed several thousand meters per second faster than a similar charge detonated in the open.

The explosion of a charge of dynamite is usually associated in our minds with a deafening concussion, but this is true only of dynamite fired in the open air. Charges of dynamite are exploded in massive steel bombs at the Pittsburgh Experiment Station of the Bureau of Mines, with only



Gelatin cartridge house, Mineral Springs plant of the DuPont company, showing earth barricades which serve as protection in case of explosions a metallic "click" to indicate that the charge has exploded and that pressures of 10,000 to 20,000 pounds per square inch have been produced inside the bomb. These bombs, known as Bichel gages, are used to measure the actual pressures produced by detonating explosives when fired in a borehole. The magnitude of the pressure is a measure of the ability of the explosive to do work.—*A. E. B.*

Trees Must Have Water

TREES need enormous quantities of water to keep them in a healthy condition, says the United States Department of Agriculture. An apple tree 30 years old gives off approximately a barrel of water a day in summer, and a good-sized birch tree gives off nearly two barrels of water on a hot day. A single oak tree is known to have given off into the air in the form of vapor more than 100 tons of water in a single growing season.

Chromium Poisoning

CHROMIUM is one of the chemical elements most commonly used in many industries. In etching zinc and aluminum plates in lithography, a mixture consisting of gum arabic, chromic acid and phosphoric acid, is applied to the plate with a brush or sponge and almost invariably comes in contact with the hands of the user. In another lithographing process, chromic acid or ammonium bichromate may be applied in other ways.

Drs. Carey P. McCord, Hobart G. Higgenbotham, and J. C. McGuire made a study of the hands of 37 workers, of whom 25 were lithographers and 12 were tanners. The application of the chromium mixture to the unbroken skin resulted in inflammation of the skin in 20 out of 25 cases among lithographers and in 10 out of 12 cases among tanners. The reactions included the inflammation of the skin and in some cases blisters.

It has for some time been realized that chromic acid or chromium compounds could bring about severe conditions when coming into contact with the broken skin, but it has been believed that chromic compounds would not attack the unbroken skin. Recent experiments indicate quite certainly that this belief is not supported by scientific evidence.

In studying eruptions of the skin it is important to keep in mind the occupation of the worker. Numerous irritants are employed in household work and in various trades. A condition called "photographer's eczema" is due to some of the chemicals used in developing pictures. Electrotypers and stereotypers and foundrymen get eruptions from the substances with which they work. Bleaching preparations of all sorts, hydrochloric acid and bichromate solutions used in the tanning trade, aniline dyes, shellac, and various plant extracts may cause irritations of the skin which must be studied carefully in order to be sure that the eruption comes from an irritant applied on the outside rather than from something in the blood developed inside the body.—*M. F.*

Spot-News via Telephone-Dictaphone

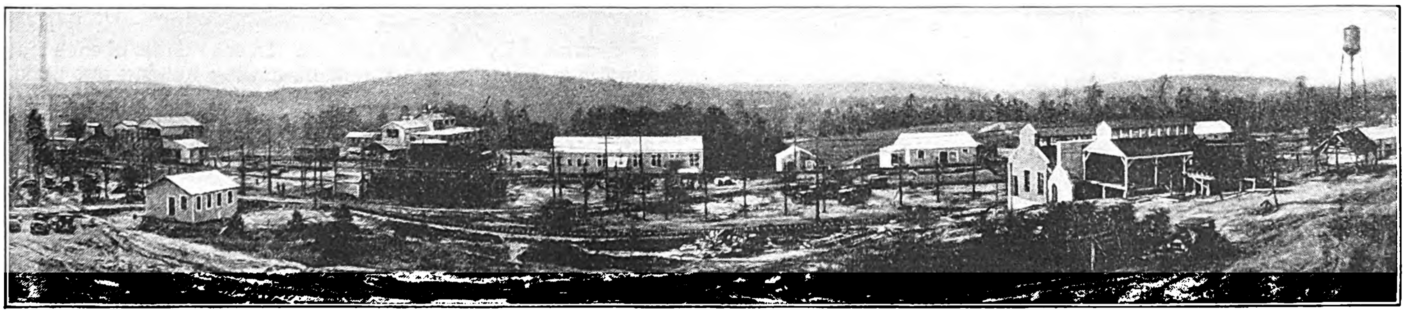
FROM the king's palace to the newspaper office may be a thousand miles, but the city editor of 1929 can look in on the coronation and be back at his desk in a few minutes. He can flash a question into the air and within 10 minutes have a reply from an explorer in the far jungle. And the wonders of news transmission are being perfected steadily to even higher efficiency. Already one of the marvels of this machine age, the modern newspaper is still concentrating effort on improving its speed in covering news. Within the past two years, the city editor has taken on another mechanical assistant. Dictaphone-telephone hook-ups are now being used to cut down the time and expense of transmitting news over long distances.

This new mechanical combination is now an accepted, regular means employed by leading Australian newspapers for reporting news from distant points. Long distance telephone lines are used at prearranged times by the newspaper's correspondent. Dictaphones with amplifier mouthpieces are attached to the telephones at the receiving end in the newspaper offices. The reporter speaks in an evenly timed voice, at the rate of 100 words a minute. An attendant "listens in" to the voice coming in over the wires, and when the machine's wax cylinder is filled, he signals the sender, who pauses while the cylinder is changed.

The cylinders containing the news material are transcribed by a corps of operators, with the regular transcribing machine and earphones. The copy is then passed directly to the sub-editor. Formerly news from distant correspondents had to be rewritten before it was turned over to the sub-editor for copy-reading, since the sentences were in choppy, abbreviated form for economical telegraphing.

The new method of news transmission, according to the *Rockhampton Bulletin*, has shortened the former all-night period for receiving news to about one hour daily. Because the correspondent can be certain of sending in all his material in one hour instead of three or four, he can now take time to organize his news carefully to present it in finished style, so that the work of the copy desk in handling his copy is reduced practically to punctuation and headline writing. The *Bulletin* estimates that the cost of receiving 15,000 words per week by telegraph, working six nights, was 30 pounds, or about 150 dollars. The cost of the same service by the new hook-up is 12 pounds a week.

In the United States, as might be expected, this new combination of machines to speed up news has been applied first to market reports and sports news. Dictaphone-radio hook-ups last fall kept Oregon poultry raisers in close touch with pre-Thanksgiving market news, so that they were enabled to sell to the best possible advantage. Their hook-up was made in the office of the county agent, where were recorded market reports broadcast during the working hours when it was impracticable for the farmer to listen in at his radio. The cylinders which caught the news from the loud speaker were tran-



A section of the new dynamite plant at Mineral Springs, near Birmingham, Alabama

scribed into reports which reached the farmer within a few hours. This meant that he could plan his marketing from reports much less than a day old.

When the American derby took place last summer Clem McCarthy, nationally known turf authority, reported the racing classic minute by minute over the radio. A receiving set in the composing room of the *Chicago Herald and Examiner* was hooked up for recording, and as the derby progressed, the story of each race was recorded on dictation cylinders in the newspaper office within the minute that it took place hundreds of miles away. This method of reporting, used in connection with the Sharkey-Stribling fight in Florida, speeded up the news so that newsboys crying the outcome of the fight met the homeward bound fans.

Huge Week's Sales of Airplanes

SALES of airplanes, engines, and gliders amounting to three quarters of a million dollars in a single week is the record established at the New York Air Show, which closed May 10, according to the Aeronautical Chamber of Commerce of America, Inc., sponsors of the show. The authenticity of the sales reports was vouched for in signed statements filed by exhibitors at the show. More than 120,000 people are said to have passed through the doors of Madison Square Garden while the show was in progress—another high record.

Flying school operators reported their biggest sale of flying school courses during a single week as a result of contacts made at the air show. Furthermore, thousands, inspired by reports of the show and by the flight of a fleet of 140 Navy planes, a number of Army planes, and 77 commercial planes over the city, took their first airplane rides from several of the flying fields near the city during the week of the show.

The sponsors of the show announce that another gigantic show will be held in the city next year.

An Electromagnetic Pump

DURING the course of some investigations in the Laboratories of the Rockefeller Institute for Medical Research, it became necessary to devise a pump which could be used to circulate sterile fluid in a system free from any rubber, metal, oil, grease, or cement. To fulfill these requirements, a pump has been constructed entirely of glass, in which the motion of the piston is actuated by electromagnetic forces.

The diagram shows the pump in cross section. The pump cylinder (1) is a glass tube which has a carefully ground valve (2) at its lower end. The piston (3) consists of two tubes with a soft iron core fused between them. The lower end of the piston has a valve (4) which is identically the same as the cylinder valve (2). Both valves close by gravity. The pump cylinder is surrounded by a lower solenoid (5) and an upper solenoid (6). Both solenoids are hooked up in separate circuits. By means of a three-pole, automatic mercury switch actuated by a rocking device, the electric current flows through the solenoids periodically in such a way that they are switched on and off, one after the other, with an intermediate state in which both solenoids are magnetized for a short time. Thus, a magnetic field is created inside the solenoids. The center of this field travels up and down periodically.

The iron core inside of the piston is attracted into the center of the magnetic field. The piston moves up and down continually, like the plunger of any pump. The up-stroke of the piston opens the cylinder valve (2) and closes the piston valve (4), while the down-stroke closes the cylinder valve and opens the piston valve. By this means, any fluid can be circulated or transferred.

The pump has many practical applications, especially where it is necessary to maintain sterility. It can also be employed for blood, and for strong acids, alkalis, or other dangerous fluids.—Heinz Rosenberger, in *Science.*

A Marine Airport

THE Engineering Service of the American Institute of Steel Construction has worked out a very interesting design of a floating marine airdrome for use near a big city. It was described in a recent issue of *Airports.*

Utilizing the experience of builders of steel railroad-car barges, the flotation principle has been applied to serve as the foundation for the drome. Although the structure weighs 7500 tons, its draft of water is but seven feet.

With this shallow draft the marine airdrome could be used near large cities, as for example in the waters of the upper bay of New York. It would then be comparatively near the center of the metropolitan area. The great problem of accessibility to large cities would be at least partially solved.

The top deck of the airdrome would have dimensions of 1000 by 200 feet. Since the airdrome could be so anchored as to head into the prevailing wind at any time, these dimensions would provide sufficient landing and get-away runs for all but the most heavily loaded aircraft. These dimensions would be greater than those available on the Navy's aircraft carriers. The deck would be entirely clear of obstructious. In the middle of each side there would be a wing bulging out about 25 feet for the convenience of passengers and visitors. The flood-lighting system would be such that the beam would be thrown into the wind or following the direction of the landing plane. The approaches for a mile or two in both directions would be illuminated by a series of lights that could easily be mounted on buoys 500 feet apart.

Aside from serving as floating elements, the pontoons are to house the heat, light, and power machinery. To keep the decks clear and to hasten take-offs, two heavy-duty elevators are to connect the two decks of the airdrome. The lower or service deck is to have an area of approximately 180,000 square feet, with an overhead clearance of 21 feet. Across the middle of the service deck there is to be a terminal building providing every airport facility including a hotel, waiting rooms, restaurant, offices, and other facilities. At each end of the structure a wide terrace is to be provided which would connect with a seaplane float below. Seaplane or amphibian facilities would thus be provided.

A novel and simple form of anchorage has been designed permitting a dual control, so that the airdrome can be headed into the wind at all times. The primary anchorage is arranged so that the structure will revolve within a radius of 600 feet.

While the marine airdome is still only in the "idea" stage, it seems feasible and plausible.—*A. K.*

Talkies for the Hard of Hearing

THE person who is hard of hearing has a most difficult existence, since he can not indulge in any form of entertainment or human activity in which the sense of hearing plays a prominent role. Recently a campaign has been undertaken in this country by the American Federation of Organizations for the Hard of Hearing to cause theaters, churches, music halls, and motion picture houses in which the talkies have replaced the silent pictures to equip some of the seats with plug-ins for hearing devices. Several theaters have already installed such plug-ins.

In the device installed in one London theater by L. E. Coussell, an engineer, a microphone is placed slightly in advance of and immediately below one of the loud speakers. There is a cable lead at the back of the screen which is taken from the microphone to a plug point on the stage, and further telephone cable is then connected with a special three-valve amplifier. A second line runs from the amplifier to a block of seats in the auditorium. This block is wired with armored cable and each seat hsa a telephone jack under the arm rest. The listening set consists of a single ear phone on a handle with a local volume control. The flexible cord of the ear phone terminates in a telephone plug, which lifts into the jack already mentioned. Each hearer can control the volume of sound to suit his own needs. The results were so satisfactory that similar equipment has been installed in other theaters.

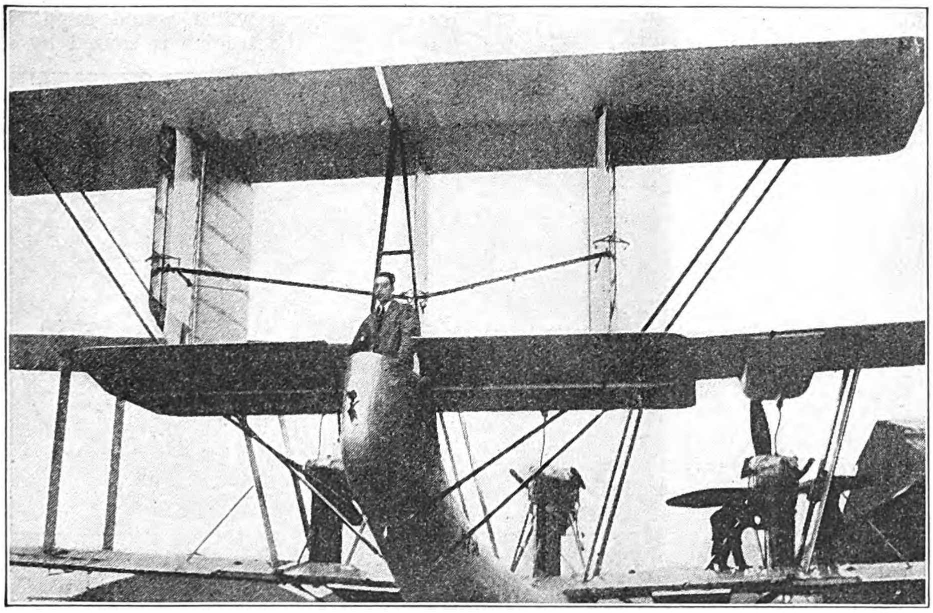
In this country the need of hearing devices is much greater and the campaign now being lead by Mrs. Louise Pelton of the Chicago League for the Hard of Hearing is tending toward the establishment of plug-ins. Already 25 out of 100 churches in Chicago are equipped and several motion picture houses are installing equipment.—*M. F.*

Cooling Transformers with Fans

A RECENT development in increasing the capacity or rating of a transformer involves the placing of fans about the radiators. The accompanying photograph shows one of a bank of three Westinghouse transformers installed at the Plymouth Meeting substation of the Philadelphia Electric Company. Each conical shaped projection houses a fan, or blower, which keeps a draft of air circulating through the radiators. The rating of this bank of transformers without the fans was 100,000 KVA; the capacity with fans as shown is 130,000—an increase of 30 percent.

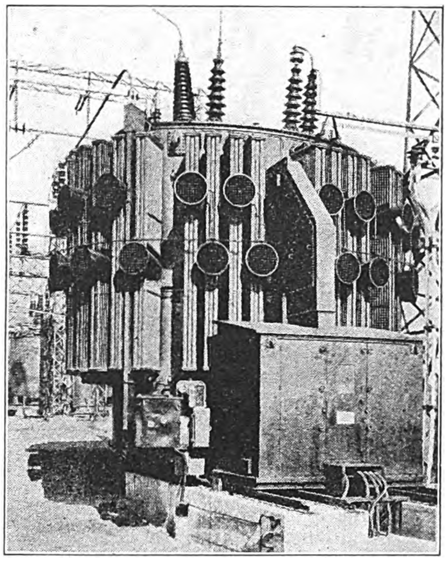
A Gunner at the Tail

THE large reconnaissance flying boats of the American and British navies are airworthy and seaworthy craft, capable of cruising long distances without the support of surface vessels, and are well equipped and well armed. Nevertheless, a large flying boat with many guns may be no match in single combat with a small combat machine, because the latter is so maneuverable and so fast. The best protection for the large and less maneuverable craft is to be able to fire in every direction.



Protecting the vulnerable point. A machine gun in the tail of a bomber

The Blackburn Company of England, has recently built a large all-metal boat, equipped with three Rolls Royce engines of over 600 horsepower each, in which an attempt has been made to give perfect fire range in the rear—where a large plane is most vulnerable—by installing a gunner's cockpit in the extreme end of the hull, aft of the tail surfaces. It is to be hoped that the gunner can easily make his way through the hull to a more central location. All the oscillations of the plane are so magnified at this distance from the center of gravity that even a hardened aviator might at times feel "squeamish.—*A. K.*



The conical projections on the side of this transformer each contain a cooling air fan or blower

To Destroy Poison Ivy

LOW-grade kerosene or crude oil, sprayed on the poison ivy vine, suffocates the plant tissues and causes destructive chemical action so that the plant dies. High-grade kerosene is not so good for it volatilizes too rapidly. Best results are obtained in hot weather. If possible, it is also advisable to cut the stems near the ground and repeat the cutting frequently until the plants are starved. Through lack of foliage, the plant, once it has used up the food stored in the roots, cannot manufacture more food for re-growth.

Loss of Hair Attributed to Deficient Diet

IF your hair is falling out it may be a sign that your diet is deficient in Vitamin G, the latest addition to the recognized family of diet principles introduced to a recent meeting of the American Chemical Society by Professor H. C. Sherman of Columbia University. Although Vitamin G has been identified for only about one year, physiological chemists at Columbia have conducted elaborate experiments of the effects of its presence or absence in the diet of rats. In these animals the vitamin is directly connected with growth. Lack of it, said Dr. Sherman, may retard growth, stop it, or in extreme cases cause death. In some rats the shortage caused premature old age. Loss of hair is one of its most commonplace danger signals. Its lack is suspected as a cause of pellagra.

"The growth requirements of rats," he said, "presumably apply to other mammals also. Vitamin G must play a prominent part in any adequately comprehensive conception of food values from now on."

Still another member of the vitamin family is suspected to be hiding behind "G." Dr. Sherman called it the "new factor" stating that it, too, is important for growth, and that evidences of its presence have been detected by several other laboratories in addition to Columbia's. This new factor is abundant in milk and presumably in meat. Vitamin "G" is abundant in milk and leaves, such as spinach, kale, and cabbage. It appears moderately, Dr. Sherman said, in meat and eggs.—*A. E. B.*

The Redrup Axial Engine

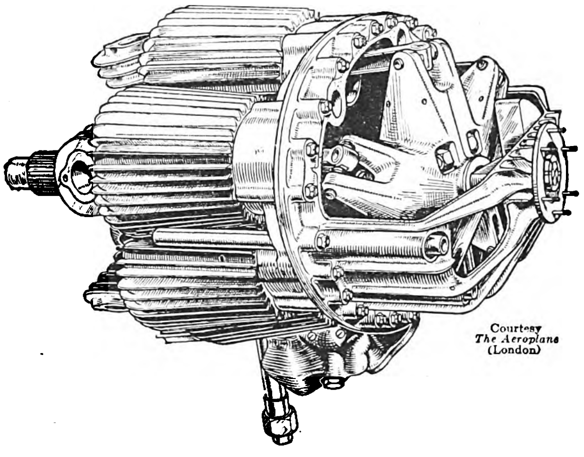
THE air-cooled engine of the star, or radial, type is always being criticized on the grounds that it impedes the pilot's vision because of its large over-all diameter and projecting cylinders, and because its head resistance is large. To make the engine more compact and to reduce the head resistance, the suggestion has often been made that the cylinders should be so arranged as to be parallel to the crankshaft, and quite near to the crankshaft center. The great difficulty in such an arrangement is the mechanical one of converting the reciprocating motion of the piston into the rotary motion of the crankshaft. The Redrup-Level axial engine, recently described in *The Aeroplane* (London), seems to offer an ingenious and successful solution of the difficulty, avoiding excessive rubbing velocities and highly-loaded bearing surfaces.

It can be seen from the drawings that the crankshaft, which lies along the axis of the engine, is carried by two roller-bearings and one ball-bearing. The crankpin is one of the special features of the engine. Instead of being eccentric and parallel to the shaft, it is set at an angle and actually crosses the center-line of the crankshaft, and is called a Z crank.

On the Z crank is a five-pointed star-member, each point of which is attached to the connecting rods of the five cylinders through a neat form of universal joint. The connecting rods carry a universal joint at their piston ends also. The star-member has two white metal bearings in which the Z crank revolves.

The easiest way to understand the motion of the star-member is to consider the instant when the top cylinder has just fired and the piston has completed half its down-stroke. There is obviously a compression force along one side of that particular arm of the star, tending to push the crank down and around.

The star-member must be allowed to oscillate but be prevented from turning. This is accomplished by a stabilizing fork or torque rod. This rod has a fork at one end which is hinged to the inside of the star-member. The axis of the hinge passes through the middle of the crank-pin and is always at right angles to the axis of the pin as the torque-tube is carried in a self-aligning journal bearing at the bottom of the crankcase.



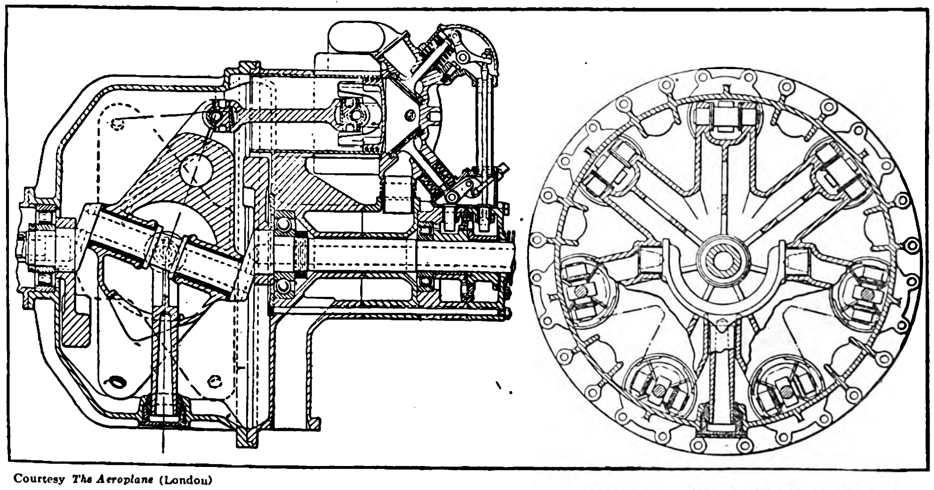
Courtesy *The Aeroplane* (London)

In this view of the Redrup axial engine for aircraft, the five-pointed star member which rotates on the Z crank (the special form of the crankshaft) may be seen at the right end. The cylinders lie parallel to the center-line of crankshaft rotation, as explained in the accompanying text

By this arrangement, the star-member is free to oscillate about the hinge of the fork, and, as the fork can twist in its journal bearing, the star-member can also twist about a vertical axis. Thus it can follow the wobbling motion caused by the rotation of the crankshaft and yet allow the full torque-reaction of the engine to be taken through the torque-rod to the crankcase.

There are three valves in each head, one exhaust and two inlet. They are of normal type and are operated by rocker-arms on the cylinder heads. These rockers are moved by push-rods with hardened steel balls at both ends.

The rods are operated by roller-ended tappets which are moved up and down by two-lobed cams running at one quarter engine-speed and driven in the direction reverse to that of the engine by epicyclic gearing off the crankshaft.



Courtesy *The Aeroplane* (London)

Cross-sectional views of the axial engine, side and front. At the left will be noted the manner in which the novel star member "rides" on the Z crank

In other respects the engine is normal in design.

The frontal area for the 60 horsepower engine has a diameter of only 18 inches. This opens many possibilities for use in a twin-engine machine, with engines mounted on the wings. The weight of the engine will be about 160 pounds or 2.6 pounds per horsepower.

The further development of the Redrup axial engine will be watched with considerable interest.—*A. K.*

Would "Perfume" Gas to Deter Suicides

"SOMEBODY is always taking the joy out of life," and now the chemist threatens to take the comfort out of dying, by mixing formalin with illuminating gas so that suicide by asphixiation will be less attractive. The interesting suggestion that formalin might be mixed with coal gas as a deterrent to suicides was made by Dr. F. J. Waldo, the London city coroner, recently. Dr. Waldo declared that the formalin admixture would make the would-be suicide's eyes water and perhaps also cause him or her to sneeze. As suicide is so often the result of a momentary brainstorm, the delay thus caused would probably give the would-be suicide time to think better of the idea.—*A. E. B.*

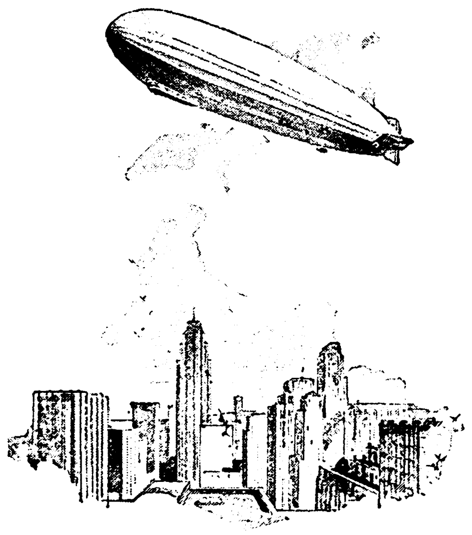
If You Ever Wash Dishes You've Wondered About This

EVEN editors have to wash the dishes occasionally, and it was in the performance of this domestic chore the other evening that we got to wondering what makes those silvery black marks on the china that simply will not wash off. By a queer coincidence, we picked up a *Technical News Bulletin* of the United States Bureau of Standards the next day, and learned that others have wondered about the same thing, and that the Bureau has investigated the phenomenon with interesting results.

It is reported that when such objects as silver-plated knives are drawn across tableware, a mark results which can not be removed by washing. The bureau has carried on certain work which would seem to indicate that the trouble is caused by a slight, almost inappreciable roughening of the surface of the ware because of its being fired in the presence of gases from sulfur in the kiln.

This was shown to be the case by taking some pieces of ware from a manufacturer which did not show any cutlery marking and giving them a firing in an electric muffle into which measured amounts of sulfur dioxide were introduced. When as little as 0.0625 percent by volume of this

CONQUERING THE FOE . . . that turned back a Zeppelin

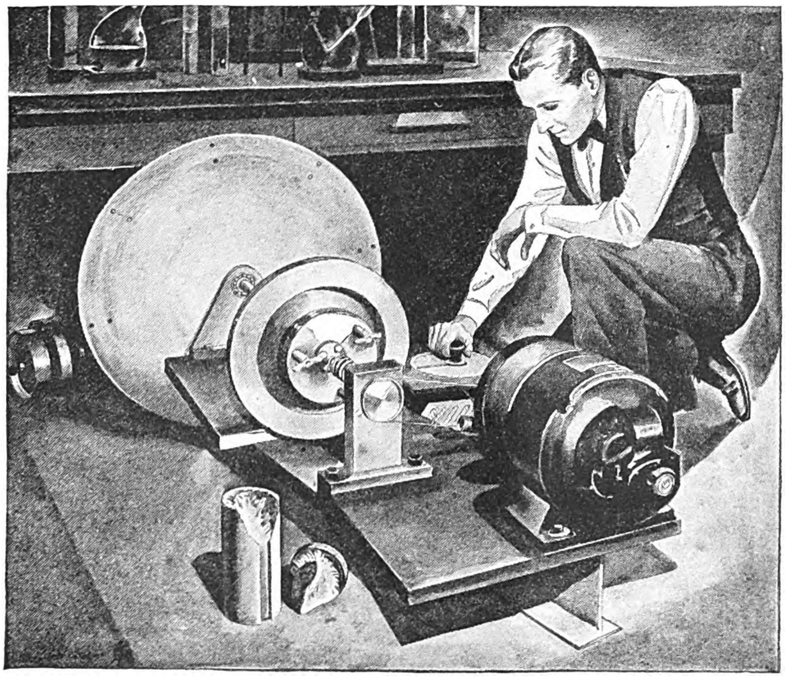


A giant Zeppelin not long ago started across the Atlantic. Hardly was it well under way, when, one by one, the drive shafts of four of its five engines cracked and went out of action. The great air ship turned back and landed—reaching its port just in time, as mechanics soon discovered, for the fifth shaft was then almost at the breaking point.

Vibration which turned back this huge Zeppelin is a foe to every modern high speed machine. In the Westinghouse research laboratories at East Pittsburgh vibration has been put on the stand to disclose its own secrets. Its ways have been charted. Its behavior has been reduced to mathematical formulas which engineers can now use in designing machinery to operate safely and reliably at the high speeds which modern industry demands.

Not only in electrical details of modern machinery, but in mechanical details as well, Westinghouse carries on its work of research and improvement—helping you to have more by making machines capable of doing more.

The results of Westinghouse research actively serve you in mines and factories, theaters, homes, stores, and offices—wherever the work or recreation of the modern world is carried on.



Westinghouse Electrification
Appliances Apparatus

W

Tune in the Westinghouse Salute over WJZ and the coast-to-coast network, every Tuesday evening.

Westinghouse

gas was introduced into the muffle the ware, on removal, gave ready evidences of cutlery marking.

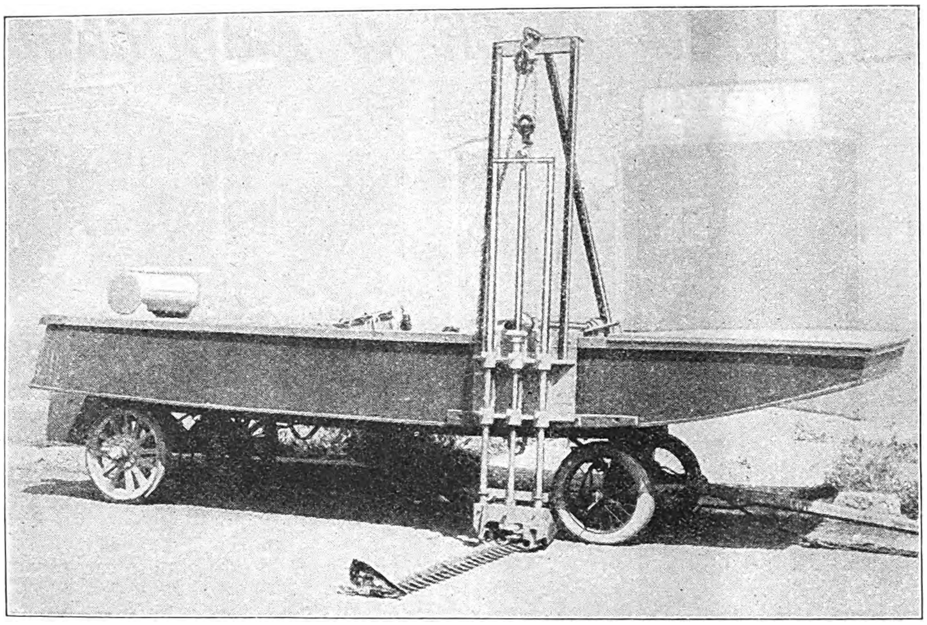
It was further found that on treating the ware, fired as described above, with solutions of ammonium acetate, lead sulfate was dissolved from the surface of the glaze. On the removal of this material by such a process as buffing, the ware no longer would mark. Samples of enameled iron similarly fired also developed a condition which resulted in cutlery marking. Commercial practices would seem to confirm the above result. One manufacturer, in substituting an electric muffle for firing his decorated ware, obtained a product that was no longer susceptible to cutlery marking. The fact, however, that this trouble was due to the formation of an extremely thin layer of lead sulfate seems not to have been noted previously.—*A. E. B.*

Steel Industry Consumes Most of Our Manganese

ABOUT 95 percent of the manganese consumed in the United States is used in the manufacture of steel, the principal base alloys being ferro-manganese and spiegeleisen, according to the United States Bureau of Mines. There is considerable manganese in many varieties of steel, including spring steels, plate steels, structural bar types, rail steels, and various steels used in the manufacture of wheels, tires, axles, armor plate, and other products of a similar nature.

Formerly manganese steels containing 1 to 1.5 percent manganese were classed as good-grade Bessemer steel, but recently they have been classified as alloy steels and have been put on the market under various trade names. Such steels have excellent tensile strength and ductility with high resistance to abrasion, and are used extensively in Caterpillar shoes, truck wheels, and other appliances where relatively low cost and high quality are required.

A manganese steel containing 12 to 14 percent manganese is used in castings for ball mills, pulverizing machinery, and rock-crusher jaws because of its resistance to impact wear and because of its hardness. Manganese is also an important constituent of nickel and molybdenum steels. Molybdenum steels usually contain 0.2 to 0.4 percent molybdenum and 1 to 1.5 percent manganese. Nickel-manganese steel usually contains approximately 1 percent nickel, 1 to 1.5 percent manganese, and 0.3 to 0.4 percent carbon. The nickel adds ductility and toughness but increases the cost.—*A. E. B.*



The lily mower which cuts the stems of these plants under water. It consists of a boat (here shown on wheels) with an adjustable mower attachment

Underwater Lily Mower

THE problem of mowing a heavy growth of pond lilies from a 50-acre reservoir in Earlington, Kentucky, resulted in the ingenious "boat mower," shown in the accompanying illustration. The growth of lilies was satisfactorily eradicated with the machine shown and a knotty problem thus was solved.

The flat-bottom scow is driven by a 35 horsepower Universal motor, which operates the cutting mechanism as well as propels the boat. The flywheel of the engine was removed and replaced by a spur gear. Between the cutter bar and the motor were placed an automobile clutch and transmission gear so that the boat could be propelled without the action of the cutter, and also to permit different speeds without having to operate the cutter bar.

The cutter bar is adjustable for different depths of water and performs at varying depths of from 18 inches to 60 inches below the surface. The middle bar on the carriage is the driving shaft on which the bevel bar slides up and down to drive the shaft by means of a key which fits in a groove. The bottom shaft is connected to an eccentric and connecting rod which gives the necessary oscillating motion. The entire gearing was arranged to drive the cutter at a slightly slower speed than the normal speed of such a bar on an ordinary mowing machine. The cutting mechanism is raised and lowered by a differential pulley.

The strange craft has been christened "The Lily Nipper."

Page From This Magazine Does Duty as Wall Paper for 78 Years

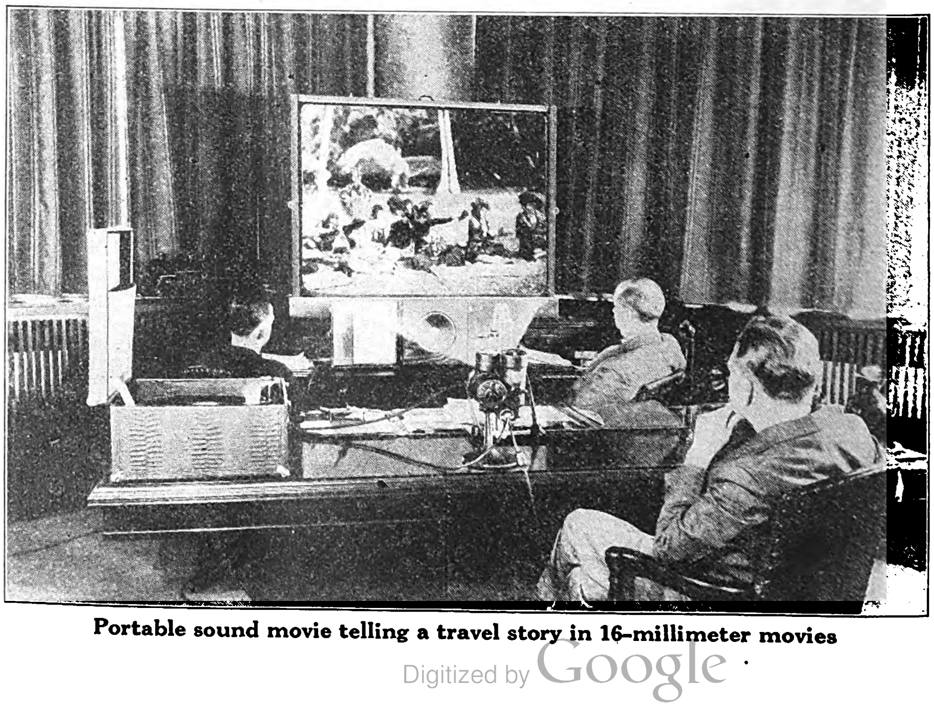
THE following item was clipped from a recent issue of *The Arcata Union*, of Arcata, California:

"While tearing down an old wall in the Vassaide Building a few days ago, carpenter Collins came across a board with a piece of newspaper attached to it which had been doing duty as wallpaper. The fragment was a portion of the SCIENTIFIC AMERICAN dated 1852 and was put in use when wall paper was scarce in Arcata."

Portable Sound Movie

A DISTINCT innovation in the motion picture field—a thoroughly practical portable equipment for the presentation of sound movies—was recently announced by the Bell and Howell Company. Amateur projectionists will be particularly interested to know that 16-millimeter films are exclusively used with this newly developed equipment.

The complete outfit consists of three small units which can be easily carried from place to place. Any Filmo projector



Portable sound movie telling a travel story in 16-millimeter movies

can be adapted for use in this equipment. A standard 16-inch phonograph record of the 33⅓ revolutions-per-minute type, is synchronized with the projected pictures. The projector, player unit, and a dynamic speaker each are contained in a separate case, and can be quickly set up and easily operated.

The Filmo projector and playing unit are driven by separate motors, each motor designed for its special purpose. The two units, the projector and the playing unit, are then coupled together mechanically by means of a flexible shaft so that positive synchronization is assured, regardless of the length of the picture or record.

Diesel Engined Ford Tri-motor Plane

SEVERAL airplane manufacturers are offering their planes equipped either with a gasoline motor or the Packard airplane Diesel engine, the purchaser to have his choice. Of these, according to *Barron's*, The Ford Motor Company, in its advertising pamphlets of the Ford tri-motor plane powered by Packard Diesel engines, says fuel consumption for each engine runs about 10 gallons an hour, which at nine cents a gallon brings total fuel cost to around 3 dollars an hour, a saving in fuel cost of more than 60 percent. Diesel engines decrease both cost and quantity of fuel necessary and use about 20 percent fewer gallons per horsepower than gasoline engines, it is pointed out.

Paper Mulches for Growing Plants

"ONE thing leads to another" may be a conversational platitude but it certainly describes the process by which one enterprising home gardener profited. A recent letter from Mr. B. K. Smith, of Newcastle, Indiana, states that he read the article "Farming Under Paper" in our August, 1928, issue and then during the summer of 1929 experimented in a small way with paper mulches. Inasmuch as his experiences may prove of benefit to others, we quote below a letter which he sent to the *Newcastle Courier:*

"We have worked out a method that can be used for garden mulch around the plants. Last year we were growing green beans. When the drought came, their leaves began to wilt and were doing no good. The first row we tried soaking the ground around them thoroughly in the evening, then taking the first or second section of the *Indianapolis News* or a whole *Newcastle Courier*, folding them to fit between the rows, thus making packs of eight to 12 or more sheets thick. We laid them close to the plants on each side of the row like shingles, only reverse, commencing at the top of the grade, so that when it rained the water would run under the packs instead of over and off. We soaked the papers thoroughly and put dirt, stones or bricks on the upper corners to prevent wind from blowing them away.

"The first week this row began to thrive and bloom. The other rows not so treated began to die.

"We also tried medium asphalt roofing cut in strips. This did not do so good as the paper packs but better than none. We find several sheets of thin paper to be better than one heavier or roofing. Also the water runs off the roofing instead of

Leica

the versatile camera

FOR travel pictures, action and sports pictures, portraits and panoramas, there is no camera like the Leica. Scientists, explorers, professional photographers and amateurs who recognize and demand superlative camera quality—all choose the Leica.

This unusual camera fits the vest pocket or purse, and its highly corrected lens insures clear, sharp negatives under the most adverse conditions of light and weather. A truly fine camera, inexpensive to operate. One roll of cinema film gives 36 pictures, and each picture is capable of perfect enlargement to 12 x 18 inches or more.

See the Leica demonstrated at your photographic supply dealer's or write for free catalog 1174. E. Leitz, Inc., Dept. S. A., 60 East 10th Street, New York, N. Y.

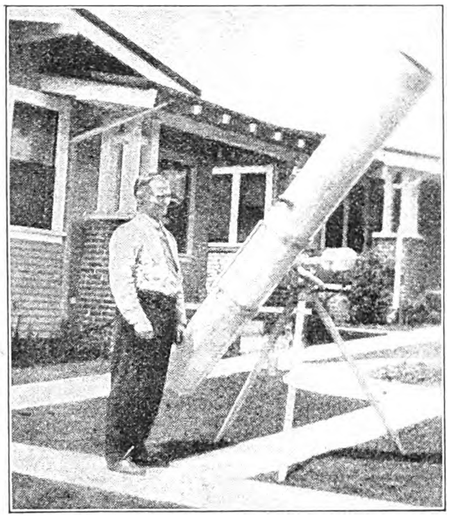
The Amateur Astronomer

A Monthly Department

THE amateur who aspires to make his own telescope is advised to begin on an instrument having a diameter of not more than six inches, as this is the most suitable size on which to get one's initial experience. Sets of materials, ready to use, may be had in this size for ten dollars, and the interesting work of grinding, polishing and figuring the mirrors should not occupy more than a dozen evenings.

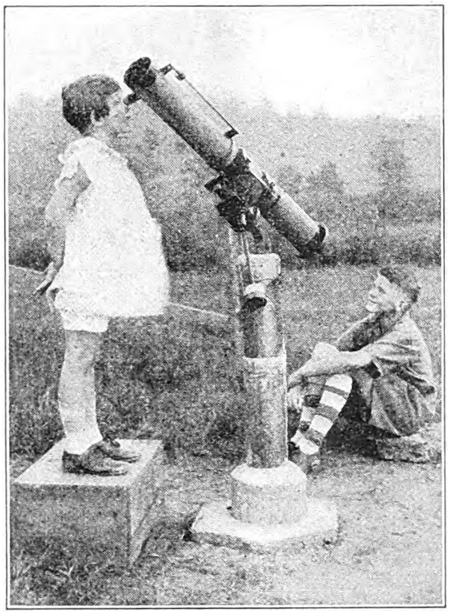
When a worker has completed a six-inch telescope, though it should magnify from 50 to 200 diameters and be the equal of a refracting telescope four inches in diameter and costing 300 dollars or more—a real astronomical telescope—he is ready to tackle something larger. A 10-inch is about the ideal size for the average amateur ultimately to possess, representing a compromise between skill, pocketbook, and pipe dreams.



Nettell and his 10-inch

MR. RICHARD NETTELL, 155 North Boylston Street, Los Angeles, California, sends us a description and photograph of his 10-inch reflector. "I have made four or five telescopes before," he writes, "but this last effort of mine was made since I got the SCIENTIFIC AMERICAN instruction book 'Amateur Telescope Making.'

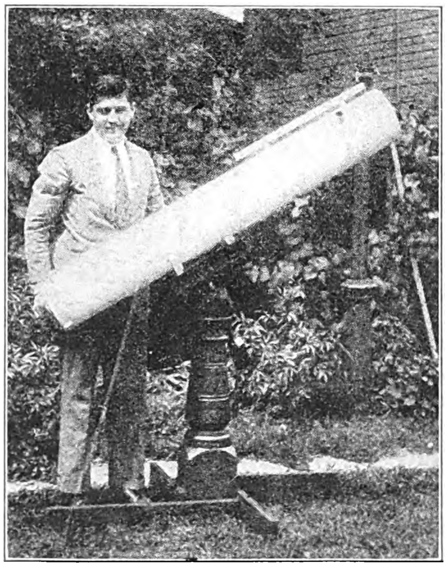
"The point I wanted to stress in my design was convenience and ease of observation and operation. The observer stands on the ground level, which is a great convenience for elderly or nervous people. The telescope is a tripod, take-down affair, as I have no room to keep it set up. The mirror is 10 inches in diameter, with a focal length of 130 inches. The tube is 11 inches in diameter and is eight feet long. At the upper end of the tube there is a three-inch flat, reflecting the rays back to the diagonal located opposite the eyepiece; making three reflecting surfaces in all. I appreciate the fact that by this design I lose some of the light, besides the loss through adding another reflecting surface, but I thought the convenience of standing on the ground more than compensated for that loss.



Lambert's four-inch

"The grinding and polishing were all done in the evenings, within three feet of our cook stove. The curve of the mirror, when I got through with polishing it, was as perfectly spherical as I could determine by the knife-edge shadow test; this with a room temperature drop of two degrees per hour. It showed in a slight degree the oblate spheroid form when the room temperature was even. All my previous mirrors had been more or less hyperbolical, and I wanted to avoid this if possible, so I estimated that the drop in temperature out-of-doors would give it the necessary parabolic form if I left it spherical.

"In performance, my mirror, when testing it on distant bright terrestrial objects, gives fairly sharp definition when using a ⅕-inch focus eyepiece. That means a magnification of 650 diameters.

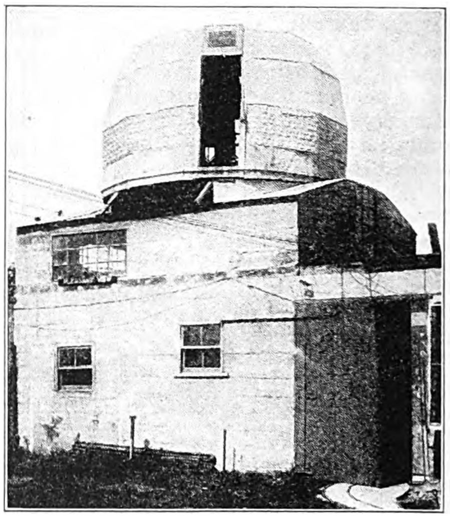


Staffa—Pyrex mirror

"The mounting is an equatorial, on a collapsible tripod, with a clock and weight drive. The pipe handle to carry it by, is also the finder."

Mr. Nettell evidently has succeeded in producing a good mirror despite proximity to a stove. Usually mirror making is done in the cellar, because there the temperature is most nearly uniform. Yet if the kitchen were also held uniform, and were about the same each night, the difficulty might not be great, for it is changing, not changed, temperature that causes trouble, as Ellison states (page 95, "Amateur Telescope Making"). One point to be considered is that ordinary pitch is too soft when used in a warm room. However, it may be boiled down to greater hardness, or resin may be mixed with it. At any rate, nothing succeeds like success, an adage which Mr. Nettell seems to have proved. He gets results from his telescope; it suits him; and that's that.

MR. ARTHUR W. LAMBERT, JR., Arcadia, Missouri, started on a four-inch mirror which he made from a disk of half-inch plate glass. His telescope is shown in one of the illustrations. Later he made a six-inch. He suggests that two mirrors should be started at the same time and "leap-frogged." He writes, "Let the worker get the first one ground and polished. Then mount it, silver it and begin to observe. He ought to get good results, at least intriguing and inspiring. Then let him try his hand on glass No. 2 and bring this to some kind of figure. He will improve on his first, then can switch mirrors, and can begin again on No. 1. By the time he has it again in the mount, he will know something more than he did, and can begin again on No. 2. This can go on indefinitely, until perfection is attained.



Pleasant View Observatory

"Another thing really surprised me. That was the real pleasures you can get from a poor glass. My first mirror, a four-inch made of windshield glass, is a very poor mirror. It brings a bright star to a sort of cock-eyed focus. Yet it splits double stars, sees the moon very well, and performs in a surprisingly good manner. I have it mounted in the telescope shown in the enclosed picture. With this little fellow I easily find the ring nebula in Lyra."

COMMERCIAL polished plate glass is the material almost universally used for the mirrors of reflectors less than 12 inches in aperture, but a finer material, though a more costly one, is Pyrex. It has the advantage of a low coefficient of expansion—about one third that of glass. Where the amateur is skilled enough to produce a nearly perfect figure he may use this material to good advantage. Mr. George Staffa, 32 Front Street, Schenectady, N. Y., used it, and reports as follows:

"The mirror was ground according to instructions in 'Amateur Telescope Making', from two 7½-inch by ¾-inch disks of Pyrex, to a focal length of 54 inches. The polishing was done on a lap made of resin, beeswax, and paraffin which, while hot, was impregnated with rouge. This took only a short time, as the grinding had been done very thoroughly; in fact, the whole process of polishing and figuring took only about four hours. The mirror was polished to the very edge, as is shown by a microscope. I experienced none of the troubles described in 'Amateur Telescope Making.'

"The figure appears just the same after standing for half an hour as it was right after removing from the lap. Very good results were obtained on Saturn; also Jupiter, on which the markings can be seen quite in detail. There are a number of other telescope enthusiasts in Schenectady who have made mirrors of Pyrex."

MR. GEORGE H. CHASE, 28 Washington Square, Newport, Rhode Island, has erected an observatory on the roof of his shop. He writes:

"The observatory shown in the photograph was built by Milton H. Chase and myself. The tower is built on top of a concrete workshop and is 14 feet in diameter. It rests on steel channels, and rolls around on eight wheels, being moved by an electric motor through a chain drive which passes around the outside of the tower.

"The electric motor control is on the post near the observer's seat. The framework of the tower is built of two-by-four joists and is covered with corrugated galvanized iron on the outside. The inside is covered with wall board. The present telescope is a six-inch, but provision has been made to take a 12-inch. This observatory is located at my home in Portsmouth, Rhode Island."

Speaking of amateurs' private observatories, *Popular Astronomy* (Northfield, Minnesota) began in January publishing an interesting series of descriptions of these, which is to run through the present year.

HOW about making a spectrohelioscope? Since Dr. Hale contributed instructions for the job, ("A. T. M.," pages 180-202) a disappointingly small number have tackled it. One big obstacle is undoubtedly the cost of the grating, 125 dollars, but the remainder of the materials can be made by the amateur. In a recent letter Dr. Hale states, "You will be glad to know that spectrohelioscopes of the

Dr. Stemmerman's Great New Book
INTESTINAL MANAGEMENT
Will Bring You Longer and Happier Life

If you seek freedom from the results of constipation, high blood pressure, acidosis, rheumatism, kidney troubles, headaches, nervousness, inability to concentrate, sleeplessness, etc.—if you would be free from the slavery of constant dieting, pill taking and the enema habit, begin thus: Send for our free brochure. It reviews "Intestinal Management" fully, contains three full chapters (to give you an idea of its readability and good sense) viz., "Insomnia," "Is Exercise Worth While?" "Shall We Eat Fruits and Vegetables?" and includes a biographical sketch of its internationally known author, William H. Stemmerman, M. D. (New York University and Bellevue Hospital Medical College).

He tells you, in simple language, how to permanently banish constipation and its serious consequences; how to flush the bowels daily without the use of drugs, minerals, oils or enema. He gives you the fruitful results of 35 years' active experience as a regular medical practitioner and as a specialist in intestinal hygiene.

EVERYONE who values health and longevity should SEND TODAY for this **free** brochure, to

The Scientific American Digest

(*Continued from page 65*)

under, as with the papers, and the packs will hold more moisture than the one sheet of roofing.

"We tried the paper packs on most of our garden last year on flowers, beets, onions, parsnips, cabbage, and tomatoes with good results. Probably we would have had better growth had we commenced using the papers before the ground dried out. As it was, however, the paper mulches proved their value.

"This year we expect to plant the seeds through the paper packs by using a sharp stick piercing the packs for plants to come through, first making a depression at the row so that the water will run to the plants."

Wood Impregnated with Metal

THERE has been developed during the last years by the German Institute for Steel Science in Duesseldorf a new procedure by which it has been made possible to fill the pores of wood with metal. The material which is thus produced combines to a certain degree the properties of metal as well as of wood. The new procedure is carried through by immersing wood in molten metal under pressure. The duration of this treatment and the temperature and pressure applied are of importance. All parts of the wood that are not filled by metal remain unchanged.

In a small trial plant, wood pieces 15 by 24 by 12 inches were thoroughly impregnated with metal. Infiltration may be limited to any desired depth. It has been found that the new material may be machined like ordinary wood. It is scarcely inflammable and does not enlarge its volume by taking up moisture. The appearance of the metallized wood is unique and it is expected that it will lend itself especially well to decorative purposes. It may also be suitable for lining journals and bearings, if a suitable metal is used for penetrating the wood. The new material was shown for the first time at a recent wood and timber exhibition in Berlin.—*A. E. B.*

New Solvents Eliminate Textile Problems

NUMEROUS textile problems have been greatly simplified or completely eliminated during the past year by the availability of certain of the new synthetic organic chemicals which formerly were not available on a commercial scale. Diethylene glycol has proven an almost ideal lubricant for wool spinning. Impregnation of the fiber with this chemical makes unnecessary the use of oils and as a consequence eliminates the costly operation of scouring for oil elimination after spinning. The glycol remains in the fibers of the spun yarn or fabric until the first treatment with either wash water or dye solution. At this point the glycol, which is water soluble, is removed without the necessity of another operation. New possibilities in the printing and dyeing of textiles have been made available by the use of Cellosolve and its derivatives as the medium for making solutions or pastes of dyes and colors. This group of solvents first developed for use in nitro-cellulose lacquers has thus found an extensive new application in textiles.—*A. E. B.*

Current Bulletin Briefs

Short Reviews of Bulletins and Papers on Scientific and Allied Subjects, and Where to Get Them

Abrasive Materials in 1928, by Oliver Bowles. Grinding and polishing processes are of great importance. This pamphlet deals with the production of natural and artificial abrasives. *Superintendent of Public Documents, Washington, D. C.—5 cents (coin).*

Studies on the Fall Army Worm in the Gulf Coast District of Texas (Technical Bulletin 138-T). Make application for this bulletin to the *Office of Information, Department of Agriculture, Washington, D. C.—Gratis.*

Foaming of Milk and Cream (Circular 108, United States Department of Agriculture) by C. S. Leete. Foaming often causes much loss of both product and labor and the present pamphlet is a practical treatise on the subject based on experiments. *Superintendent of Documents Washington, D. C.—5 cents (coin).*

Architectural Acoustics (Circular of the Bureau of Standards No. 380) are not yet generally understood even by those who design auditoriums. In this circular the principles are stated and an example is worked out showing their practical application to the planning of a new auditorium. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

Chemistry and Analysis of the Permitted Coal-Tar Food Dyes (Department Bulletin No. 1390) by Joseph A. Ambler, W. F. Clarke, O. L. Evenson and H. Wales, deals with a subject in which there have been recent changes. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Automatic Line Voltage Regulation is a folder containing practical information on this subject as related to radio receiving set operation. *Clarostat Mfg. Co., 285-7 North Sixth Street, Brooklyn, N. Y.—Gratis.*

Wall Diagrams of Electro-Magnetic Waves. A heavy paper chart 22 inches high by 72 inches wide, presenting in clear diagrammatic form the 62 known octaves of ether waves, including cosmic rays, X rays, ultra-violet rays, visible light, infra-red rays, and Hertzian waves, with summarized data on each—frequency per second, wavelength, how generated, and how detected. Just the thing for the student of the new physics. *John Murray, publisher, 50 Albemarle St., London W 1, England.—Unmounted 4/6 net. On linen, with rollers, 12/6 net.*

PHOTO CELLS. A loose-leaf pamphlet which will be added to from time to time. First release includes photoelectric effects, operation of cells, applications, and circuits.—*Jenkins Television Company, 346 Claremont Ave., Jersey City, N. J.—25 cents.*

MARKETS FOR FUEL-OIL BURNERS IN THE EASTERN HEMISPHERE (Trade Information Bulletin No. 679, Department of Commerce). *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

PREPARING SHIPMENTS TO CANADA (Trade Promotion Series No. 91, Department of Commerce) deals with documentation and customs entry. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

AMERICAN UNDERWRITING OF FOREIGN SECURITIES IN 1929 (Trade Information Bulletin No. 688). Compiled by Paul D. Dickens. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

FINANCIAL DEVELOPMENTS IN THE FAR EAST (Trade Information Bulletin No. 680, Department of Commerce) gives a brief survey of financial happenings in the Far East during 1929. It is based almost entirely upon the first-hand reports of field officers of the Departments of Commerce and State. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

THE SOCIAL PHILOSOPHY OF PENSIONS WITH A REVIEW OF EXISTING PENSION SYSTEMS FOR PROFESSIONAL GROUPS (Bulletin No. 25. The Carnegie Foundation for the Advancement of Teaching) by Henry S. Pritchett, President of the Carnegie Foundation. *The Carnegie Foundation for the Advancement of Teaching, 522 Fifth Avenue, New York City.—Gratis.*

FINLAND. AN ECONOMIC REVIEW (Trade Information Bulletin No. 681, Department of Commerce) deals with the most densely wooded country in Europe, where 80 percent of the population is rural, affording an expanding market for United States goods. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

THE MOTORIZATION OF NORTH AFRICA is the title of Trade Information Bulletin No. 689, by the Department of Commerce, dealing with the rapidly growing market for automotive products in North Africa. In 1929 it took nearly 2,000,000 dollars worth of American automotive products, an 85 percent increase over the previous year's figures. Any branch office of the Bureau of Foreign and Domestic Commerce, or *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

PULP-WOOD CROPS IN THE NORTHEAST (Leaflet No. 57, United States Department of Agriculture) by M. Westveld. Illustrated. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

THE WEATHERWOOD HANDBOOKS: 1. For Plasterers; 2. For Contractors and Carpenters; 3. on Sound Deadening Construction; and 4 on Industrial Roof Insulation; and How You Can Make Your Farm More Profitable, and The New Standard of House Construction constitute a useful series on the application of Weatherwood, an insulating board fabricated from hardwood. *Chicago Mill and Lumber Co., Chicago, Ills.—Each gratis.*

GLOSSARY OF TERMS USED IN FIRE CONTROL (Miscellaneous Publication No. 70, United States Department of Agriculture) has been prepared by the Forest Service. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

THE APPLICATION OF SILVICULTURE IN CONTROLLING THE SPECIFIC GRAVITY OF WOOD. (Technical Bulletin No. 168, United States Department of Agriculture) by Benson H. Paul, describes some interesting results which show that the specific gravity of the woods studied may be modified by controlling local factors which affect the growth either of forests or individual forest trees. *Superintendent of Documents, Washington, D. C.—15 cents (coin or money order).*

CAESIUM, RUBIDIUM, AND LITHIUM, Information Circular 6215, details the history of discovery of these minor alkali metals, their various odd uses, alone and in alloys, their sources, and the markets for them. *United States Bureau of Mines, Department of Commerce, Washington, D. C.—Gratis.*

PRINTING AND PUBLISHING AND ALLIED INDUSTRIES. (Census of Manufactures, 1927) gives full information in tabular form as to the industries relating to printing. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

CELLULOSE. A new trade paper devoted to cellulose, its derivatives and products. *The Cellulose Publishing Co., 114 East 32nd St., New York City.—$3.00 a year, not $3.50 as previously stated. 35 cents a copy.*

ANALYSIS BY MOVIETONE OF A CRICKET'S CHIRP. By Doctors Lutz and Hicks. Scientists apply the Movietone principle to the analysis of insect music, with rather surprising results. *American Museum of Natural History, 77th St. and Central Park West, New York.—15 cents, postpaid.*

but you can't *fold* a "Muskie!"

ONLY 29 pounds — that's all this world's lightest twin outboard motor weighs. *And it f-o-l-d-s!* Up comes the lower unit, down swings the tiller handle to form a comfortable carrying handle. *Snap, snap . . .* in 30 seconds Fold-Light f-o-l-d-s to only 11¼ x 13¾ x 17 in. Stow it, carry it anywhere.

FOLD-LIGHT

Full 2¾ horse power; 3 to 11 miles an hour; runs 2¼ hours on a gallon of fuel. Gets *efficient* speeds out of canoes, rowboats, yacht tenders, etc. First to cushion power head in rubber, minimizing vibration. Automatic circulation of oil to main bearings. Twin silencers.

SCIENTIFIC AMERICAN

The Amateur Astronomer

(*Continued from page* 67)

type shown in my article are already in use at Pomona College, California; the University of South Dakota; the University of Michigan; Yerkes Observatory; Ohio State University; Vassar College; the Royal Observatory at Greenwich; the Astrophysical Observatory at Arcetri, Florence; the American College at Beirut, Syria; the Government Observatory at Canberra, Australia; and the Observatory at Samoa. Others have been ordered for use in Chicago, England (2), and China, and two native Indians in Madras (one an amateur) are building outfits for themselves." Isn't it time more amateurs jumped into this interesting game? Thus far, five American amateurs have nibbled at it, and of these some are believed definitely to be "hooked." The blueprints cost only a dollar and a half. Reread Dr. Hale's chapters, also the *Astrophysical Journal* for December, 1929, and see whether these do not make you want a spectroheliscope.—*A. G. I., Tel. Ed.*

Our Point of View

Analyzing the Naval Treaty

(*Continued from page* 16)

of the Japanese delegation was buttressed by three very solid factors; first, they attended a conference jointly arranged by Great Britain and the United States, and as guests were under no obligation to make the party a success; secondly, since 1922, in submarines, they had outbuilt both Great Britain and the United States and possessed more modern submarines than any other state at the Conference, nor had they weakened their position by advocating the abolition of submarines as weapons of war; thirdly, during the same period they had outbuilt the United States in cruisers, had built up to a 9 to 6 ratio in destroyers with Great Britain, and were fast attaining a 5 to 3 ratio with us in destroyers, the only category in which we had full strength.

The continuous and comprehensive naval program of Japan since 1922 has only one modern counterpart in time of peace, that of Germany prior to 1914, and it has been carried out despite financial difficulties and the destruction of Yokohama and part of Tokio by earthquakes. This vast naval program would be no proper concern of ours except for the fact that in Washington, in 1922, we scrapped our capital ships and agreed to limit the fortifications of our Far Eastern possessions when we believed the 5 to 3 ratio with Japan would be extended to all categories of ships. Now, by the provisions of the London treaty we concede parity to Japan in submarines, a 10 to 7 ratio in destroyers, and a 10 to 7 ratio in six-inch gun cruisers. As a climax, Japan expressly reserves the right, at the end of the treaty period, to reopen the question of further increasing her ratio of eight-inch gun cruisers to 10 to 7.

At present we have only a 5 to 3 ratio in capital ships because, although granted a 5 to 3 ratio in aircraft carriers, actually we have built only 66,000 tons of modern aircraft carriers against 61,270 tons for Japan, and we have authorized one more carrier of 13,800 tons while Japan is building one of 7600 tons. Thus, unless we accelerate our building program from now until 1936, we will be practically equal to Japan in modern aircraft carriers, and inferior in cruisers. We will have only a 10 to 7 ratio in destroyers, and all of Japan's destroyers will be modern post-war tonnage, while the bulk of ours were designed and hurriedly constructed during the World War to meet the German submarine menace.

Our position relative to Japan during the life of this treaty may be recapitulated: in capital ships we will have a 5 to 3 ratio; we will have a 10 to 7 *tonnage* ratio in destroyers, but our destroyers are all over 10 years old, while Japan's are all under 10 years, and one half are less than five years old; Japan has eight eight-inch gun cruisers in commission, we have one; by the end of 1931 we will have eight, Japan will then have 10; by the end of 1932 we will have 11 and Japan will have 12; by 1936 we will finally attain a 5 to 3 ratio in eight-inch gun cruisers. In six-inch gun cruisers, Japan today has 20 of 95,000 tons against our 10 of 70,500 tons. By the terms of the treaty if we build 18 eight-inch gun cruisers we can build six-inch gun cruisers only in the ratio of 10 to 7. Provided Congress acts promptly and we lay down four six-inch gun cruisers per year, it will be 1935, one year before the treaty expires, before we will attain a 10 to 7 ratio in six-inch gun cruisers. In modern aircraft carriers we have a scant margin on Japan at present, and unless we accelerate our building program during the life of the treaty, it will remain about 8 to 7. In modern submarines we are at present inferior to Japan and by the treaty she concedes us parity.

THUS, by resolutely carrying out her comprehensive building program between 1922 and 1930, Japan was able to send to the London Conference a delegation in a position to insist upon her demands. This position was rendered impregnable by the solid support the Japanese government and people gave their delegation. No group of Japanese pacifists weakened the arguments of their delegation with demands for naval reduction. As a result, Japan obtained practically every item in her demands, and yet following an ancient custom, the leader of her delegation, in his report to the Emperor, deplored his unworthy talents that so inadequately represented his country's case; while our delegation returned almost jubilant because the Japanese did not insist at this time on a 10 to 7 ratio in eight-inch gun cruisers.

The Japanese press states that Admiral Kato, Minister of Marine, strenuously opposed any concessions, and made at least one personal appeal to the Emperor to overrule the decision of the Government. This effort failed, but to placate the Navy Department, the Cabinet promised to find money for the following new projects:—

(a) An increase in the air force from 17 air battalions to 20 battalions.

(b) Building of some special service ships (types unspecified).

(c) Strengthening of fortifications.

(d) Increase of expenditures on account of the upkeep and repair of ships.

In short, the Japanese government will divert to other naval and military measures the money saved by the Conference.

The Japanese press also explains to the Japanese people that their government felt obliged to yield to Great Britain and the United States, lest the resulting estrangement between Japan and these two countries produce serious effects on Japan's international position, both politically and economically. One paper emphasizes the important fact that if the Conference failed and replacements of capital ships began next year under the terms of the Washington Treaty, Japan would have to find 75,000,000 dollars for building purposes which would necessitate still higher taxes. Finally the Foreign Office reminds the Japanese public that although under the compromise plan Japan's ratio was fixed at 62 percent, Japan's actual ratio up to 1936 would be 72 percent and that she had specifically reserved the right to restate her demands at the next conference.

It seems patent, therefore, that the small abatement Japan made in her total claims was due to her apprehension of the political and economic consequences if she offended both Great Britain and the United States, to her belief that a total failure of the conference would start battleship replacements in 1931 which she could not afford, and to the knowledge that during the life of the treaty she would actually have a 70 percent ratio in big cruisers. Having made this small concession it is significant that her government, to appease her Navy Department, authorized the Finance Minister to promise increased expenditures in the categories not limited. It seems plain, therefore, that just as Japan diverted the money saved by the limitation of capital ships in 1922 into cruisers, destroyers and submarines, she now intends to devote the money saved by the limitation of the smaller categories into increasing her air force, building special-type vessels, expending more money on the upkeep of vessels already built, and, finally, increasing her fortifications. There is a little irony in this last item, for on the presumption of a 5-to-3 naval ratio we have promised not to increase any of our fortifications west of Honolulu.

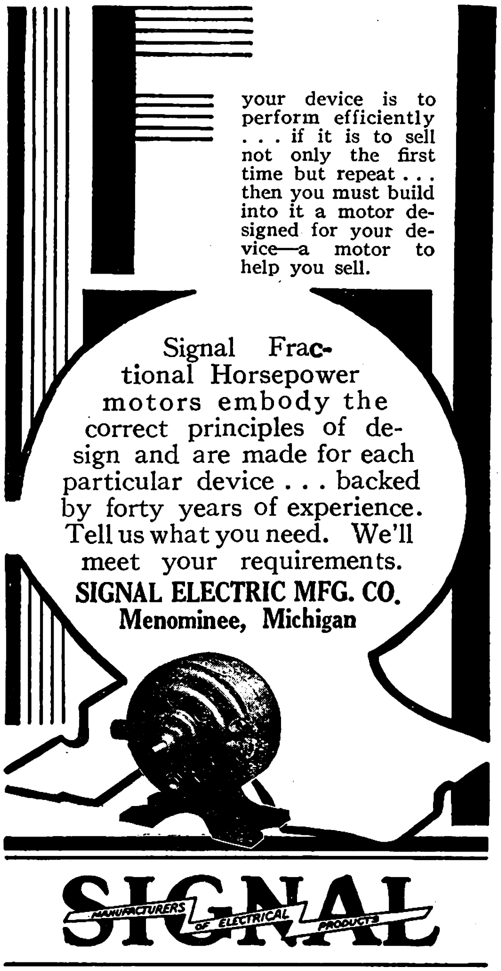
WE can find no fault with Japan for nicely adjusting her foreign affairs and her naval strength, nor for supporting as large an army and navy as her finances will bear. Many Japanese still alive can remember their two wars with China and Russia whereby Japan established her present proud position in the Far East; it is natural they should prefer to trust their future to their own military strength rather than to international agreements. For this reason they patiently submit to severe taxation before they will reduce the efficiency of their armed force. We would remind Americans, however, that the 5-to-3 ratio with Japan exists only in capital ships, that opulence is not military strength, and commercial supremacy is no safe substitute for armies and navies.

On the credit side of the Conference, we place the removal of much of the previous friction between Great Britain and our country. We believe the great majority of the people of Great Britain have finally reconciled themselves to a naval parity with the United States and, while Americans properly regard that action as due our position and responsibilities as a world power, we should remember that for the first time since attaining sea supremacy, Great Britain has peacefully conceded another nation naval parity. Our relations with Great Britain during the next decade can be stabilized better on the basis of parity than on any other ratio. We have fought against her in two wars; we have been to the brink of war with her on at least two other occasions; during the World War we fought shoulder to shoulder with her; and we know better than any other nation that she can be a formidable foe or a faithful friend on land and sea. We have no conflicting interests with the British people that cannot be arbitrated and we have a common background of language, literature, and self-government. The manful manner in which they are meeting their post-war difficulties deserves all praise, and Americans do not enjoy haggling with them over cruisers or disputing over the technicalities of gun power.

Great Britain cannot ignore the European situation; the simple solution is for us to obtain parity upward to the minimum of her necessities and to cease our insistence that she reduce her building program to satisfy the wishes of our pacifists. This statesmanlike procedure would not only benefit our relations with Great Britain, but it would enable us to safeguard our world-wide commerce and meet our responsibilities in the Far East—and the few million dollars per year additional cost will be well spent.

REGARDLESS of its imperfections, the treaty should be ratified, unless the Senate discovers some technical clause that may need a clarifying reservation. The Congress and the Administration should then promptly inaugurate a six-year building program that will place our fleet on a parity with Great Britain and in its allowed ratio with Japan. Unless Congress does this, we are in the untenable position of demanding that other nations restrict their building programs because we are too penurious to spend money on our fleet. Now is an excellent time to begin building, for it will stimulate the steel and shipbuilding companies and give work to the numerous skilled artisans whose services are necessary to create a modern man-of-war and all its accessories. Practically every industry in the country would benefit.

We repeat that Congress should adopt a continuous and comprehensive naval program that will raise our fleet to the maximum treaty strength by 1936 and maintain it at that position without the frequent fluctuations that prevent economy and efficiency in our naval establishment; for, having settled their continental interior, Americans are returning to the ocean that nourished and sustained their seafaring ancestors until the forests were cleared and farming commenced. Shipbuilding was our first great industry; our merchantmen carried the commerce of Europe and Asia when our factories were still in our homes and our railways unbuilt. Our factories now produce more than we can consume; an extraordinarily efficient railway system deposits our enormous foreign trade on our wharves to load upon *foreign* merchantmen. We are taking measures to revive our merchant marine so that we will no longer be dependent upon foreign carriers, and we should not delay providing and maintaining a navy that will protect our citizens and our foreign trade in all parts of the world. This done, Americans can continue to go about their peaceful tasks, envying no other people their prosperity, avoiding foreign political entanglements, and developing friendly commercial ties with the whole world.



your device is to perform efficiently . . . if it is to sell not only the first time but repeat . . . then you must build into it a motor designed for your device—a motor to help you sell.

Signal Fractional Horsepower motors embody the correct principles of design and are made for each particular device . . . backed by forty years of experience. Tell us what you need. We'll meet your requirements.

Books Selected by the Editors

The Biological Basis of Human Nature—*By H. S. Jennings, Prof. of Zoology, Johns Hopkins*

GENETICS—concerning the actual physical mechanism of inheritance as carried in the germ cells, male and female—has reached brilliant levels. What concrete results may be brought about in the future when as a result of its findings eugenics and race control come into practice no one dares predict, but it seems certain to bring about some astounding changes for the better. The present book, by one of the foremost geneticists of the world (America leads in this branch of pure science) is a semi-popular exposition written for those who are willing to do some thinking. Dr. Jennings deserves a world of thanks for making available to the lay reader this subject, hitherto locked up in such abstruse form. Through his facile style of writing he has brought out its latent interest to an extent few would have thought possible. This book is not for the moron, but others—even those who are innocent of elementary biology—may expect to absorb its significant contents. $4.20 postpaid—*A. G. I.*

Generations of Adam—*By. A. L. Wolbarst, M.D.*

"IT is the duty of a doctor to tell the public the truth about sex in so far as he knows it, regardless of where it may lead. Prudery, cant, and hypocrisy have brought us nowhere," writes the author. So he attacks the fallacy that sex is sin and emphasizes the difference between the biologic aspect of sex and the moral aspect as theology would like to have it. This he delineates with frank fearlessness, yet with delicacy and the broadminded humanitarianism demanded by civilized social sense. It is a work only for parents and educators and for those whose problems arise from adolescence. His explanations and advice are given informally, in a clean-cut way that cannot offend, yet with the dignity and force necessary to carry weight. $3.65 postpaid.

The Science of Biology—*By G. G. Scott, Prof. Biology, City College of N. Y.*

AN up-to-date revision of a standard text book suitable for independent reading by adults. It contains a systematic survey of the elements of the broad science of life and its known principles. To the reader who would be willing to devote an occasional hour to a systematic study of this book, current newspaper and magazine accounts of discoveries in medicine and biology would take on much deeper significance. It is also an excellent reference book. 633 pages, 390 illustrations. $3.90 postpaid—*A. G. I.*

Stuff—*By Pauline S. Berry, PhD., Asst. Prof. Chem. Penna. State College*

A SOLID book of 517 pages telling the story of materials in the service of man—a popular survey of chemistry, amply illustrated. In quite an ingenious way historical facts are woven into the thread of development, together with the personality of the accomplishment, giving a most humanistic tone which beguiles the reader. An unusual presentation. $5.20 postpaid.

Conquering the Air—*By Archibald Williams*

THIS fifth revised and rewritten edition is of importance because more of the history of foreign accomplishment is given than one finds in most of the popular aviation books published in this country. Detailed accounts of major efforts make an historical record that will be more valuable as time passes. Hence this book should be included in any aviation library. $2.20 postpaid.

The Science of Everyday Life—*By Van Buskirk and Smith*

THIS is a school book of the newer type—which means it was designed to get its hold on the reader because of its inherent *interest*. The variety of scientific subjects dealt with is vast, and the illustrations so interesting that the reviewer found the book hard to put down. If anyone *knew* only what is in this book he would have a right to claim an unusual knowledge of all around elementary science, both pure and applied. A fine book to put into your boy's hand. It would hold his interest past bedtime—after which father will sit up with it past midnight. $1.75 postpaid—*A. G. I.*

The Use of the Microscope—*By John Belling, Cytologist, Carnegie Institution*

FROM this treatise the microscope worker may glean with comparatively little effort the experience—technique, wrinkles, dodges, and shifts—which an expert has acquired after a long career. If you do research with a microscope, especially in biology, this book will extend your arm. It is very practical and should be at the elbow of every microscopist. $4.20 postpaid—*A. G. I.*

Skyways—*By William Mitchell, Genl., U. S. A. (Ret.)*

EVERYONE will concede the author to be one of the foremost authorities in the world on aviation from the standpoint of its practical aspects. Here he covers the technical features of aeronautics with a general view of its development throughout the world. Considerable space is given to a discussion of the physical conditions of modern flying, the difficulties, aids, differences in equipment, et cetera; in fact the bigger, broader aspects are handled in a way to satisfy many of the questionings which perturb the lay mind. It would be strange indeed that 30 years experience would not afford much valuable material which is not elsewhere duplicated. We predict this book will be digested by every student of aviation. $3.20 postpaid.

How to Fly an Airplane—*By Percival White*

IN this textbook for beginners, the author seeks without using technical formulas or abstruse physical explanations, to give the reasons why one should learn to fly, gives the fundamentals of plane construction, and merely touches on aerodynamics. It speaks direct to those who want to handle the controls themselves as well as to those desiring to become licensed pilots. The numerous illustrations are interesting and descriptive, the whole presentation being from an angle quite different from other books on the subject. $5.20 postpaid.

Dead Towns and Living Men—*By C. Leonard Woolley*

A FAMOUS archeologist presents intimate touches about digging at typical sites: how excavating gangs of natives are employed, bossed, and paid; how unruly small bosses are coped with; how local petty grafting officials are handled and their bluffs called. This group of narratives makes the reader sense the difficulties under which most archeological field work is carried out, and reveals what a keen insight into human nature the field archeologist must exercise in Egypt, Palestine, Italy, and so forth. The book answers the question so often asked and so seldom answered, "What is the actual every-day work of archeological excavation really like?" $2.15 postpaid—*A. G. I.*

From Recent Publications

JUMP—*By Don Glassman*

TALES of the Caterpillar Club with a chapter devoted to Lindbergh, its illustrious fourth degree member. Members of this club must qualify by a parachute jump from a disabled plane or balloon (exhibitions not counted). From War Department archives, from ancient records, from unpublished manuscripts, the author has assembled the entire history of the parachute. A complete description of parachute construction and the education of a parachutist is given, with a list of members of the Caterpillar Club as qualified. $3.20 postpaid.

MODERN LIGHTING—*By F. C. Caldwell, Prof. E. E., Ohio State Univ.*

THIS is the best technical—though not too technical—new treatise we have seen which takes up artificial lighting from every angle. There are chapters on theory of light; good lighting (adequacy, glare, diffusion); types of lamps technically described; measurement of illumination; globes, shades, et cetera; design of lighting systems in buildings; industrial lighting for efficiency; lighting for all sorts of purposes—schools, residence, streets, signals, signs, decorations; a chapter on light projection; and scientific treatment of other aspects of lighting too numerous to mention. It is a book suited both in scope and depth to the business man, industrial man, home owner, and general reader, any one of whom could claim after reading its 360 illustrated pages that he knew the elementary principles of good, efficient, scientific modern lighting. $4.45 postpaid—*A. G. I.*

TOWARD CIVILIZATION—*Edited by Charles A. Beard*

HEREIN the scientists and engineers, the makers and directors of machine progress, are given their day in court. This book follows another—"Whither Mankind"—in which it was developed that western civilization, as distinguished from other cultures, is in reality a technological civilization resting at bottom on science and machinery. This thesis was discussed and developed mainly by specialists in the humanities—law, economics, and ethics. "Outsiders looking in" reported their findings and impressions. A group of prominent engineers in New York considered this a challenge to the whole profession; for are not technologists thinkers as well as doers? This group of "doers" sees at hand the promise of great advances for mankind, and is considering the drift of things and the nature of the readjustments for a better future. In the present volume we have "Insiders looking out." "Toward Civilization" is not concerned with history but with prospects, with work "in process." The result is a very significant volume, as a wider promise of co-operation and as a revelation of the engineering mind to the lay public. $3.20 postpaid—*A. A. H.*

THE AWAKENING COLLEGE—*By Clarence Cook Little*

ONE might say that it was inevitable that Clarence Cook Little would write such a book as this, for he was a college president when he was still young enough to understand youth, its aims and ideals, *its individuality*. Formerly president of the University of Michigan, president of the University of Maine, and Assistant Dean of Harvard College, he has witnessed the rebellion of youth against "spoon-fed" facts, the discarding of outworn teaching methods—in fact all the momentous changes that have taken place in our colleges these past few years; and has treated the subject in a sympathetic style that is critical, sometimes dogmatic, yet always superbly analytical and readable. The influence of extra-curricula activities such as fraternities, athletics, religion, and even automobiles and liquor is discussed in this volume for parents and educators. $3.20 postpaid—*F. D. McH.*

IN SEARCH OF AMERICA—*By Lucy Lockwood Hazard*

"WE all go forth to seek America. And in the seeking we create her. In the quality of our search shall be the nature of the America that we create." This quotation from Waldo Frank gives Professor Hazard an opportunity to measure up to the text with a very unusual book. It is divided into five parts: "Biography," "History," "Folk Song and Story," "Locality," and "Criticism." Each part is subdivided and under each are given admirable selections in prose and poetry bearing on the subject. Some of these selections are quite long—which is an excellent fault—and there are copious bibliographies. Primarily intended for college students, this book is a welcomed addition to the general library. It correlates the practice of composition with a study of American life by stimulating discussion on the provocative problems of today. There are several explanatory introductions. $3.90 postpaid—*A. A. H.*

THE AMERICAN YEAR BOOK—*Albert B. Hart and William M. Schuyler, Editors*

THIS work of 904 pages, including a most complete index, represents the combined effort of 196 contributors with the co-operation of representatives from 46 societies, covering the entire field of science and the humanities. It is a record of events and progress during 1929. No more adequate or authoritative treatment can be found in this type of reference—it is essential to every cultural library. Arranged in seven parts to include historical, American government, governmental functions, economics and business, social conditions and aims, science, and the humanities, a clear-cut, succinct review is given under each heading by an authoritative writer. A superb bit of editing has been done to keep the work of so many and diversified contributors within the prescribed limit set for each subject, without reducing their style to uniformity. $7.70 postpaid.

WORD SHADOWS OF THE GREAT—*By Thomas F. Madigan*

ONE of the most fascinating hobbies in the world is the collection of autographs and manuscripts, and we might add, one of the most expensive. It is not, however, necessary to own autographs to enjoy them. Our libraries, museums, and historical societies are constantly showing material of this kind. Now we have a most entertaining book by a well-known dealer in autographs of celebrities, manuscripts, and historical documents. The technique of collecting is adequately described. It is very necessary for the beginner to avoid pitfalls and this is exactly where Mr. Madigan's long experience enables him to speak with authority. The many facsimiles are admirably chosen and are well reproduced. Mr. Edison quotes Gray's "Elegy" erroneously and Thomas Jefferson gives his opinion on the "liquor question" as it was called in those days. But why multiply tempting examples? The whole three hundred pages are filled with them. $5.20 postpaid—*A. A. H.*

THE LAND OF THE PEPPER BIRD—*By Sidney de la Rue*

LIBERIA, in all its phases of life—flora, fauna, customs, social and economic aspects—is portrayed by the author who spent a number of years there as Financial Adviser. The interesting return of the American Negro as well as the native cults, superstitions, and the dread black magic

For Your Consideration

are given by this trained observer. Altogether readable and historically important, as little has been written concerning this black republic. $3.65 postpaid.

THE AMERICA'S CUP RACES—*By Herbert L. Stone, Editor Yachting*

WITH the widespread interest in Sir Thomas Lipton's new challenge and the building of four syndicate boats to defend the cup, this book is of timely interest by offering, in entertaining style, the stories of the many races sailed in the past; told by one who is an ardent enthusiast as well as a technician in matters of yachting. $3.65 postpaid.

SWIMMING THE AMERICAN CRAWL—*By Johnny Weissmuller*

PROBABLY no better proponent of this particular style could be found than this modest youth who as an amateur was never beaten in a free style race. He tried out all methods, rejected some ideas and adopted others, and perfected the crawl stroke till he was acknowledged the greatest swimmer up to 400 yards the world has ever developed. Much of his knowledge and all of his training are devotedly attributed to his coach William Bachrach. A most interesting, readable story lavishly illustrated. $2.65 postpaid.

THROUGH BLOOD AND ICE—*By Ferenc Invrey and L. S. Palen*

IT would seem impossible that any one person could have had such a varied experience of horror and suffering, yet the publishers state it is an "authoritative personal narrative." An Hungarian artist serving as corporal is captured and sent to a Russian prison camp—subsequently to Siberia. He escapes, is captured, escapes again, and eventually is evacuated through Vladivostok. A vivid picture of prisoner's life and the civil war between the Bolsheviki and the Whites. $3.90 postpaid.

GEORGE EASTMAN—*By Carl W. Ackerman*

ORIGINATOR of the universal system of film photography, a pioneer in chemical research and in large-scale production at low cost while preparing the market by extensive advertising, the subject of this biography has been a potent force in the economic life of the nation, as well as a beneficent patron of culture and the arts. From an immense amount of material the author has produced an authoritative and vivid account which is delightfully readable. $5.20 postpaid.

THE GREAT CRUSADE—*By Jennings C. Wise*

TWO methods of presentation are always indicated in the relation of any series of historical events and this is particularly true with regard to narratives of the late war. "All Quiet On the Western Front" was a most graphic presentation of the human emotions of the enlisted man. "Zero Hour," which had an extraordinary sale in Germany, likewise told of the disillusionment of a gifted youth of good family. It has remained for the present author, a man of education from old Virginia stock, who had previously served in the regular army and had lectured and taught military tactics, to give a critical account of the operations of the Blue Ridge Division as well as his extended observations along the whole battle front; facilities for which he was particularly fortunate in obtaining. Extremely well written, the facts are given without acrimony, yet there is no hesitation in calling attention to error and omission. It is no hero story, though one can not but thrill to the accomplishment of our under-trained and poorly supplied troops. Lessons for future protection are made obvious though with minimum comment. $2.15 postpaid.

HEROES OF THE FARTHEST NORTH AND FARTHEST SOUTH—*By Kennedy McLean and Chelsea Fraser*

BEGINNING with the search for the northwest passage and continuing down through the heroic attempts to reach the poles, culminating in Admiral Byrd's recent spectacular accomplishment, here is a comprehensive account of high adventure which fires the imagination and stirs the blood. Maps showing the course of each major effort, with 32 reproductions of photographs, make this one of the most interesting and historically valuable of any of the titles on polar exploration. A chronology completes the text. $2.15 postpaid.

LAUD, STORM CENTRE OF STUART ENGLAND—*By Robert P. Tristram Coffin*

WILLIAM LAUD (1573-1645) lost his head in two senses. If he had been less of a tyrant he might have escaped the block. He was a powerful factor in Caroline England and brought down ruin all about him. Oxford owes much to him and he really did accomplish a great many reforms as he was all-powerful both in church and state. He was the Man of Thunder who became the storm center of the Civil War, but he preserved much of the ceremonial beauty of the Anglican communion. As Archbishop of Canterbury he wielded great power. An implacable enemy of the Calvinists, he even tried to reach the Colonists of New England; he tried to force his ecclesiastical system on Scotland, but failed. His infatuated policy at last brought on his impeachment, imprisonment in the Tower of London, and finally his sentence to death when he had some difficulty in getting the axe substituted for hanging. His mutilated body rests in his beloved Oxford but his best monument is the very fabric of the Anglican Church. $3.65 postpaid—*A. A. H.*

MAHATMA GANDHI'S IDEAS—*By C. F. Andrews*

GANDHI has been much in the limelight by reason of his civil disobedience campaign to secure Indian Independence. His mass disregard for the salt laws is front page news and when we last heard of him he was on tour in an automobile and having tire trouble in the cactus regions. Wherever he goes he spreads discontent, for he has an uncanny faculty for casting a spell by the sheer force of his personality. He is a powerful thorn in the Indian government's side but they were wise enough not to martyrize him by hurrying his arrest. We have often wondered what this Indian Moses really wants. He seemsal most as bewildered as anybody else. It is the mission of this book to try to make known the principles for which he stands, giving his thoughts and aspirations in his own words as far as possible. Gandhi is a legend, but a personified legend. The author has been with him on recent tours, therefore the information outside of Gandhi's writings is authentic. $3.15 postpaid—*A. A. H.*

Facts and Notes of Interest to Inventors, Patentees, and Owners of Trademark Rights

Secrecy of War-Time Inventions

GREATER secrecy for inventions useful in the national defense is proposed in the draft of a bill submitted to the House by the Acting Secretary of the Navy, Ernest Lee Jahncke, reports *The United States Daily*.

The proposed measure was prepared, he said, by the interdepartmental Patents Board as a substitute for one originally submitted by the Navy Department, and has the concurrence of representatives of the War and Navy Departments on the Patents Board.

"The efficiency and international superiority of all armament, equipment, appliances, and facilities for the Army and Navy," he added, "are of primary importance and are always the subject of first consideration on the part of the War and Navy Departments. Constant effort towards improvement and unremitting vigilance in the pursuit of it are practiced at all times by both departments.

"The only source from which the maximum of efficiency and the possibility of superiority may be hoped for is continuous invention. Of course, many inventions of military value are made in other countries and never come to light in the United States. Also many inventions that are offered to and are acquired by one or the other of the two military departments become public beforehand.

"However, a large number of valuable inventions, and sometimes fundamentally important inventions, are made by persons connected in some way with the government service and in numerous instances by patriotic citizens in private occupations, and are brought to the knowledge of one department or the other before any information concerning them becomes public. During such time as it is desirable to keep inventions secret, it is necessary that patents on them be not issued, because as soon as a patent is issued it becomes public. But for the proper protection of the government's rights in and to such inventions it is necessary that they be filed in the Patent Office with applications for patents thereon.

"While in the Patent Office, in the status of 'patent applied for,' an invention is a secret so far as the inventor and his assignee do not divulge information concerning it. In these circumstances, a legal method of maintaining for a proper time the secrecy of an invention of value to the Army or Navy is a vital need. This can be accomplished in the way that seems most feasible, all this considered, by filing applications for patents and holding back the allowable patents at the discretion of the department concerned."

Standardized Bottles

WITH the purpose of promoting exports, regulating distribution and standardizing types, the leading bottle manufacturers of Germany have formed themselves into a syndicate to be known as the German Bottle Sales Company, according to a report received in the Department of Commerce from Assistant Trade Commissioner A. Douglas Cook, at Berlin.

Both domestic and foreign sales will be handled by the syndicate. It is estimated that between 500,000,000 and 750,000,000 bottles (colored glass only) are produced annually in Germany. Exports, which before the World War amounted to about 35 percent of the output, have declined to approximately 20 percent. It is expected that the combine will be able to increase exports again.

The bottles concerned are especially beer, mineral water, wine, liqueur, and alcohol bottles. Under the new arrangements, all patented manufacturing processes will be pooled for the benefit of all members of the syndicate, thus avoiding competition between the different manufacturing processes.

British Tire Importation Decreases

BRITISH imports of rubber tires and tubes recorded a further extensive decrease (except as regards solid tires) in 1929, while exports in the same commodities, following a decline in 1928, evidenced considerable recovery, according to a report from Consul General John J. Davis, London, the Department of Commerce anounced recently. The announcement follows:

Imports of pneumatic outer covers were valued in 1929 at 2,143,739 dollars, against 12,808,555 dollars in 1927; inner tubes at under 400,000 dollars contrasted with more than 1,574,000 dollars; and solid tires at 455,000 dollars, compared with upwards of 800,000 dollars, but this last-named description rose by about 10,000 dollars above the value in 1928.

The cause of the marked decrease in imports of tires and tubes, the report stated, can be traced mainly to factories for these goods having been set up by certain foreign firms, in consequence of the imposition of an import duty as from April 12, 1927.

Oil Trademark Upheld

IN the case of Vacuum Oil Company versus Walter and Company, First Assistant Commissioner Kinnan held that Walter and Company, of Rio de Janeiro, Brazil, is entitled to register, as a trademark for lubricating oils, a mark consisting of the pictorial representation of a griffin with the word "Griffin" appearing thereabove and the notation "Domina Attricto" therebelow, notwithstanding the long use by the Vacuum Oil Company of New York and registration of a mark for the same goods consisting of the pictorial representation of a gargoyle, with the word "Gargoyle" thereabove.

The ground of the decision is that these marks are not so similar that their contemporaneous use would be likely to cause confusion.

In his decision, after noting that applicant had taken no testimony and that it appeared from the opposer's evidence that it was long prior in the field and had carried on a very extensive business and consequently doubt, if it exists, must be resolved against the applicant, the First Assistant Commissioner said with respect to the marks:

"Both parties have adopted a pictorial representation of a fictitious or fanciful creature, that of the opposer being only somewhat similar to an eagle as to the body although the head is quite dissimilar to such a bird, while the griffin simulates the head and wings of an eagle with the body, feet, and tail of a lion. The similarity of the two pictorial representations is very remote. The names of such fanciful creatures are likewise wholly dissimilar in spelling, sound, appearance, and significance. Unless it be held that the opposer is entitled to such an interpretation of its trademark rights as would preclude any rival in business from using any pictorial representation of a fanciful animal, however distinct from that used by the opposer, in connection with a name of such fanciful creature, it is believed the applicant is entitled to registration of its trademark."

With respect to the testimony as to the dress of applicant's goods and certain activities in connection with their sale and the former commercial relations between the applicant and the opposer, he said:

". . . but all these matters refer to activities in another country, Brazil, and are immaterial and irrelevant to the issue to be determined in the case at bar. The opposer has alleged that the applicant has not used its mark in interstate or foreign commerce in this country, but has submitted no evidence to support such allegation and it is thought the opposer is not entitled to raise such a question in the instant proceeding."

Patents and Trademarks In Panama and China

PATENTS and trademarks, of which the certificates of registration already have been granted, must be recorded in the mercantile register of Panama regardless of whether or not the company owning the registered patents or trademarks is doing business in Panama, according to information received from Assistant Trade Commissioner Fred C. Rogers, Panama City, and published in *Commerce Reports*.

As a result of the inclusion of such matter in the office of the Secretary of Agriculture and Public Works, and according to the provisions of the Commercial Code which became effective on July 1, 1917, all factory and trademarks and patents for inventions, for which certificates of registration have been acquired since that date, must be recorded in the mercantile register.

The provisional regulations for the promotion of industrial manufactures in China, promulgated by order of the National

Government on June 18, 1928, apparently limit to persons of Chinese nationality the right to apply for and obtain patents. According to these regulations, Americans, as well as other foreigners, will be unable to protect their patent rights, for under the clauses of encouragement which are intended to promote industry only Chinese may make application for permission to exploit new inventions and industrial processes.

It is understood that this matter has been brought to the attention of the Chinese Government on behalf of American citizens in order that their rights in patents may be protected against infringement.

Centrifugal Casting Process Claims Allowed

CLAIMS defining a process for the centrifugal casting of hollow bodies of steel have been allowed by the Board of Appeals of the Patent Office, *ex parte* John Chapman Bell. The claims had been rejected on the ground that they merely set forth the obvious way of using the apparatus disclosed, or one equivalent thereto. It was pointed out by the Board of Appeals that a process of treating matter to produce a given result, and a machine suitable to perform the process, constitute distinct entities, and if new and useful, each may form the subject matter of a patent independently of the other.

The applicant stated that the essential novel features of his process lie in two manipulations. The first consists in maintaining the nozzles through which jets of metal are delivered into the rotating mold at a constant distance from the surface upon which the metal is deposited. The other consists in maintaining constant the pressure in the spout through which the metal is delivered to the mold.

While it is undoubtedly true that the mere function of a machine is not subject matter for a patent, yet it is equally true that a process consisting of certain operations upon matter to change its form or condition constitutes patentable subject matter, if new and useful. This is true, even though such an operation may be performed by an apparatus devised to practice the process and such apparatus may have no other function.

Deceptive Advertising Discontinued

THE practice of advertising a concern as occupying an entire building in the conduct of its business when it only utilizes a part of the building, creates an erroneous impression upon the public trade, according to announcement by the Federal Trade Commission, stating that an individual so advertising had signed a stipulation agreeing to discontinue the practice. The Commission's statement follows:

Manufacturing and selling toy airplanes, an individual circulated advertising matter containing illustrations of what purported to be a picture of the building in which his business was carried on.

On the front of the building, as shown in the picture, appeared in large display type the following: "World's Largest Manufacturers, Model Airplane Sets and Supplies," and over the door of what seemed to be an annex of the building appeared the words "Shipping Department."

However, the business was limited to the manufacture and sale of miniature toy airplanes and repair parts for them. The volume did not exceed 10,000 dollars a year. The enterprise was carried on in two small rooms of the upper story of a small building and no separate space was utilized for shipping.

Signing a stipulation agreement with the Federal Trade Commission, the individual agreed to stop circulating advertising matter which tended to create the erroneous impression that he occupied all the space in the building, and which contained the representation that he was the world's largest manufacturer of model airplane sets and supplies.

(Names of individuals or firms signing stipulation agreements are not mentioned in the Commission's press releases or publications, but the facts in the proceedings are presented to show methods of competition condemned by the Commission as unfair, for the guidance of industry and protection of the public.)

"Must Sell" Must Not Be Used

TWO individuals in different parts of the country, engaged in selling and distributing diamonds in interstate commerce, signed stipulations with the Federal Trade Commission agreeing to cease and desist from use of the words "must sell" in an advertisement when there were no emergencies compelling the immediate sale of their products.

They advertised as follows: "Diamond ring. Must sell. Beautiful lady's setting. Large blue-white perfect cut diamond. For quick cash, 100 dollars."

Rural Electrification

ELECTRIC utility companies and the State administration in Ohio are cooperating in plans to extend rural electrification on a basis that will insure the widest possible use of electricity on the farms, was a recent oral statement of Governor Myers Y. Cooper, according to *The United States Daily*.

Conferences between the governor, representatives of the electric companies, the public utilities commission, the Ohio Farm Bureau Federation, and officials of the Ohio State Grange have been held on the subject and are producing results, the governor said.

One of the principal plans is to have the utilities provide lines to rural territory without cost to the farmers. Heretofore the subscribers have had to pay for the line, which in many cases made the cost prohibitive, the governor said. Further conferences are planned by the governor in which it is expected that a basis of mutual agreement will be reached.

"The administration feels that rural electrification is one of the most important social and economic benefits which possibly can be extended to the farmer and is bending every energy in bringing together a meeting of minds of the farm groups and the utilities interested on the basis of fairness and equity, making the program attractive to the farmer from the standpoint of costs."

Frozen Fresh Meat

THE rapid development of the quick-freezing process of preserving fresh-cut meats to be sold in packaged form is said to be one of the most revolutionary developments in food merchandising since the advent of canned foods, according to a recent oral statement on behalf of the foodstuffs division of the Department of Commerce.

The new system, it was said, calls for butchering the carcass promptly into individual cuts, which are frozen solid in airtight wrappers and chilled to 50 degrees below zero. It is claimed that the quick-freezing process brings the meat to the consumer with the weight, flavor, texture, and appearance unchanged.

The present cost is about 2.45 cents per pound, which is expected to be reduced under large-scale production. Savings will be realized in the elimination of waste. Transportation savings are expected, since the space taken up by packaged meats is less, it was pointed out. (A similar method of preserving fresh fish was described in our issue of March, 1929.—*Editor.*)

Roofing Trademark Upheld

IN respect to the case of The Duro Company versus Central Paint and Roofing Company, First Assistant Commissioner Kinnan held that the Central Paint and Roofing Company of Louisville, Kentucky, is entitled to register, as a trademark for smooth surface and slate surfaced composition roofing, a mark consisting of the notation "Dur-A-Bull" and the pictorial representation of a bull, notwithstanding the prior adoption and use by The Duro

Patents Recently Issued

Classified Advertising

Advertisements in this section listed under proper classifications, rate 25c per word each insertion; minimum number of words per insertion 24, maximum 60. Payment must accompany each insertion.

Anyone desiring the address of a patentee listed in this section may obtain it by addressing Munn & Co.; those desiring official copies of patents herein listed, may secure them by remitting 15 cents for each one (state patent number to insure receipt of desired copy) to Munn & Co., 24 West 40th Street, New York City.

Pertaining to Aeronautics

AIRPLANE—Having rotatable members operating independently of the wings, and adapted to adjustably receive air under pressure for increasing the lift, and acting as stabilizers for retarding rolling, pitching and slipping of the plane in the air. Patent 1753112. George R. Engledow.

Pertaining to Apparel

GARTER—Wherein a plurality of disengagable supporting members are connected with the shirt and hose in order to provide supports at

Company of Dayton, Ohio, of the notation "Duro" as a trademark for various goods used in connection with houses.

The ground of the decision is that the goods of the two parties are not of the same descriptive properties and the marks themselves are not deceptively similar.

In his decision, after noting that the opposition had been dismissed on the grounds above stated, the First Assistant Commissioner said, with reference to the goods:

"I am of the opinion that the decision of the acting examiner of interferences is without reversible error. Obviously the applicant's composition roofing is not of the same descriptive properties as any of the goods enumerated in the opposer's trademarks."

With reference to the marks, he said:

". . . it is equally true that the applicant's mark, consisting of the word 'Dur-A-Bull' and a pictorial representation of a bull, does not so nearly resemble the opposer's mark 'Duro' as to be likely to cause confusion or mistake in the mind of the public."

And then, after citing certain registrations to show that the term "Duro" did not originate with the opposer, he said:

"In view of the prior adoption and use by others of the word 'Duro' both as a trademark and as the whole or an essential part of the names of companies or corporations, it is believed that the opposer is not entitled to such broad protection of its mark as to exclude from registration the applicant's mark."

Type Font Patent Granted

THE Commissioner of Patents was in error in refusing to grant a design patent on a font of type known as "Cooper Black," the District Court for the District of Maryland has ruled, in ordering a decree entered requiring the issuance of the patent.

The plaintiff, in his action under section 4915 of the Revised Statutes, also sought to require the issuance of design patents on two other fonts known as "Cooper Old Style" and "Cooper Italic," but the court dismissed the action as to these, holding that it lacked jurisdiction under section 4915, as it read before the 1927 amendment, since an appeal had not been taken from the action of the Commissioner.

The question of jurisdiction was held to be governed by the statute as it stood before the amendment, since appeals were pending before the Commission when the amendment became effective. The court explained the jurisdiction under section 4915 both before and after the amendment in 1927.

A design for a font of type was held by the court to be a proper subject for a design patent. The claim for the "Cooper Black" font was not anticipated by the prior art, it was also ruled.

The court in dealing with the requisites for a design patent held that the tests of invention for such patents are the same as for mechanical patents, and there must be originality and exercise of the inventive faculty; in the former novelty and utility, in the latter novelty and beauty. In designs, it was stated, invention is measured by the appearance as an entirety when judged by the taste and fancy of an average person. The design must disclose at least a rudimentary esthetic appeal, it was pointed out.

distant points, without causing any undesirable pinching of the leg, and holding the shirt against rising. Patent 1753125. Max Lederman.

Toe-Dancing Shoe—A ballet slipper of the usual sandal type which will not pucker at the sides and is so constructed as to obviate the use of ribbon fastenings, but to draw the upper in hugging engagement with the foot. Patent 1754054. James Selva.

Heel Pad—For use between the heel of the foot and the inside of the shoe, an inexpensive elastic cushion pad for supporting the body and relieving the jars incident to walking on hard floors. Patent 1756107. Tomizo Tanigawa.

Chemical Processes

Granulated Product and Process for Making Same—A process for granulating dust resulting from the metallurgical reduction of arsenic bearing ores and material which comprises mixing said dust with sulphuric acid and water, agitating and at the same time drying the mixture. Patent 1755985. Harry C. Gardiner.

Process for Treating Animal Hair and Wool with Chlorine—A process for carroting comprising applying to the hair or wool an aqueous solution of hydrogen chloride and a chlorate and oxalic acid and causing the substances to react with each other in contact with the hair and wool. Patent 1756723. Erich Bohm.

Designs

Design for Lace—The inventor has been granted seven patents on ornamental designs for lace. Patents 80820, 21, 22, 23, 24, 25 and 80826. Ben A. Ball.

Design for a Dress—The inventor has been granted two patents, 80845 and 80846. Dorothy Long.

Design for a Combination Airplane and Thermometer—Patent 80873. Frank Alessi.

Design for a Carton or Similar Container—Patent 80909. Frederick W. Peterson.

Design for a Coat—The inventor has been granted two patents for ornamental designs. Patents 80899 and 80900. Dorothy Long.

Design for a Mirror or Similar Article Patent 80956. Edwin B. Langsdorf.

Design for a Dress—The inventor has been granted two patents, 80957 and 80959. Dorothy Long.

Design for an Ensemble Suit—Patent 80958. Dorothy Long.

Design for a Coat—Patent 80960. Dorothy Long.

Design for a Bracelet or Similar Article—Patent 81019. William Reichert.

Electrical Devices

Electrical Plug and Socket—Whereby the plug when its lead or contact arms are inserted in the socket will have an engagement with the socket in a manner to prevent accidental withdrawal of the plug. Patent 1753064. William Nonnenman.

Electric Measuring Instrument—A modified form of volt meter, for use with secondary batteries, primarily for giving indications to the driver of a motor vehicle the amount of energy in the battery at any particular time, or when recharging will be necessary. Patent 1753043. Howard Butler.

Trolley-Wire Splice Joint—A two piece interlocking splice for resisting longitudinal separation, is particularly useful in splicing broken wires, providing a proper electrical contact and mechanical strength, and a smooth path for the trolley wheel in passing thereover. Patent 1754991. Samuel J. Evans.

Vegetable Oil Trademark

IN the case of The Southern Cotton Oil Company versus Globe Grain and Milling Company, First Assistant Commissioner Kinnan held that Globe Grain and Milling Company of Los Angeles, California, is not entitled to register the term "Westola," as a trademark for shortening for frying and baking foods, in view of the prior adoption and long use by The Southern Cotton Oil Company of the term "Wesson" as a trademark for a vegetable-oil product used as a shortening in the same processes.

The ground of the decision is that the goods are of the same descriptive properties and the marks confusingly similar as applied thereto.

In his decision, after noting that the testimony showed long and extensive use by the opposer and therefore, doubt, if any, must be resolved against the later comer, and noting applicant's argument that since its product is normally about the consistency of lard and sold in large quantities, whereas the goods of the opposer are usually sold in liquid form and in small containers, there would be no likelihood of confusion, the First Assistant Commissioner said:

"There is some attempt on the part of the applicant to show that the opposer's goods are not used for the same purpose as are the goods of the applicant but the evidence seems fairly satisfactory that the uses of the goods of both parties very largely overlap. Even if the applicant generally sells its goods in bulk to bakers, there is nothing to restrict its activities to this class of customers, or to prevent a considerable expansion of its business in connection with small quantities of its product put up in small containers sold to a different class of customers."

"Both marks employ the initial syllable 'Wes' while the remaining portions of the marks are quite dissimilar. It may be conceded that the first syllable of the applicant's mark is 'West' but when the entire mark is pronounced it is quite likely that the second syllable would be regarded by the public as made up of the letters 'to.' The first portion of a fanciful mark is more likely to be retained in the memory of a casual purchaser or observer than the other part of the mark. It would seem there is at least some probability that purchasers would confuse the two marks since they seldom have both marks before them at the same time for comparison but decide from memory and without much reflection."

With respect to the argument that although applicant's mark had been in use since 1920, no confusion had been shown, the First Assistant Commissioner, after noting that the testimony showed that applicant's sales had largely been on the Pacific Coast and in Honolulu, that it had never advertised its goods and that applicant, prior to the adoption of its mark, was familiar with opposer's goods and trademark, said:

"In view of these facts there is no showing upon which to base a holding that the goods of the applicant have appeared to any considerable extent in the same market and in competition with the goods of the opposer. No inference can, in consequence, be drawn that had the goods been in the same market with those of the opposer for nine or ten years no confusion would have arisen and, therefore, none would be likely to arise in the future

Electric Service Tray—Whereon different electrically operated units, such as a toaster, boiler, perculator, etc., can be removably disposed on the tray and electrically connected with a source of current; the tray is composed of two parts, the upper part being washable. Patent 1755247. John S. Fielding.

Of Interest to Farmers

Harrow—Adapted for removing roots of plants from the soil by means of a plurality of ground engaging teeth carried along a horizontal path by chains operated by the usual traction wheels, stationary at will, or with movement retarded. Patent 1754103. John M. Hjermstad.

Agricultural Device—A mechanism which may be used for various operations, such as seeding, discing, plowing, harrowing or cultivating, dispensing with labor ordinarily necessary, working the field backwardly and forwardly without supervision, other than starting and stopping, the operations being automatic. Patent 1755247. John S. Fielding.

Feed Grinder—Having a plurality of concentric rows of teeth projecting from oppositely disposed plates, movable in an inter-fitted relation so that the feed passing between the teeth will be thoroughly ground and ejected at the plate periphery. Patent 1755037. Tom Tamen.

Of General Interest

Ship's Pilot Ladder—A foldable portable ladder, the steps having roughened surfaces, and being of durable construction, consisting of but few parts which are interchangeable and readily assembled without requiring the employment of skilled labor. Patent 1753060. Andrew Myerstuen.

Disappearing Lawn Sprinkler—A casing, with water actuated means for raising the nozzle into operative position above the ground and automatic means for lowering the nozzle and closing the upper end of the casing to prevent manipulation by unauthorized persons. Patent 1751723. Charles A. Borgeson.

Adjustable Top for Type Cabinets—As used by compositors, consisting of a separate top above the type draws, and means for vertically raising and securing the top, at any desired elevation in accordance with the height of the user. Patent 1753048. Merritt W. Haynes.

Refrigeration Coil—With the tubes so arranged and spaced as to prevent icing of the coils to such an extent that the plant must be shut down long enough to defrost the coils. Patent 1753042. Charles M. Brenner.

Movable Camera Support—Comprising a frame or platform, constructed to encircle a column, mechanism for raising or lowering the platform, a camera mounted thereon and adapted to move in spiral convolutions for taking pictures of the column surface. Patent 1751774. William L. Trullinger.

Phonograph Construction—Provided with novel means for reproducing a plurality of tones in unison but from separate sound reproducing units. As for example a separate sound reproducing unit for each member of a quartet. Patent 1752357. Hugo Wiener.

Crochet Needle—Having the usual hook at one end, but a needle point at the other, instead of being blunt, thus permitting other forms of work, a zig zag portion between the ends preventing slipping or turning over in use. Patent 1751796. Charlotte I. Denner.

Powder Puff—The back of which is formed of a plurality of members suitably joined, with a handle extending from the center and secured by novel means, the face-contacting surface having no out-stitching, thereby avoiding any roughness. Patent 1754090. Leonard Friedberg.

Match Package—Wherein a single or double arrangement of matches may be carried and the matches properly protected, while permitting the ready removal at any time and the ignition of the match as it is removed. Patent 1754036. Roman A. Novinsky and Edward O. Barton.

Compass—A marine compass, including a bowl, two liquids of different specific gravity, and a compass card having turning movement, and located approximately at the line of junction of the liquids, said card being supported solely by the liquid of heavier specific gravity. Patent 1754055. Frank G. Senter.

Egg Rack—Or shelf provided with a plurality of openings for supporting eggs in spaced relation and constructed to occupy a minimum of space, may be in "dead space" yet clearly exposed to view the articles carried. Patent 1754020. Albert J. Hyde.

Window Construction—Wherein means are provided by which each sash may be completely reversed into the room, for cleaning or reglazing, without removing outside screen or the like, adapted for use with standard window sashes and frames. Patent 1754316. Fred Hamilton.

Camera Attachment for Making Artificial Reflections—By means of an angularly disposed reflecting surface in a hood, attached to the end of the lens barrel, on which the object to be photographed is reflected, giving the impression of the mirror effect of still water. Patent 1755036. Jacob H. Sussman.

Umbrella Guard—In the form of a permutation locking device, connecting the staff and canopy of an umbrella, and locking the same, whereby the opening of the umbrella by all others than the rightful owner will be prevented. Patent 1755039. Harold M. Vandenhove.

Tile-Roof Closure—An interlocking metal plate which is easily applied to the lower end of a slanting roof, to fill the usual openings of standard tiles, and thus prevent the inconvenience caused by birds roosting under the corrugations. Patent 1752593. John Giordano.

Sewing Wire for Flat Rope—A composite sewing strand or lacing for metal rope composed of hard and soft wires, the soft wires being positioned outside the hard wires, to protect them from cutting contact with the strands of the rope when in use. Patent 1755018. Richard Nitsch.

Basement Circulator—A hose nozzle which may be lowered into and suspended in the hold of a ship, or basement, for fighting a fire, the water being thrown from the nozzle in an apron-like spray, substantially at right angles. Patent 1753686. Charles A. Borgeson.

Safety Apparatus for Oil-Storage Tanks—A fire extinguishing apparatus for preventing the oil from being ignited by lightning, by drawing off and condensing the vapors which arise in the air space above the oil, also providing an emergency steam pipe as a last resort. Patent 1753401. Henry J. Bucking.

Milk-Container Holder—For tapering paper milk bottles, the construction being such that when the handles are grasped part of the holder will grip the container and hold the same against movement while being tilted or carried. Patent 1755335. Max Roman.

Merchandise Package and Display Rack Therefor—In which a number of packages may be associated with the rack in such a manner as to require the tearing of the package to effect its release, whereby to thwart pilfering, particularly adapted for displaying handkerchiefs. Patent 1755927. Louis N. Levinsohn.

Window-Cleaning Device—A thin flat pad of absorbent material adapted to contain a washing fluid, together with a handle member detachably connected, which obviates the necessity of leaning out when cleaning the outer surfaces of the window panes. Patent 1755881. John J. Kilbride.

Demonstration Device—An educational apparatus for symbolically representing certain allegorical passages of the Bible descriptive of some of the views and visions of certain of the prophets, the primary purpose being for use in Sunday schools and similar assemblies. Patent 1755952. Charlie Gant.

Citrus Fruit Juice Extractor—Which is manually operated, extremely simple in construction and in which the parts are so assembled that they may be removed for cleaning and oiling, the device is compact and durable. Patent 1754591. Guy B. Baker.

Humidistat—Adapted to supply water to any evaporating medium to maintain proper humidity in the air in a room or house, the device is provided with novel means for automatically regulating and indicating the humidity. Patent 1755276. Roy B. Somers.

Glove - Drying Rack — Whereon rubber gloves used in hospitals, or other places, may be quickly and thoroughly dried inside and outside after each washing, all the fingers being held open with the closed ends extending upwardly. Patent 1755902. Salvatore Tascarella.

Scale and Attachment for Reducing and Enlarging Cameras—Wherein means are provided whereby the scale and associated parts may be adjusted to take care of any slight variation in the focal length of the lens used, without being made especially therefor. Patent 1755177. Arthur Fruwirth.

Animal Trap—More particularly a trap for catching rats, which operates automatically by the weight of the animal as it enters, killing and removing the prey, and re-setting itself, ready for the next victim. Patent 1755947. Walter G. Baker.

Nonspillable Container—An automatic closure for a glass or container for liquid, which will permit the contents to be poured therein, or withdrawn therefrom, while preventing spilling if accidentally tilted, or during transportation, thus preventing soiling of clothes, etc. Patent 1756249. Solomon Kaufman.

Key Case—Of the type having individual key holders connected with a carrier plate, the latter being attached to a flexible and foldable cover adapted to enclose the keys and render each key conveniently accessible when the cover is opened. Patent 1756627. Joseph Brewer.

Handle-Adjusting Means—For connecting a handle with a brush head by means of a threaded hole, and permitting the handle to be readily swung laterally at various angles, spring pressure securing the handle assemblage to the base. Patent 1756801. Charles S. Trippeda and Anthony J. Dichiaro.

Hardware and Tools

Regulator for Windows and Doors—A rotatably mounted shaft, particularly adapted for use with outwardly opening casement windows having inside screens, whereby the window may be readily opened or closed from within the room, without moving the screen. Patent 1751718. Eric Sodergren.

Rotary Core-Drill Attachment—Employing a greatly simplified gyroscopic element which will operate to determine the exact direction in which an inclined stratum of earth dips, so that the crest of an anticline may be determined by a series of drilling operations. Patent 1751678. Arthur L. Armentrout and Elwin B. Hall.

Blade Holder and Handle—For safety razor blades, formed from a single sheet of metal providing a pair of arms defining blade clamping jaws, so constructed that pressure effects a limited separation to allow the removal or insertion of the blades. Patent 1753459. James A. Gafney.

WIRE SPLICERS—Specially constructed for carrying out wire-splicing operations quickly and easily, and which is especially useful for splicing the ends of fence wires closely arranged with respect to each other. Patent 1754023. Sidney J. Jones.

DRAW-PUNCH—By means of which holes may be cut into sheet metal of any thickness, is especially adapted for electrical work for cutting holes in metal boxes, or for cutting in places where little room is available. Patent 1754568. John C. Nischan.

Heating and Lighting

INCINERATOR—Wherein articles may be dropped from above into the oven, while a blast of air acting as a damper, prevents gas or smoke from escaping through the opening by which articles are fed to the furnace. Patent 1755027. Aatto P. Saha.

Household Utilities

COMBINATION STOOL, LADDER AND KITCHEN BLOCK—Comprising a stool about the proper height for working at a kitchen sink, a stepladder higher than an ordinary kitchen chair, and the top forming a meat block adapted for conveniently chopping or cutting meat. Patent 1753372. Richard G. Gober.

CARD TABLE—Composed entirely of metal, having hollow legs constituting ash receptacles, the corners of the table having depressions and openings registering with the hollow leg tops, the depressions being convenient for the support of glasses. Patent 1756777. Frederic E. Wright.

Machines and Mechanical Devices

FLOTATION MACHINE—Whereby the pulp is thrown in the form of a film or attenuated condition into a gaseous medium for maximum aerating effect, producing flotation with a minimum of energy and a maximum of aeration. Patent 1752434. Albert L. Howard.

GUIDE DEVICE—Which may be readily installed in position on the pump rod of a windmill to maintain the same accurately in line and thereby reduce loss of power by eliminating undue friction and wear. Patent 1753126. Arthur L. Ligon.

SEWING-MACHINE THREADER—An attachment for sewing machines comprising a swingably mounted bar, having a semi-conically shaped end formed of a pair of spring-pressed members which provides a guide for the thread to the eye of the needle. Patent 1753114. Allan McC. Fluharty.

APPARATUS FOR THE REDUCTION OF IMPURITIES CONTAMINATING MOLTEN METAL—Comprising an open vessel formed of a metal shell and a refractory lining, in which the improvement of the metal, by the reduction of certain impurities, is brought about by forcing air upwardly through the molden charge. Patent 1753891. Llewellyn Jones.

DEVICE FOR EXPANDING AND MOUNTING PISTON RINGS—Whereby piston rings may be expanded, and positioned in expanded condition in juxtaposition to their piston groove, into which they may be forced by hand, breakage through over-strain being practically eliminated. Patent 1755044. Kenneth J. Bailey.

BAGLE-FORMING MACHINE—Which receives a batch of dough, forms the same into strips, cuts it into sections, and rolls the sections into rings, ready for cooking, the entire treatment being automatic, without the dough touching the operator's hands. Patent 1755921. Louis Gendler.

METHODS OF PITTING FRUIT—A machine particularly adapted for pitting dates, having in view the removal of the pit from the fruit without unduly mutilating the fruit, as well as insuring precision and reliability in operation. Patent 1755872. Anthony Gotelli.

GRINDING MACHINE—Characterized by a novel form of means whereby the grinding elements and the holder thereof may be readily adjusted to the proper size for grinding worn engine cylinders of varying bore diameters. Patent 1755862. Alvin R. Berck.

BELT REPLACER—Which may be readily handled by a single operator for replacing a belt on a pulley, and operated from an advantageous position without danger from the usual revolving shafts and pulleys, and without stopping the machinery. Patent 1755876. Frank L. and Wilson R. Homstead.

FRUIT PITTER—Which will sever the flesh from the stones of peaches, apricots, etc., the flesh being cut into two halves, and removed from the stone, which is held while the flesh is severed therefrom and then automatically released. Patent 1754636. Alvan B. McCollom.

APPARATUS FOR APPLYING A SOFT-METAL SURFACING TO HARD-METAL PLATES—By flowing said substance while in a fluid molten state onto the plate over a heating medium, while automatically smoothing off the coating substance to a uniform thickness prior to cooling off the medium. Patent 1756739. August Gunthard.

Medical and Surgical Devices

BIPROXIMAL TOOTH AND INTERLOCKING KEY —A substitute for the natural tooth, and device for attaching the substitute tooth or teeth to any of the recognized abutments, characterized by the fact that it can be used in fixed or removable bridgework and dentures. Patent 1753644. Fred E. Burden.

Musical Devices

METHOD OF AND APPARATUS FOR EMPLOYING TUNING FORKS TO GENERATE AUDIO FREQUENCY CURRENT AS A MEDIUM FOR SOUND—A musical instrument, a tuning fork, and an electromagnet positioned in space relation between the prongs, an electro-mechanical sound reproducer and means for amplifying the current in a suitable form of telephone or loud speaker. Patent 1753069. Max Schumm.

Prime Movers and Their Accessories

PISTON FOR INTERNAL-COMBUSTION ENGINES —Consisting of a metal having a great coefficient of expansion, and cross members of a metal having a small coefficient of expansion fitted at one end into the peripheral part of the piston thereby eliminating danger of gripping. Patent 1756884. Charles Schaeffer.

Pertaining to Recreation

BOXING GLOVE—Constructed with a novel form of grip which is disposed within the glove permitting an unobstructed palm portion, thereby obviating danger of injury such as would be occasioned by grips protruding beyond the palm surface of the glove. Patent 1752977. Frank Dieterle.

FISH LURE—Constructed of such material as to be always bright and shiny, having the proper balance and weight to be useful for trolling or casting, and when used in casting will not be unduly impeded by the resistance of wind. Patent 1755047. Chester A. Braidwood.

FISHING GEAR—In which one or more attractors, in combination with a sinker, are disposed slidably relative to a fish hook, so that the attractors will freely recede from the hook when the fish is hooked, thereby facilitating landing. Patent 1754567. Gwendolan Newell.

DOG-RACING APPARATUS—Wherein a mechanical rabbit is caused to travel around a track and maintain its position ahead of a pack of dogs, a novel form of trap being provided for the ultimate disappearance of the rabbit. Patent 1755676. William R. Twiford and George Oehler.

AMUSEMENT DEVICE—A combination merry-go-round and see-saw which may be conveniently used on play grounds or beaches, whereby a plurality of persons may oscillate or see-saw and at the same time revolve about a vertical axis. Patent 1756854. August de Freitas.

Pertaining to Vehicles

COLLAPSIBLE KIDDY CAR—In which the supporting legs and steering handle can be folded into substantially parallel position with respect to the seat, when collapsed will take up very little room, and may be shipped in a small container. Patent 1751765. Thomas G. Shannon.

HOOD LEDGE PLATE AND MULTIPLE-COMPARTMENT HOOD FOR AUTOMOBILES—Whereby a large percentage of the space not reserved for the machinery, may be formed with separate compartments for storage purposes, yet the hood may be reduced in weight and at the same time strengthened. Patent 1754086. Earl Feilcke.

APPARATUS FOR MEASURING AND INDICATING EFFICIENCIES—Having means whereby the operator of an automobile or aeroplane, may know the speed at which his machine has the highest efficiency, whereby he may become aware of the best adjustments, and the best fuel suited for the machine. Patent 1754039. Otto A. Pawlick and Raymond C. Giese.

RELEASING COUPLING—For use in connection with pulling vehicles, such as tractors, and drawn vehicles, such as plows, for releasing the plow should it encounter a rock or other obstruction, to avert injury or breaking of parts. Patent 1754048. Fred W. Reimold.

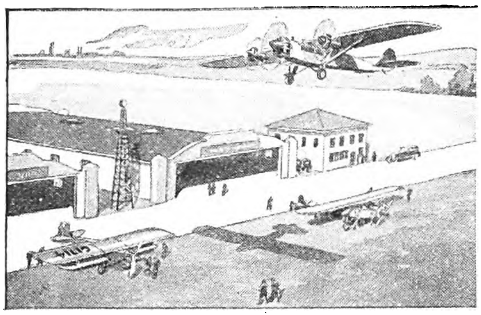
CLUTCH-PROTECTING DEVICE—An attachment designed to protect a clutch mechanism from undue wear and tear, incident to the habit of "riding the clutch pedal," which causes the clutch parts to wear unnaturally, the attachment is capable of being easily installed. Patent 1755002. Charles M. Hibbets.

SPRING BOOT—Comprising a sheet of flexible and liquid-proof material constituting a liner, adapted to embrace a spring, for the protection, retention of lubricants, and permanent preservation against deterioration by exposure to the elements. Patent 1753257. Alfred R. Ulp.

VEHICLE SPRING—Which permits greater vertical play, adds to the length of the working wheel base, transmits less vibration, prevents distortion of the frame, counteracts momentum in rounding corners, and can be adjusted to meet varying loads. Patent 1753420. Joseph N. Johnson.

AUTOMOBILE RADIATOR CAP—Having an outwardly-closing, inwardly-opening valve which permits the filling, or addition of water to the cooling system, without the necessity of removing the cap, thereby eliminating the danger of scalding or injury to the car finish. Patent 1755316. Francisco O. de Alcocer.

BERRY-PICKER'S VEHICLE—An argicultural machine whereon a number of persons may be drawn over a berry patch supported in a convenient leaning seated position, with their hands free to pick berries, and their backs relieved of strain. Patent 1756803. Jacob D. W. Williams.



A Career in Aviation

AVIATION is the great career of the future! Get into it *now*, by practical, proved routes—study International Correspondence Schools Courses in Aviation Engines and Ocean Navigation!

Captain Lewis A. Yancey, hero of the recent New York-Bermuda flight, says: "The I. C. S. books on Navigation are about as fine as have ever been prepared on the subject, and are to be highly recommended to the aviator who is desirous of learning the navigational side of his calling."

The Aviation Engines Course includes necessary study of Mathematics, Mechanical Principles, Combustion and Fuels, Principles of Gas Engines, Construction, Carburetion, Ignition, Lubrication and Cooling, Pumps, Propellers, etc. You can start at *once*. Study *at home* in spare time. Mark and mail the coupon!

Across the Editor's Desk

WE'RE quite aware that the call of the outdoors, of sports, and the like is stronger than the appeal of science right now, but this month we've given you some absorbing features you won't dare pass up and others that will add scientific interest to your vacation trips. Take, for example, Dr. Russell's article on the green flash. Maybe you've never heard of the green flash, but here's your chance to see it—if conditions where you are going are just right—or to see the mirages which he also discusses. They are never-to-be-forgotten sights. During the past year Dr. Russell has been traveling here and there in Europe and the Levant but expects to return to his duties at Princeton soon.

And those insects which you see walking on water while you're in the country—another article tells how they do it. The secret is in the surface film of the water. Now if this surface film were so tough that human beings could emulate the water skipper, how would you like your high diving then? Another article is an "appreciation" of the hoary old man of the meadows: the sycamore; still another warns you to "be careful with fire while in the woods" but it also tells of the extensive system of forest fire protection and fire fighting necessary in this careless country. Summer heat may make you wish that you could, when traveling, sleep in the refrigerated dining car described on page 108, but it just isn't being done. You may dine in such cars soon, however.

"Zoogenesis" doesn't sound like light summer reading but it concerns a subject that concerns all of us: the new theory of evolution. Whichever side you're on, you will want to know this theory. The article was written by Dr. Austin H. Clark, a note about whom you will find on page 87. When his theory was first announced months ago, it was sadly distorted by the newspapers but we went straight to the source and got Dr. Clark's own story.

Unlike the daily press, you know, we don't try to give last minute news just because it is new; we choose our features carefully and then get the man who has made the theory or performed the experiment to write it up for us, but only after it has simmered a bit. "Basic Patents in Evolution," for example, was written by invitation after a member of our staff heard Dr. Gregory give a talk on the subject before the Explorer's Club. By the time he could put into writing the substance of his talk, he was on his way to Africa, and the manuscript of his series was written on the deck of a steamer in the Red Sea.

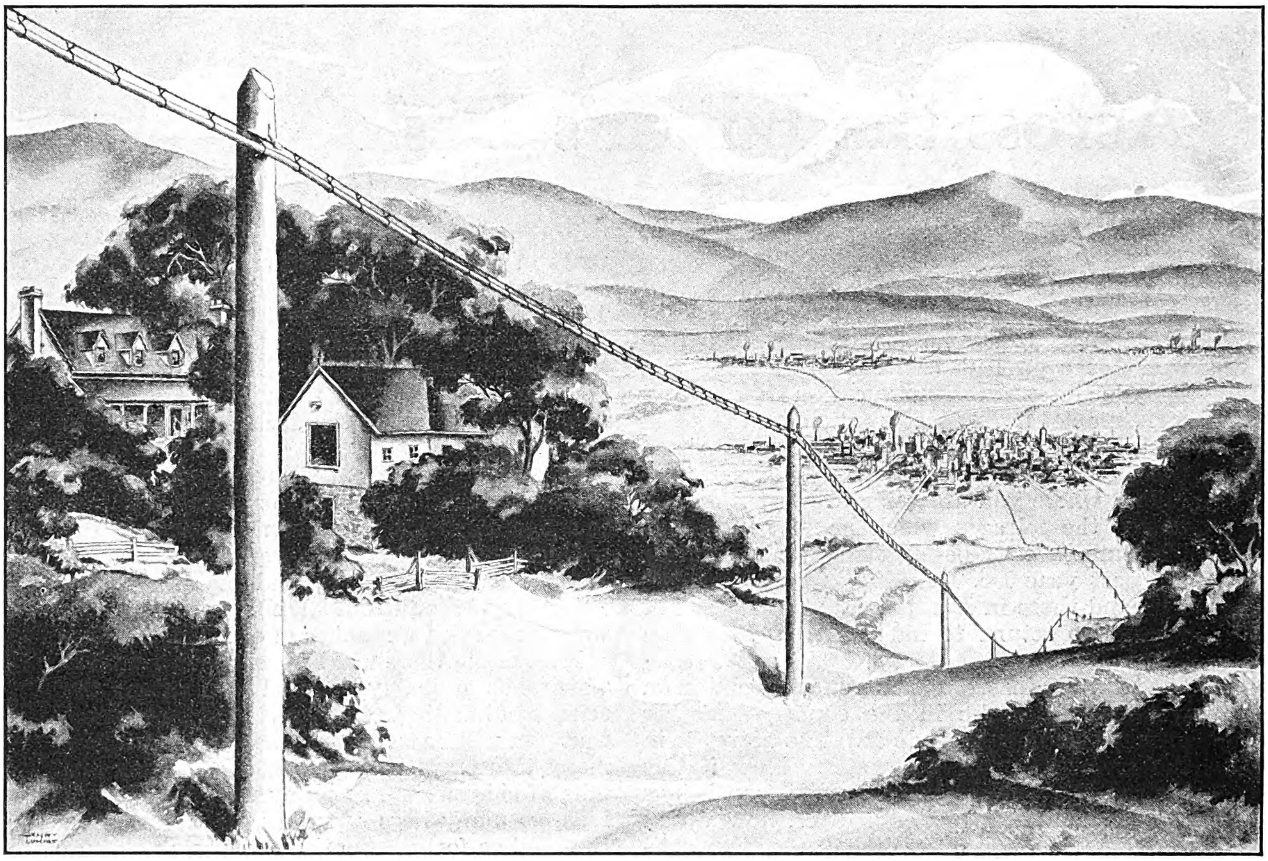
But enough of this. There are other good features in this issue—on the burying of a river in a gigantic sewer, on industrial fatigue by the well-known Dr. Laird, on perfumes, a home-made cheap microscope, and many others—but what of the future? Well, for next month we've scheduled a number of excellent articles.

First of all, there will be one about a subject which has probably puzzled you often: the science of building a railroad. And we warrant that you will be surprised when you learn how many thousands of dollars it takes to lay one mile of shiny rails—so many thousand feet of rails, so many kegs of spikes, so many cross-ties, and so forth. Another discusses volcanology. As you have surmised, the word simply means the study of volcanoes; and the article is as interesting as volcanoes are mysterious. Dr. Jaggar, who wrote it, has been the next door neighbor of so many volcanoes that he can, and does, let us in on many of their secrets. He now lives and works in a little house on the rim of the crater of Mount Kilauea, Hawaii.

You may expect an absorbing story of the Indianapolis race which was run on May 30. This will cover the scientific aspects and give some of the highlights of the spectacular performance. Water sports come in for their share of space also, for the building of the yachts to defend the America's cup is a highly specialized science. You'll be treated to a story of the races for which these yachts were built.

Of course we can't begin to go into detail regarding all that is to come. The foregoing articles are simply a few samples. There will be others in true Scientific American style; and that naturally means that your interest was considered when we scheduled them. We hope you'll enjoy them all.

Orson D. Munn



AN INTER-CITY CABLE, PART OF THE BELL SYSTEM NETWORK THAT UNIFIES THE NATION

Vast, to serve the nation . . . personal, to serve you

An Advertisement of the American Telephone and Telegraph Company

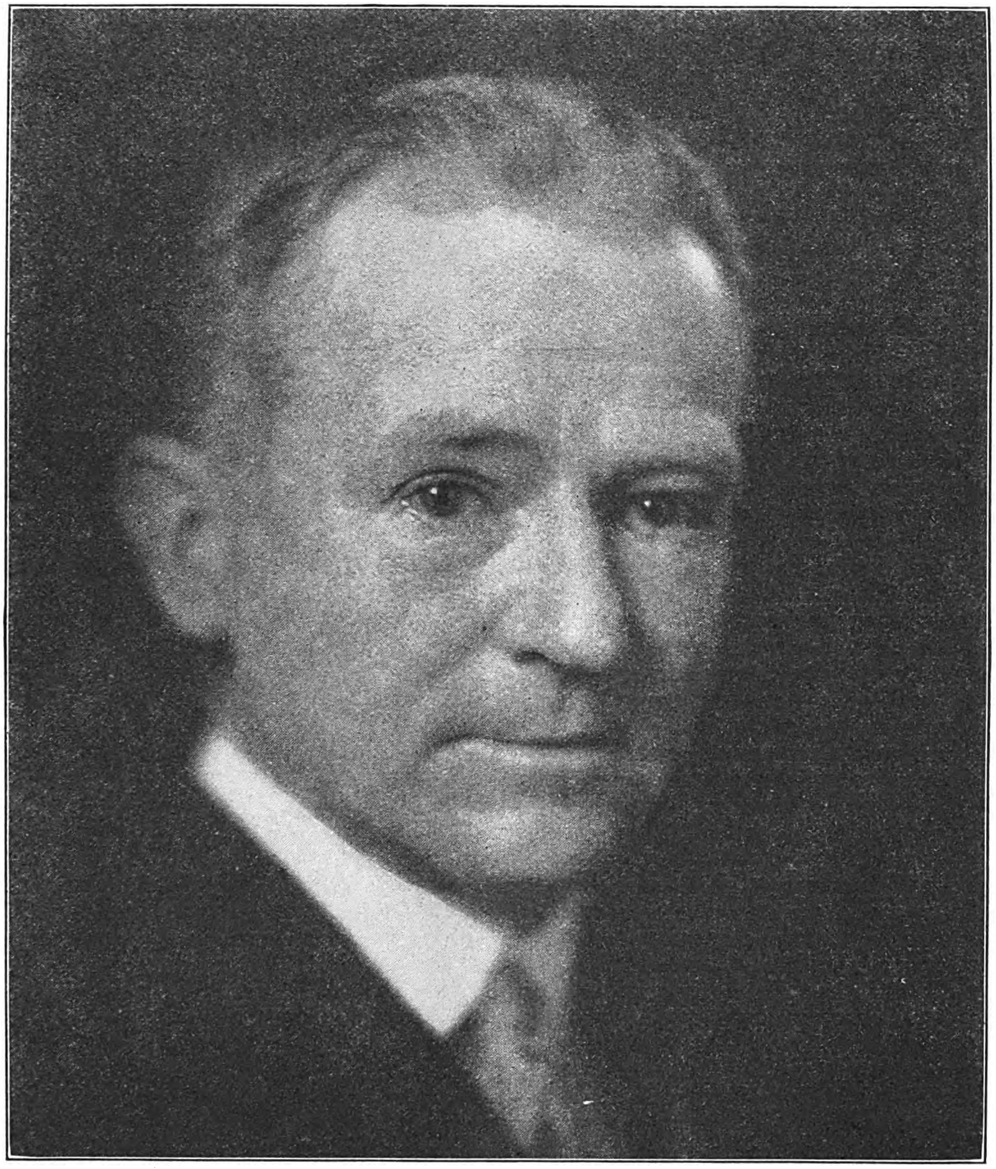
So THAT YOU may telephone from house to house in a Southern village, from farm to farm in the Middle West, or from the Pacific to the Atlantic Coast—the Bell Telephone System *must* be large. Its work is to give adequate telephone service to one of the world's busiest and most widespread nations. There is 4000 million dollars' worth of telephone plant and equipment in the Bell System, any part of which is subject to your call day or night.

Every resource of this system is directed to the end that you may have quick, clear and convenient telephone service.

In order to meet the telephone needs of the country most effectively, the operation of the Bell System is carried on by 24 Associated Companies, each attuned to the area it serves. Working with these companies is the staff of the American Telephone and Telegraph Company, giving them the benefit of its development of better methods.

The Bell Laboratories and the Western Electric Company utilize the talents of thousands of scientists for constant research and improvement in the material means of telephony. Western Electric, with its great plants and warehouses in every part of the country, contributes its specialized ability for the precise and economical manufacture of equipment of the highest quality for the entire system.

The Bell System is vigorously carrying forward its work of improving the telephone service of the country. It is building for today and tomorrow—for the benefit of every one who lives and works in America.



Austin H. Clark

ABOUT a year ago, as many will recall, newspaper accounts, some accurate and some not, concerning a new and rather extraordinary theory of evolution proposed by Dr. Austin H. Clark, widely known zoologist of the United States National Museum, attracted the attention of the scientific world. "Zoogenesis" is the general name Dr. Clark employs to cover his theory about which he has just published a semi-popular work "The New Evolution—Zoogenesis." He also has prepared for this journal the article on the same subject, which starts on page 104. Since the new theory of evolution was announced it has been discovered that Dr. Clark's career in science parallels that of Charles Darwin, the famous proponent of another theory of evolution which has made history. Like Darwin, Clark never was a "closet student"; for 30 years he has traveled widely and observed actual things in Nature. Both scientists spent many years studying at first hand a wider scope of material than the average zoologist finds accessible. Clark specialized in the study of birds and insects and then, to enlarge his point of view still more, he spent some years specializing in oceanography—as did Darwin. Both also made long cruises on specially equipped sea vessels, Darwin on the *Beagle*, Clark on the *Albatross*. Only after so catholic a study of the interrelationships of the different forms of animal life can a man of science feel equipped to synthesize a broad theory such as Clark's theory of evolution—Zoogenesis.

The fighting front line. Bringing up a hose from a water tank

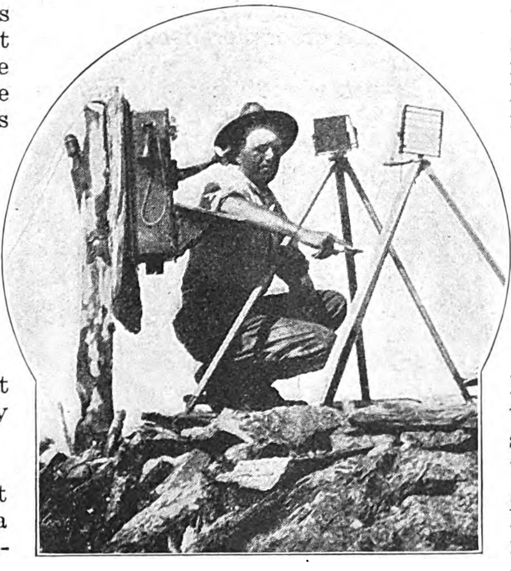
Fire: the Enemy of Our Forests

By CHARLES W. GEIGER and WALLACE HUTCHINSON

PERCHED on the top of a rugged mountain peak stands a small square house with steep sloping roof to shed the heavy winter snows, and with long windows on all four sides. From this elevated lookout point during the fire season, sharp-eyed sentinels scan the vast expanse of green forests stretched on all sides below them, searching, always searching for the telltale wisp of smoke that marks the newly started forest fire.

This scene, common enough in the great forested areas of the west is somewhat rare in the east, but the disastrous fires of the past spring have brought home to many people the fact that the east needs many more lookouts. In the west a forest fire as a rule rages through woods without endangering very many habitations; in the east many farms and villages have been wiped out by fires that began in the forests. In either case, the monetary loss often runs into millions of dollars and yet it is a strange trait of human nature that very little thought is given to forest-fire prevention, and it has always been difficult to obtain appropriations necessary for such work.

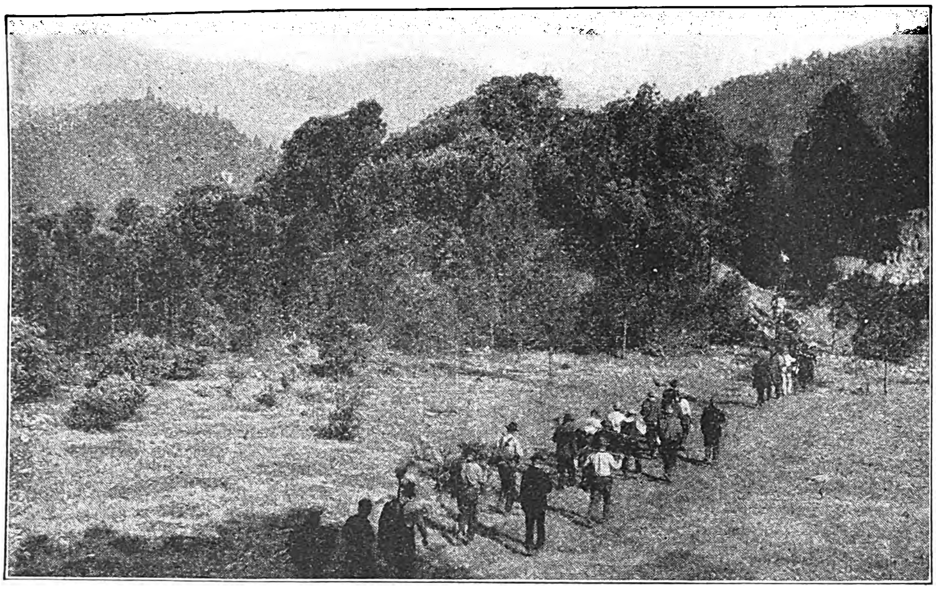
OUR forests are one of our greatest natural resources. They furnish a playground for thousands of vacationists and nature lovers and are the storehouse of waters that feed our lakes and rivers which make year 'round hydro-electric power possible. They furnish lumber, pulp for our paper, and many other necessities of life. The people of the United States use in house-building and otherwise, two fifths of all the wood consumed in the world. To perpetuate the source of supply, federal and state governments are practicing reforestation and have expended every effort to save our forests from the fire menace. In carrying out this huge task the most modern equipment is used whenever possible.



The guard may report a fire by either telephone or heliograph

In cities and towns fires are usually discovered shortly after breaking out. In the mountains, however, extensive areas of our forests are so thinly populated and afford such obstructed views because of mountain ranges and deep canyons, that fires might become very large before they were discovered if some special means of detection were not employed.

IN California and many other states, a careful watch is maintained over forested areas by United States Forest Service men stationed on high peaks, who act as fire lookouts, and by fire guards or patrolmen who travel along ridges and other routes where they have a good view of areas in which fires are likely to occur. The lookout men go to their stations in the high mountains early in the summer and remain constantly on duty, from daylight to dark, until the first rains come in the fall. Food supplies and mail are sent to them by the rangers. These lookout men occupy small buildings or observatories with windows on all sides. Many of these houses are set on steel towers 30 to 60 feet above the ground, so that the lookout man can see over the surrounding trees or other obstructions. In addition to the fire lookouts, everyone within or near the forests (miners, stockmen, hunters, campers, motorists) is constantly on the watch for any fires that may occur.

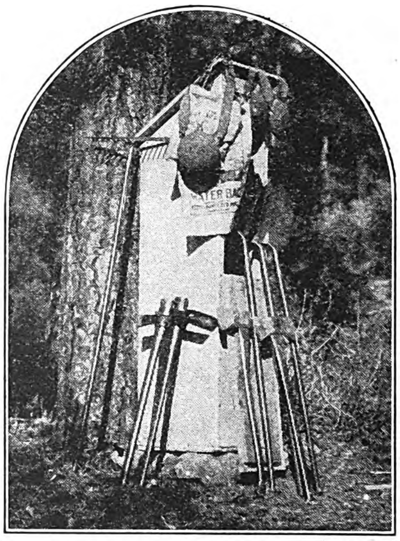


Fire fighters on their way to a fire, carrying their tools

Throughout the Pacific coast states, in addition to lookouts, airplanes are used to discover fires. A man in an airplane flying at 5000 to 10,000 feet above the ground can look down upon a wide expanse of country and quickly detect the smoke of a small fire which may be hidden by mountains or forests from the lookout men. The airplane, however, does not fly daily over the forest. It is used largely as a scout for making air surveys of large fires that are burning, in order that the forest officers may know how best to fight them, and for forest patrol after lightning storms and during hazy or smoky weather. Under such conditions the airplane is a valuable aid in forest protection.

At the side of the lookout in the tower mentioned in the first paragraph, stands a telephone, one of the nerve ends of the efficient system of telephone communication lines that play such an important part in combating the fire menace in our great national and state forests. There are other instruments of the magneto type located at intervals along the forest trails and roads. These latter telephones enable the forest guards to keep in touch with the central ranger station at all times.

If the guard discovers a fire, he goes to the nearest telephone, calls the ranger station, and reports the location and the extent of the fire. Men with fire fighting equipment are immediately dispatched to the scene of action and if the fire is likely to assume large proportions, one or more fire camps may be established. Temporary telephone lines are quickly stretched between these camps and the central station so that the men engaged in fighting the fire may keep in constant touch with the supply base to report progress and order more men, food, or equipment.



Fire fighting tools stored on the trail ready for future use

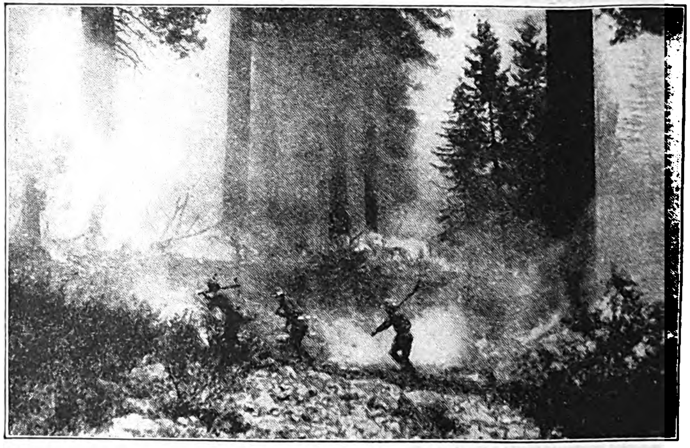
In districts where it would be impracticable to maintain a permanent fire fighting force, volunteer fire fighting units have been established under the direction of a fire leader. This man designates an individual to act as local "dispatcher" whose duty it is to take care of the lines of communication during a fire.

Since forest fire prevention is so largely dependent upon telephone communication, forest rangers must be efficient linemen. A course in telephone construction and maintenance is given each ranger during the training period and he is furnished with a manual giving specifications and details of telephone line construction. This construction is unique because it would be difficult to construct a pole line in thick timber, high underbrush, and rocky ground. Therefore, lines are strung along on trees, usually following trails or paths. In brush country where fire damage to wooden poles would be heavy, iron tubing is used.

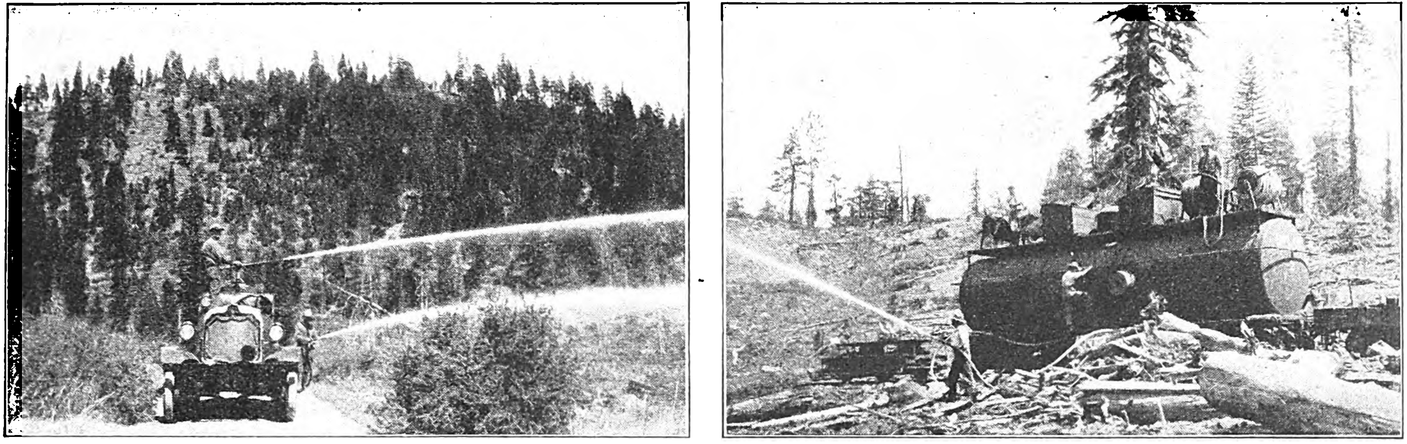
Before the beginning of the fire season a careful check is made on the communication system and the damage done by weather during the winter months is repaired. Thereafter, all lines are tested daily. Most of the forests are situated in high altitudes and the forces of nature combine to make this job of maintaining perfect communication more difficult. It is said that over 1500 telephones directly constitute the service of communication between the extensive system of forest protection in California alone.

In a few localities where there are no telephone lines, the heliograph is used. This instrument sends messages

A camp in the path of the flames



Advancing to meet the roaring enemy



A water tank on a motor truck and a railroad tank car

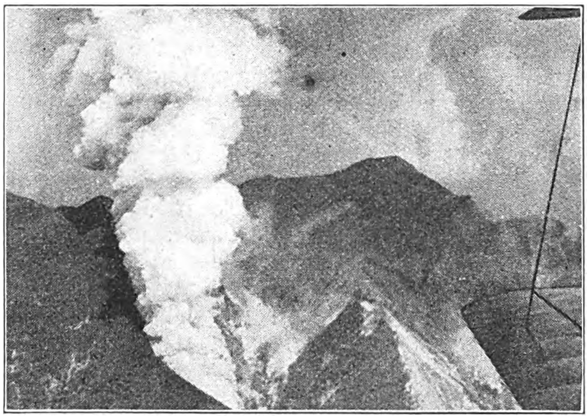
in telegraphic code by means of a small mirror which reflects the sun's rays. This method is therefore valueless in cloudy weather, or when the sun is obscured by the haze and smoke from a fire.

Inasmuch as weather conditions have much to do with the prevalence of forest fires, an intensive fire-weather service has been in operation in California since July, 1926. The principal object of this service is to aid all fire prevention and suppression agencies in their efforts to reduce losses from forest, grass, grain, and brush fires. This fire-weather service works in close co-operation with fire-agencies, federal, state and private.

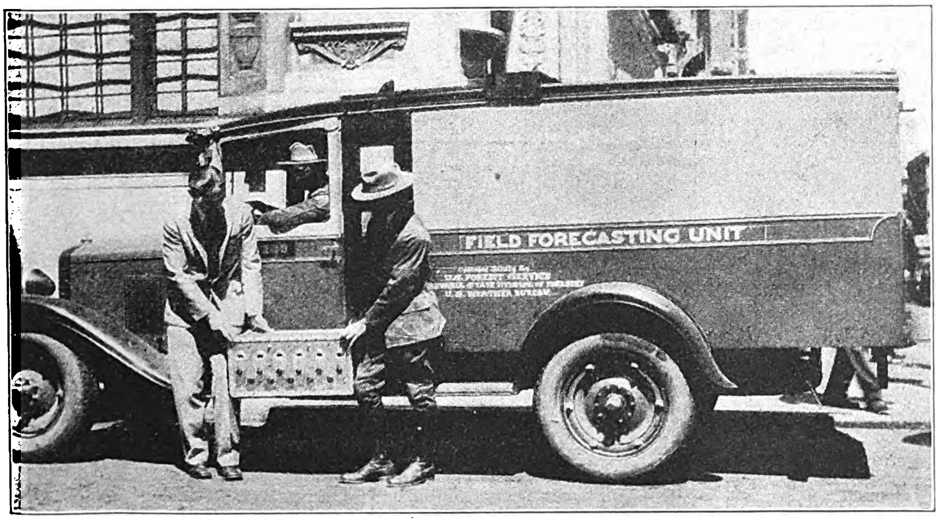
THE term "fire-weather" aptly describes those combinations of weather conditions which cause fires or which favor their rapid spread when once started. Lightning, for example, causes as high as 45 percent of all the outdoor fires in California, depending upon the season. Severe lightning concentrations in the state have caused more than 350 lightning fires in national forests during a single thunderstorm period of two and a half days.

Hot, dry, windy weather constitutes the fire-spreading phase of fire-weather. Thus a knowledge of atmospheric relative humidity, and of wind direction and velocity, have a very important bearing upon both fire prevention and fire fighting work.

The service rendered by the Weather Bureau is primarily a forecast service. Systematic fire-weather forecasts are issued by the district forecaster of the Weather Bureau at San Francisco based on the usual synoptic weather reports and charts, supplemented by daily telegraphic reports from especially established fire-weather observing stations in various areas in the state.



Airplane view of a fire in a distant canyon



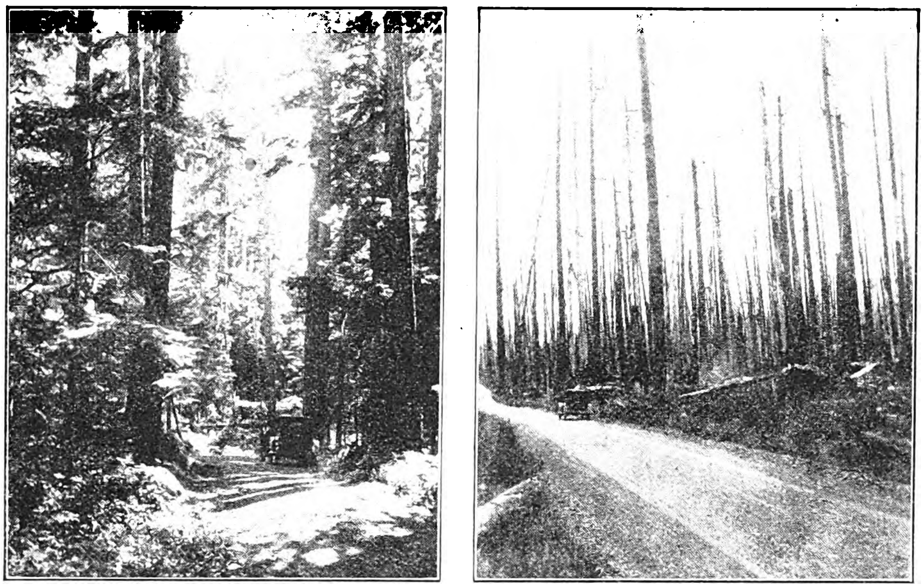
The fire-weather forecasting unit which travels throughout the state of California during the fire season and gives information to aid in fighting fires

Since fires and their complex topographical surroundings cannot be taken to the district forecast center for analysis, a mobile weather bureau office has been provided to take equipment and a meteorologist to the fires. This unit consists of a motor truck equipped with meteorological instruments including anemometers, hygrothermographs, psychrometers, maximum and minimum thermometers, rain gage, and a small aneroid barometer as well as radio receiving instruments to catch the detailed weather reports which are broadcast twice daily from the naval radio station at Mare Island. The truck has accommodations for two men who will operate it, one a meteorologist in charge and the other a combination observer and radio operator.

Traveling throughout the state during the fire season, the unit proceeds immediately to a large going fire upon receipt of telegraphic orders. Radio apparatus is set up and temporary check or key weather stations are established in the fire vicinity. These stations issue detailed forecasts of all weather conditions influencing the choice of fire tactics and the ultimate control of the fire. Such forecasts are issued twice daily together with any special advice that may be required in connection with back-firing and similar operations.

PREPARATIONS for the fire season are quite elaborate. Before the season opens, an ample supply of fire fighting equipment is distributed to points where it will most likely be needed. This equipment consists of axes, shovels, rakes, hoes, canteens, cooking utensils, and emergency food rations.

During the summer months the rangers are assisted by guards, patrolmen, and firemen, but they also make arrangements with nearby merchants,



The contrast of beauty and stark ugliness of a skeleton forest made by fire: two views of the same location. Perhaps carelessness was the cause

ranchers, and others for supplies of laborers, transportation, and food in case of emergency.

When a fire is reported, the forest ranger or one of his assistants may go to it alone if it is very small. For a larger fire, three or four men with rations for two days may be sent. If the report indicates that the fire is likely to become a big one, a large number of men, with the necessary tools, are gathered and sent to the fire. Food, supplies, and further equipment follow by slower transportation because the rangers continue fighting the fire until it is completely out and do not waste time in going back and forth for food, bedding, and tools.

Small fires in grass and forest litter can often be beaten out with branches or wet sacks, but if burning fiercely it is usually necessary to clear a wide fire line which the flames cannot cross, some distance in advance of the fire. Sometimes back-firing is necessary to control big fires. In back-firing, a fire is built in advance of the main fire, usually along a road, trail, or other suitable place where it can be properly controlled; and it is allowed to burn back toward the main fire. When these two fires meet they die out for lack of further inflammable material. Since back-firing itself is dangerous if not properly handled, only experienced fire fighters should employ it.

In all fire fighting, advantage must be taken of natural conditions. A fire may burn very rapidly up steep canyon sides, but may be stopped easily at the top of the ridge. Fires usually die down during the night and the best time for fighting them is immediately after daybreak when relative humidity is high.

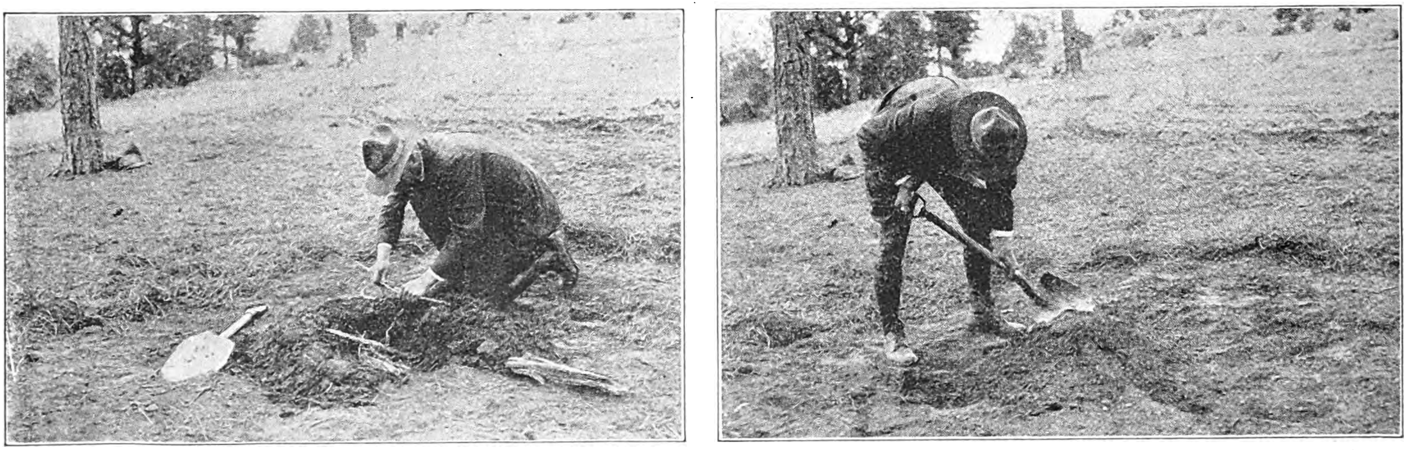
In many cases the fire-fighting equipment is supplemented by water tank pumping trucks if highways run through timber lands susceptible to fires. In many cases also, railroads have built special tank cars with necessary pumping equipment for fighting forest fires along their rights of way.

Although a large percentage of forest fires are started by lightning, a greater number are caused by the careless use of fire by tourists, campers, hunters, and fishermen. Many people know, either from actual experience or hearsay, the havoc that fires play in our orests each year; they know the necessity for precaution in using fire for any purpose in forests, but strangely, as has been noted, carelessness still seems to be the predominant characteristic of many people when they are in the woods.

Nothing betrays the tenderfoot sooner than his fire. The woodsman, before he builds a fire, clears a space of all grass, leaves, and trash, digs a small hole, and in it builds a small, quick fire. When the fire burns down he sits beside it and does his cooking. The tenderfoot, on the other hand, makes a bonfire and cooks himself while he burns his food. A woodsman never builds a fire near leafy trees, dead logs, or underbrush; nor does he build bonfires in windy weather where there is the slightest danger of the fire becoming uncontrollable.

HE never leaves camp even for a short time without first putting his fire out with plenty of water and then covering it with earth. He is always a careful smoker. He breaks his match in two pieces to make sure that it is out before he throws it away and stamps with his foot every spark in discarded pipe heels, and cigar and cigarette stubs. Many voluntarily refrain from smoking in the woods during the dry season.

Someone once said that if we could educate every American to be careful with fire, 95 percent of our national forestry problem would be solved. In closing, therefore, we shall repeat a few rules which, if followed, will aid greatly in the solution of the forest fire problem: 1, Build camp fires like those of the woodsman; 2, Be sure the camp fire is entirely out before you leave it. Be sure that matches, cigars, cigarettes, and pipe heels are out before being discarded; 3, If you discover a small fire, put it out. If it is too large for you to handle, go to the nearest telephone and notify the ranger, local dispatcher, or whomever else may be directly concerned in your particular locality and then stand by until help comes.



The woodsman is never careless with fire. He builds his campfire in a hole in the ground in the middle of a cleared space; and when he leaves, he first drenches it thoroughly with water and then covers the ashes with plenty of soil

OUR POINT OF VIEW

The Improved Patent Situation

INVENTORS who have for years been led to believe that it must take an unconscionably long time to obtain a patent, have in store for them a pleasant surprise. A keen note of optimism is now heard wherever one goes regarding the situation in the Patent Office, for things have happened there.

Admittedly, the Patent Office has had a steadily increasing file of unfinished business, patent applications that must await their turn. At the present time, it is farther behind in its work than ever, but this is partly because of the curious fact that more free-lance inventors seek patents during periods of unemployment than at any other time. But even in normal times, the majority of delays in the granting of patents are due to the fact that inventors or their attorneys exercise their statutory right to delay, for various reasons of their own, their answers to official actions of the Patent Office. The Commissioner has been diligent in his supervision and is not to be blamed when he has such conditions to face and especially when his office has been functioning under the handicaps of inadequate facilities, an inadequate examining force, and inadequate salaries for the examiners. The salary question alone has worked a great hardship on the Patent Office for years, for the examiners were never paid as much as they could command in outside practice. As a result of this, there has been a large turn-over in personnel, and new men were constantly being taken on and put through a training period that was largely unproductive.

The situation has changed. Some time ago, Congress authorized salary increases all along the line and also gave authorization to augment the force of examiners. The salary increases went into effect January 1, and the extra examiners, totaling 110 men, were on the job July 1. The examining corps now totals 708 and the total professional force 722. Members of the patent bar worked with the Patent Office for years to bring about these changes, and when final consideration was being given them, they had the unqualified support of the President, Congress, and the Budget.

An Assistant Examiner now starts at 2000 dollars yearly, a very good salary, we should say, for a man just out of college and especially in Washington where this amount is equal to 3000 dollars in most other large cities. This new man can go to 3700 dollars before he takes the next step upward to become Assistant Chief Examiner, with a fine salary increase. Then comes the Principal Examiner, head of a standard examining division of which there are 63, who now gets a larger salary than did Mr. Robertson when he became Commissioner. Still higher in the salary scale are the Assistant Commissioners and the Members of the Board of Appeals, one more of the former and three more of the latter having been included in the recent authorization to enlarge the force.

The larger force is going to improve the patent situation greatly, and the salary increase has already shown its effect in improving the *esprit de corps* of the Office to such an extent that it is felt that there will be an increasingly smaller turn-over in personnel. Besides this, further hope for the betterment of the situation is seen in the fact that within the year, the Patent Office will have moved to its larger, more modern quarters in the Department of Commerce Building, now under construction.

Sir Henry Segrave

SPEED mania has again taken its toll. This time it was Sir Henry Segrave who, piloting *Miss England II* on Lake Windermere in England, had just made a record run at over 98 miles an hour and was on a second trial run when his powerful boat swerved, somersaulted, and capsized. Sir Henry was to have entered the boat in the Harmsworth Cup races in the Detroit River August 29 to September 2.

While we still do not feel that the end justifies the means in these attempts at world speed records, we do not wish to detract from Sir Henry's reputation as a man of high and dauntless courage. Those who knew him, the entire sporting world, the automotive industry for which he performed invaluable service, and many others in high places who knew him as a gentleman as well as a sportsman of the highest type, have all been shocked and saddened by his death. His was the breed of daring that feared more to fail in what he set out to do than any physical hazards he had to face. We offer our sincere condolences to his family and to his country.

Commissioner Robertson has done much to bolster up the Patent Office and is to be commended for his part in bringing about the changes. Because of them, the Patent Office may be expected to act upon patent applications with more expedition than has heretofore been possible. In but a short time, therefore, we feel that the situation will begin to clear up; but in the meantime, we urge upon inventors a little patience, a spirit of co-operation, and promptness in replying to official communications; and upon critics of the Patent Office, more judgment in analyzing the situation.

Returning Prosperity

CURIOUSLY, last fall's stock market break did not mark the downfall of the capitalistic United States, as the small group in control of the Soviet so hopefully predicted. Of course we wouldn't think of suggesting that the prophets played too loosely with an idea—for they are very *wise*—but something happened to nullify their opinions. This capitalistic country which "bled its people dry" will soon be back at its old tricks of making and spending money and enjoying prosperity. We're sure of it!

Business has been down for an unprecedentedly long time now. An article in a bulletin of The National City Bank of New York, however, states that: "During the period of curtailed production, consumption has gone on—in somewhat reduced volume, it is true, but nevertheless at a rate in excess of production—so that it is only a question of time until shortages will begin to develop and necessitate the speeding up of the productive machine." In other periods of depression, the business of the country was far less diversified and lacked the recuperative power demonstrated in recent years. With the present easy money and "with the record of past depressions so suggestive of the country's ability to regain its stride, there seems reason for confidence that business will soon begin the climb back to normal prosperity."

Almost everywhere we hear the same opinion expressed, sense the same feeling of hopefulness. With everybody thus "tugging at the wheel," we are sure that boom days are not far in the offing. Perhaps our Soviet ill-wishers won't like to hear this but then, once *they* have a taste of prosperity—the success of some of their programs—doubtless they will feel less envious.

Navies and World Problems

WE still believe the treaty should be ratified, in spite of the very positive handicap it places on our Navy; and we believe there would have been less opposition to it from the press and the people if the Adminis-

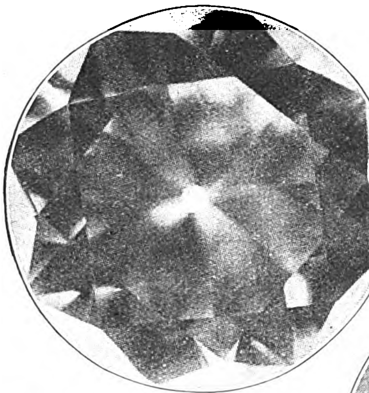
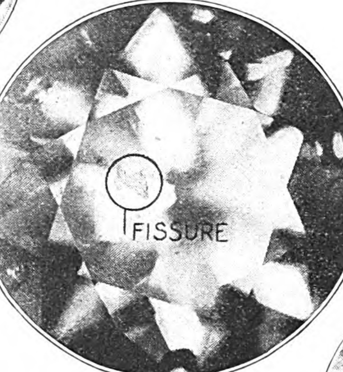
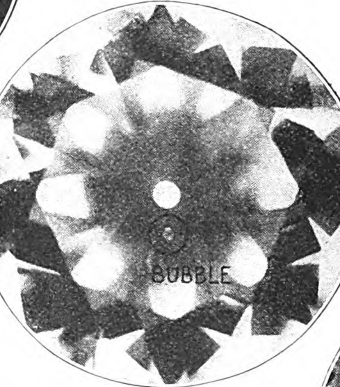
Photography Identifies Gems by Their Flaws

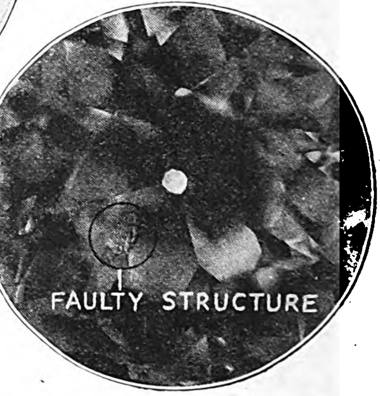
By FRANK HEITZLER



The diamond is apt to have defects such as irregularities in cutting, incipient fractures and imperfections in crystallization, included bubbles of air or gases, and specks or flakes of metallic oxides or carbon. *Above:* photograph of a perfect stone







THE diamond is always recognized as the chief among precious stones. It is the hardest and most brilliant of minerals, but it is a curious fact that the artisan is necessary to develop nature's raw product, for there is no indication of beauty until it has been faceted and polished by the hand of man. Nature does not always give us a perfect product and, even when polished, the diamond is no exception to this rule. Ninety-six percent of the stones found are more or less marked with imperfections in their creation, and as there are no two stones exactly alike, these flaws can be used for the purpose of identification by recording them, superimposed on a photographic plate. Stones without obvious imperfections can be recognized and identified by their shape, cut, color, and weight.

Imperfections or flaws in diamonds are classified in the following way:

FIRST, there are the carbon spots which may appear as a single defect or in a group. If very fine and located toward the edge of the stone, their interference with reflection is not great, but if located toward the center of the table of the gem they will prevent the colors from striking through, and consequently will depreciate the stone.

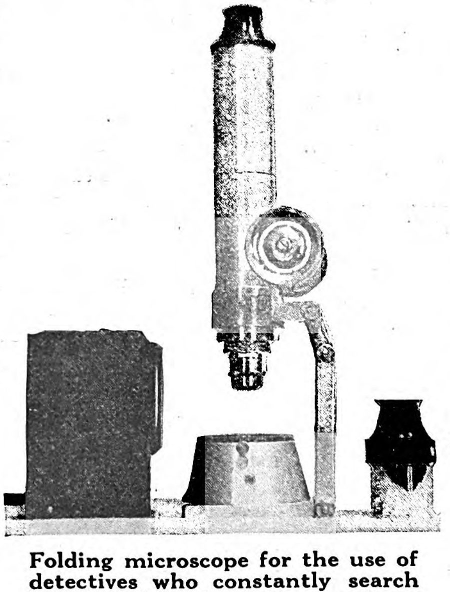
Next there are discolorations in the optical homogeneity of the stone. These may appear milky or brownish in hue, or like fine gravel. They are named "faulty structure" and are very depreciating to a stone. Another defect is the presence of bubbles; they are often filled with water or gas. As they are transparent, they do not cause any appreciable obstruction to the spectrum of colors, if not too large in size. Very fine fissures are not very detrimental, if they do not run across the table of stone, and often cannot be seen by a jeweler's glass. "Feathers" appearing on the table of a stone do not exactly improve its appearance, although they are not as detrimental as carbon spots.

Colors are ascertained through a low-powered microscope equipped with a polarizer and analyzer, intensified by a selenite plate. The operation is speedy and absolutely certain as the lens system shows the colors as they are actually present, not omitting the slightest hue. Color is the predominating factor which gives the stone its value, and it is the distinguishing favor that nature gives certain stones in their making. No cutting of facets can produce the brilliancy and wonderful display of colors imparted when rare minerals are molten in Nature's manufacture of the diamond.

It is a foregone conclusion that identification photographs of diamonds do not constitute a "beauty contest," as their purpose is to show all imperfections to the smallest detail no matter where located, as clearly as is possible with a modern scientific system of lenses. Thus it will be possible to duplicate the photographs 10 or 20 years hence, and to produce them in court as proof of ownership. In the system for identification of diamonds, the slip attached to each photograph always states size of apparatus and kind of lens used, as well as the depth of imperfections and their character.

The colors of diamonds are governing factors in obtaining a good picture. A perfectly white stone photographs an even color and the blue, greenish white, and pink tints are not so bad. However, red and yellow are two interfering colors which no filter will overcome. The reason for this is that although a filter may prevent one color from affecting the plate, the filter itself reflects back to the stone, producing another color which is usually worse than the one it prevented from coming through. In order to overcome this mixed color effect to some extent, specially prepared emulsion plates are used.

The illustrations show the equipment used; important factors are the different holders constructed so that



Folding microscope for the use of detectives who constantly search pawnshops for stolen jewels

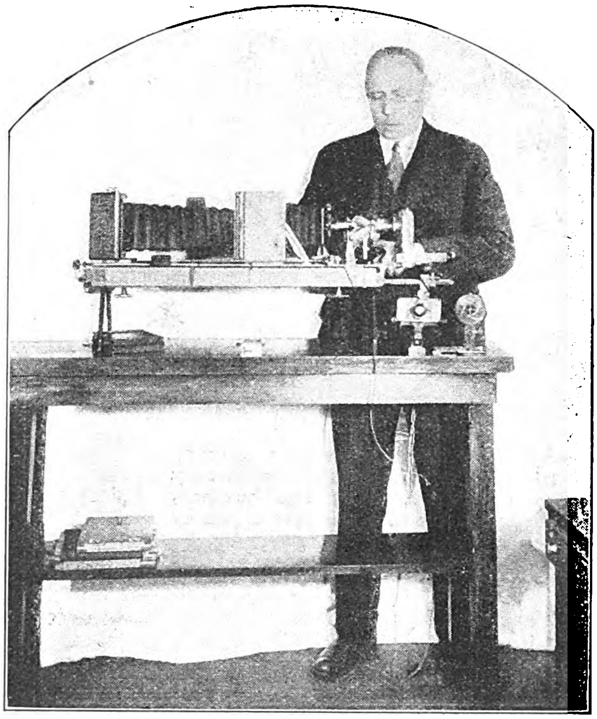
rings or stones cannot be jarred out of position while operating the apparatus. The slide which carries the lens must be a perfect fit, otherwise moving it will shift the image. The camera is of the photomicrograph type with a 42-inch bellows.

The magnification used depends entirely upon the experience of the operator. An attempt to employ too much magnification will distort the outlines of the stone, making it unsightly on account of the manifold reflections of the cut and the facets of the stone. Medium or high-power lenses are useless as the index of refraction and curve of the lens produces an interfering color. Therefore a Micro No. 1 lens is used, and the stone is inserted in the holder, after cleaning it carefully. The lens is then focused and the image appears. The back of the camera is provided with a mask having a circular opening about 3½ inches in diameter, which is placed very close to the plate. The image of the stone has to be centered by simple mechanical movements so that it fits perfectly in the mask. This is all done from the back of the camera where the operator is seated.

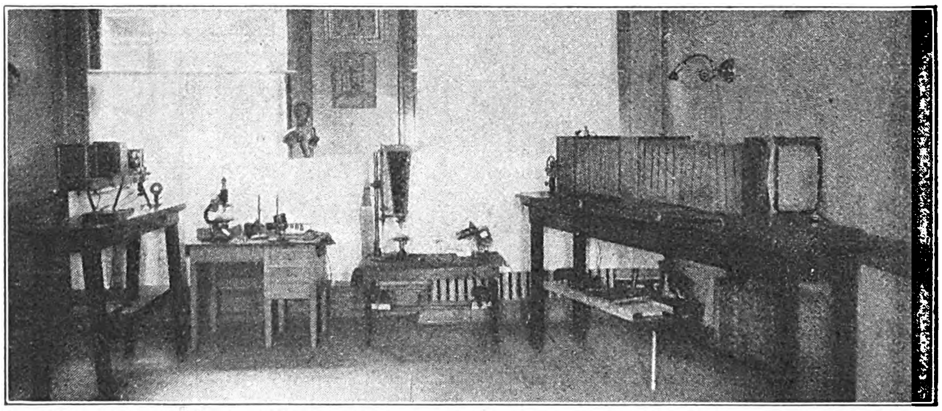
To eliminate differences in exposure due to changing daylight and to take pictures at any time, a constant-intensity electric light is used, operated by a 6- to 8-volt source. The lamp is placed in back of the stone. The condenser lens and reflector are made in such a manner as to keep the rays of light from the lens proper, confining the pencil of light to the diamond. For rubies, sapphires, and emeralds, two lamps are placed in front of the stone to give the darker stones the proper illumination. The same method is also used for settings which have no back opening or insufficient space. The time of exposure for mounted stones is from 6 to 10 seconds, and for loose stones, from 2 to 3 seconds.

After the gem is securely mounted, and the lamp turned on, the next operation is to set the micrometer to zero. This micrometer is an important feature, and is attached on the back of the camera. A rod connects the lens slide and the micrometer. The lens focuses sharply on the table of the stone, the hand of the micrometer reads zero, and the search for characteristic imperfections begins. The lens is moved toward the interior of the stone, and the depth of any flaws appearing in a certain plane is read off on the micrometer and noted. This searching is continued until the end of the stone is sharply defined. Turning backwards to the table, focusing sharp, the plate is inserted. The first exposure is of the table; second, the first imperfections as indicated by the micrometer reading. If a third exposure is necessary, all three are superimposed on the same plate.

After prints have been made, a written record is attached for further reference, the negative and the record are numbered and filed, and in case of theft, prints are made and distributed to police, jewelers, and pawn shops. If a very valuable stone, the photograph can be radiographed to foreign countries thus quickly closing to the thief all possible markets for his ill-gotten treasure.



The photomicrographic apparatus in the author's laboratory used to examine gems



This laboratory is filled with interesting apparatus for the examination of diamonds and other precious stones by the means described in the article

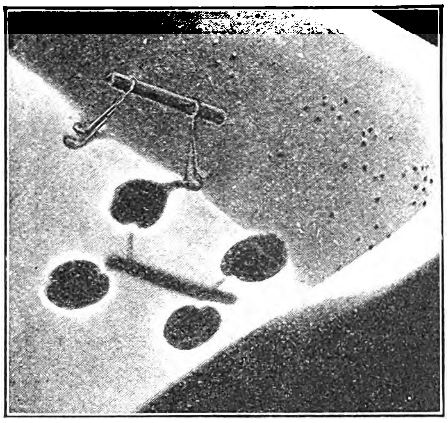
Walking On Water

By HENRY J. TOMLINSON, B.Sc.



Illustrations by the author

A little artificial water skipper made of a match stick, with tiny wire legs waxed at the bottom, will float on the surface of water

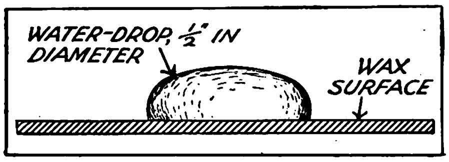
IF we stroll in the country by a pond on a summer's day, the chances are we shall see insects moving on its surface; some of them, such as whirligig beetles, are swimming, but others, for example the so-called water skippers or pond-skaters, are actually walking on the water. This is in itself a most interesting thing, but there is something else well worthy of attention.

If the sun be shining brightly, a number of little shadows will be seen on the bottom of the pond. Each of these corresponds to a foot of a water skipper, or some other insect walking on the water surface. Each is surrounded by a narrow, bright halo of light, reminding one of a tiny dark cloud with a silver lining. At the top is a photograph showing such shadows, together with their halos. How comes it that some insects can walk on water, and what is the explanation of the beautiful little shadows and their attendant halos? When a liquid is brought into contact with a solid, the liquid in certain cases is said to "wet" the solid, while in others it is said not to do so. To the non-scientific mind this would seem strange, as naturally one would expect a solid to be wetted when in contact with any liquid. It is, of course, all a matter of definition, and a simple experiment will make the point quite clear.

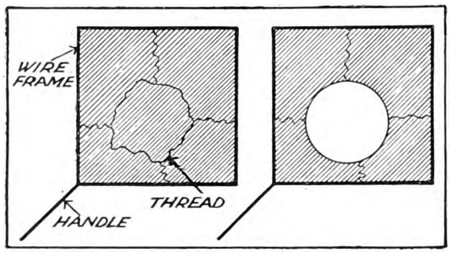
LET a drop of water be placed on a horizontal sheet of glass which has been cleaned and repeatedly scrubbed with nitric acid, and is perfectly free from grease. It will be found that the water spreads in all directions over the glass. Now let the glass be coated with a thin layer of melted candle-wax which is allowed to solidify. If a small quantity of water be placed on the solid wax surface it will not spread as in the previous case, but will gather up into a drop, the shape of which depends on the quantity of water taken; one such drop is shown at the right. The clean glass surface is wetted but the wax surface is not wetted by the water, in the scientific sense. In the same sense, the clean glass surface is not wetted by mercury since the latter, when placed on it, collects into drops.

The surface layer of every liquid behaves in many, though not all, ways as if it were a very thin *stretched* elastic skin; that is, an elastic skin under tension. Of course, the surface layer does not differ in chemical properties from the rest of the liquid, but it behaves in a different way.

A very thin, stretched, horizontal sheet of rubber will serve as a rough model indicating the behavior of the surface "skin" of any liquid. One property of the stretched rubber sheet is its tendency to shrink again, and it is evident that it will do so if the stretching force be removed. The following experiment shows that a liquid surface has the same tendency.



A drop of water on the waxed surface of glass remains heaped up



An interesting experiment made with silk threads and soapy water

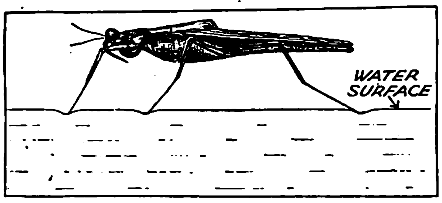
Above, at the left, is represented a wire frame to which a loop of very fine unspun silk has been attached, by means of four tethering threads of the same material. If the frame be dipped into soap-solution, such as is used for blowing bubbles, and then removed, it will be found to have a soap film stretched over it, indicated in the figure by the shading. In this film the silk loop floats. The film has two surfaces, just as a sheet of paper has, and each surface is tending to shrink. If now the portion of the film *inside the loop only* be broken by touching it with the end of a hot wire, the remaining film will pull the loop into the form of a true circle, as shown at the right. The reason is that the remaining film shrinks to its smallest possible dimensions, and in doing so it obviously pulls the loop into that shape for which the area inside it is the greatest possible—the circular one.

Returning now to the model of the stretched rubber sheet, imagine a mouse to be walking on it. The rubber will sag under the feet of the mouse, just as a tight-rope sags under the performer. In a similar way, the surface "skin" of water sags under the feet of a water skipper. In fact a tiny hollow or dimple is made in the surface under each foot, as indicated in the drawing below (not intended to be accurate in detail), and this sagging enables the weight of the insect to be supported.

IT is absolutely necessary that the nature of the insect's feet should be such that they are not wetted by water, for if they were the water would spread over them. In this case, the feet would go through the surface layer and walking on it would be impossible.

Another figure shows, on an enlarged scale, how one of the dimples mentioned can be used to explain the formation of the shadows and halos on the bottom of the pond. The black object indicates the insect's foot. For simplicity it is drawn as a vertical stump, after the manner of a wooden leg. Also for simplicity, all the rays of light falling on the water, represented by lines with arrow heads on them, are taken as being perpendicular to the undisturbed surface of the pond.

When a ray of light, for example *AB*, strikes the water surface perpendicularly, it passes into the water without any bending or deviation. But when it strikes the surface obliquely, as in the case of the ray *CD*, it is bent on entering the water and takes the path *DE*. The amount of bending depends on the magnitude of the angle which the ray makes with the surface, and if the paths of the various bent rays to the left of the central line *FG* be traced, it will be found that they are all tangential to a certain curve *HJK;* an exactly similar and symmetrical arrangement holds good for the bent rays to the right of *FG*.



The skin or surface film on water sags under the weight of the insect

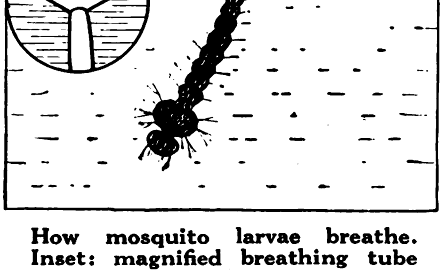
Now let the bottom of the pond be represented by the line *LM*, and consider the narrow beam of light *NP*, which is shaded in the figure. It will be seen that this beam, after entering the water, comes to a focus at the point *J*. Consequently *J* is a bright point on the bottom of the pond, and, for the same reason, *Q* is a bright point too. No light rays fall on the bottom of the pond between the points *J* and *Q*. Therefore all points between *J* and *Q* are dark; in fact *JQ* corresponds to the shadow.

As the figure shows only the rays in the plane of the paper, it is necessary, in order to obtain the explanation of what occurs in nature, to imagine the figure to revolve about the line *FG* as an axis. The bright points *J* and *Q* then travel 'round a circle so that, when we take into account all possible rays and not merely those in the plane of the paper, we see that there is a bright circle on the bottom of the pond. This is the halo to the dark circular shadow of diameter *JQ*. The rest of the bottom of the pond, illuminated by such rays as *AB*, is bright, but not so bright as the halo, owing to absence of focusing of the rays.

It is interesting to observe that the diameter *JQ* of the shadow is greater than that of the stump representing the insect's foot. Also, if we imagine the bottom of the pond to be transferred to the level of the line *RS*, so that the water is now deeper than before, the halo will be produced by such beams of light as *TW*, which comes to a focus at *K*, the diameter of the shadow being *KY*, and therefore greater than in the previous case. Thus the deeper the pond, within limits, the greater is the size of the shadow.

In nature the shadows are not circular, but of an irregular oval form, owing to the shape of an insect's foot differing from that of the stump shown in the figure.

No doubt many readers will like to know how to produce the shadows artificially by means of a little model which takes the place of the living insect. This model, which is made from a match-stick and very thin wire, is shown at the right, its total height being about three eighths of an inch. To prevent the wire feet from being wetted by water, they must be coated with little masses of wax.

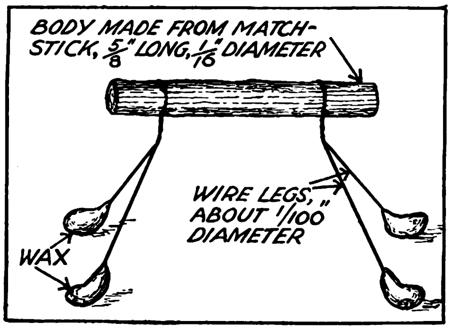


How mosquito larvae breathe. Inset: magnified breathing tube

The model will stand on water, provided it has the dimensions given, and if the bottom of the containing vessel be white, it will show very clearly the shadows and their halos when a bright source of light such as an electric lamp (in the absence of sunlight) is placed directly above it. One figure shows the corner of a white dish containing water, in which air bubbles can plainly be seen. The model, with body blackened, is standing on the water.

As wax floats on water, it may be thought that the wood and wire are buoyed up by the little masses of wax and that therefore the weight of the model is not supported by the water skin; in other words, that the model is not really standing on the water. Any doubt on this point can be removed by completely immersing the model, when it will be found to sink.

So far, we have considered insects moving on the upper side of the "surface" skin of water, but pond-snails can hang from, and crawl on, its underside, somewhat in the same way as a fly can walk on a ceiling.

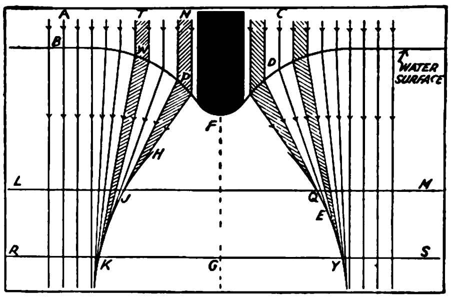


BODY MADE FROM MATCH-STICK, 5/8" LONG, 1/16" DIAMETER
WIRE LEGS, ABOUT 1/100" DIAMETER
WAX

How the synthetic water skipper described in the article is made

The power of hanging from the surface layer is of great importance to mosquitoes. These insects in their larval stage, which corresponds to the caterpillar stage of a butterfly, live in water and can be found in summer in almost any place where water collects.

A drawing of the curious looking larva of one species of mosquito is shown enlarged below at left. The side tube *A* is used for breathing purposes and five little plates are hinged to the end of it at B. When the larva is wriggling through the water, these plates are brought together, so as to form a kind of conical lid to the end of the tube, thus preventing the water from entering. But when the larva needs air, it rises to the surface, pushes the end of the tube through it, and then splays the little plates outwards, so that they form a kind of miniature funnel (indicated in the figure), by means of which the larva hangs from the surface "skin." Air, but not water, now enters the tube, and in this way the larva breathes, much like a diver.



The sag on the surface film makes a negative lens, causing a shadow

Now the strength of the surface "skin" differs with different liquids and, in addition, the strength of the skin of any liquid is altered by contamination. It so happens that the skin of kerosene oil is weaker than that of water and the skin of water is therefore weakened by being contaminated with kerosene. Hence, if kerosene be poured on a pond in which mosquito larva are living, the surface is no longer able to support their weight when they attempt to hang from it, and they can not take in air through the breathing tubes. The kerosene not only cuts off the normal supply of air, but also gets into the breathing tubes and chokes them, so that the larvae die.

This method of killing the larvae has been successfully used to reduce very considerably the number of mosquitoes in those regions where, at one time, they were a pest, acting as carriers of the germs of malaria.

The surface film of water is only one example of the many existing phenomena of capillarity and surface tension in liquids. These form a fascinating chapter in the modern science of physics, from which a wealth of fact concerning the size and shape of molecules has been revealed, and there is a large though mainly technical literature on them.

Numerous examples of surface tension and other capillary phenomena exist. A familiar one is exhibited when we wash our hands with soap. Though soap is a chemical, based on stearic or some related acid, it has been learned within recent years that its main work is not done chemically but physically; the molecules crowd around and work beneath the dirt particles, actually shouldering them off by reason of the strong capillary forces they exhibit.

Soap bubbles, too, may be used in many interesting ways to display the laws regulating surface tension; some of these have been described, rather technically it is true, by A. S. C. Lawrence, former assistant to Sir James Dewar, in his recent book "Soap Films"; while the earlier researches of Dewar himself on soap films are widely known. The English physicist C. V. Boys also has written accounts of numerous related experiments. In short, the whole subject of surface tension and capillarity provides endless interest.

The normally small Des Peres River flowed behind the houses at the left. This photograph was taken during the flood of 1928. The great flood of 1915, however, reached nearly to the tops of the street lamp posts at this point

St. Louis Buries a River

By **W. W. HORNER**

Chief Engineer, Sewers and Paving

THERE is now being constructed in St. Louis a municipal drainage project on a somewhat larger scale than anything American cities have heretofore undertaken. The River Des Peres in St. Louis is, or was, a creek draining a basin of about 110 square miles. It flowed through St. Louis' best residence district, through the great Forest Park, through a heavily used industrial area, and, finally, across six miles of a developing semi-suburban district to discharge into the Mississippi River in Carondelet.

As the city has grown into this valley, sewers have been constructed discharging into the stream; as early as 1905 it had become an open sewer. Then, too, the great increase in the coverage of the permeable soil, which came about through paving and building, increased the runoff of storm waters so that the flooding of the lowlands occurred yearly with increasing severity.

The city discussed improved drainage along this stream for years but no administration was able to secure the necessary funds. Then in 1915, as an offshoot of a Gulf hurricane, a rain of over 10 inches occurred on this watershed in 20 hours. The resulting flood produced high-water marks many feet higher than any previous record; it isolated sections of the city, stopped operations on trunk-line railroads for as long as two days, and caused a serious loss of life. Thus the problem assumed alarming proportions.

Thereafter the carrying out of an improved drainage plan was a major issue in municipal affairs. Preliminary attempts to secure the funds failed but the matter was kept alive, and in 1923 a fund of 11,000,000 dollars was made available as part of the 87,000,000-dollar municipal improvement bond issue of that year.

IN the meantime sufficient funds had been available to permit surveys and detailed engineering studies to proceed, and in 1916 under the instructions of Hon. E. R. Kinsey, President of the Board of Public Service, a definite plan of improvement was worked out by the writer and adopted by the Board. This plan has been elaborated and revised, but is essentially the scheme on which the present construction is being carried out.

At the upper end of the project the river is taken into a 32-foot reinforced concrete sewer which extends for two miles to a point in Forest Park where it is enlarged to a double 29-foot concrete sewer and continues for another two miles. Below this point the drainage area is much larger and the cost of the complete "burying" or enclosing of the river would have been too great. A different plan was, therefore, adopted for the remaining nine miles to the Mississippi River, consisting of an open floodway for storm drainage and an underlying sanitary intercepting sewer.

At this time, three of the four miles of concrete sewer have been completed and the last is under contract. The central three miles of channel and sewer are complete and in service, while nearly all of the channel work for the lower six miles is under contract or has been partly completed. The whole project is scheduled for completion at the end of 1931. When finished, it will have substituted 13 miles of closed sewer and rectified channel for about 18 miles of the old natural tortuous river bed.

Two phases of this work must be of unusual interest to technically minded readers. The first of these involves the engineering studies underlying the design of the system and the more recent tests by which some of these are being checked, and the second the construction approach to the project which involved an unusual choice of tools and an organization of the work to be carried out under recurring flood hazards.

The radical difference in the character of the plan, as between the upper and the lower valley, was due to a combination of surrounding circumstances. The plan for the upper valley involves the unusually large combined sewers, 32-foot and double 29-foot in size. The adoption of this type of plan was the result in part of the restricted conditions north of Forest Park, where residential and industrial development had encroached so closely on the creek banks that there was no room to maintain a flood channel of proper size unless arranged by the acquisition of very expensive lands. Then, too, the river could be completely inclosed in combined sewers at an expense within the limits that the people were willing to consider. Finally, the city had had to live so closely in conjunction with the unsanitary stream flow and continually recurring floods, that the popular irritation with the situation had passed ordinary limits, and no improvement would have been satisfactory which would not have removed these old sores completely from the surface.

IN the lower valley, each of these considerations was reversed. There was in most instances room to construct ample floodways on land that could be acquired at moderate cost, while the expense of complete enclosures of sufficient size to carry the great floods from the larger drainage basin would have involved costs many millions more than had ever been considered. Finally, this section of the city was not densely populated and, except in parts of the upper three miles, the flood damages and the nuisance factor had not injured a great number of people.

With the adopted plan definitely fixed, the first important factor and the most significant to the whole scheme was that which would fix the amount of flood water for which the works would be designed.

In sewer design, the question of rainfall and flood frequency has been extensively studied and engineers in different cities have adopted a variety of answers to the economic question. In general, city sewers are designed for such an amount of water that they are expected to be overcharged at frequencies of once in 15 years, under conservative policies, down to an average of once in one or two years where lower property values do not justify the greater expense.

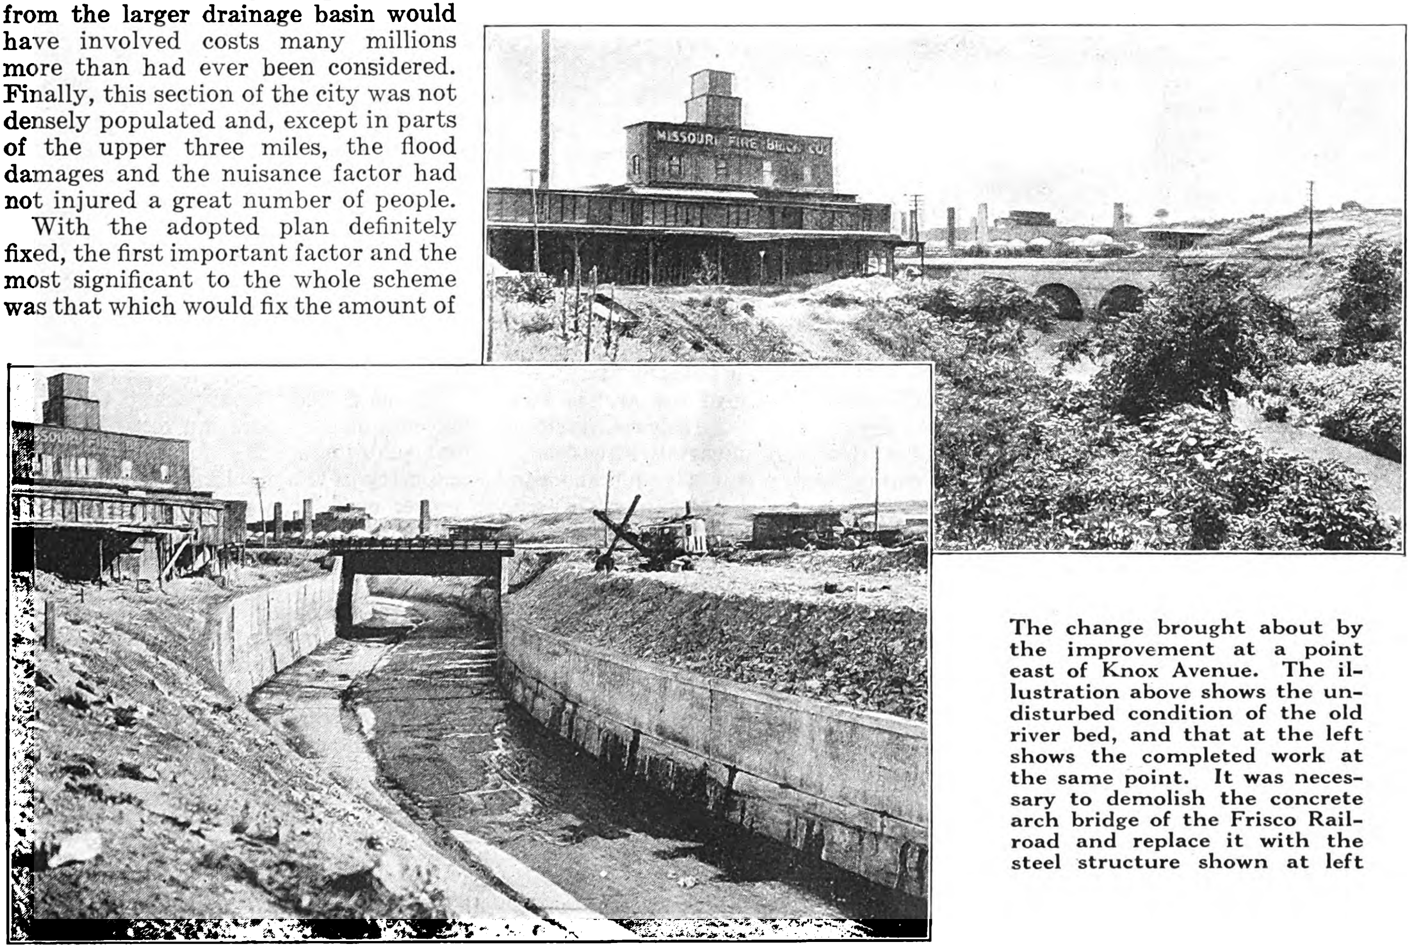
In the instance we have here, it was decided that the capacity of the River Des Peres works should be such as to care for any flood likely to occur once in 15 or 20 years, a slightly more ample basis than that used for smaller sewers. Obviously the determination of the volume of such a flood is not susceptible to exact analysis nor is there available any great amount of data of good character from which the answer can be worked out.

The figures of the amount of water per second for which provision must be made are very interesting, as showing what really terrific floods can come from small valleys with good slopes if the surface is not permeable. It is particularly surprising that the high-water flood of this little 110-square-mile valley may actually be greater than the low-water flow of the Mississippi River as it passes the city of St. Louis.

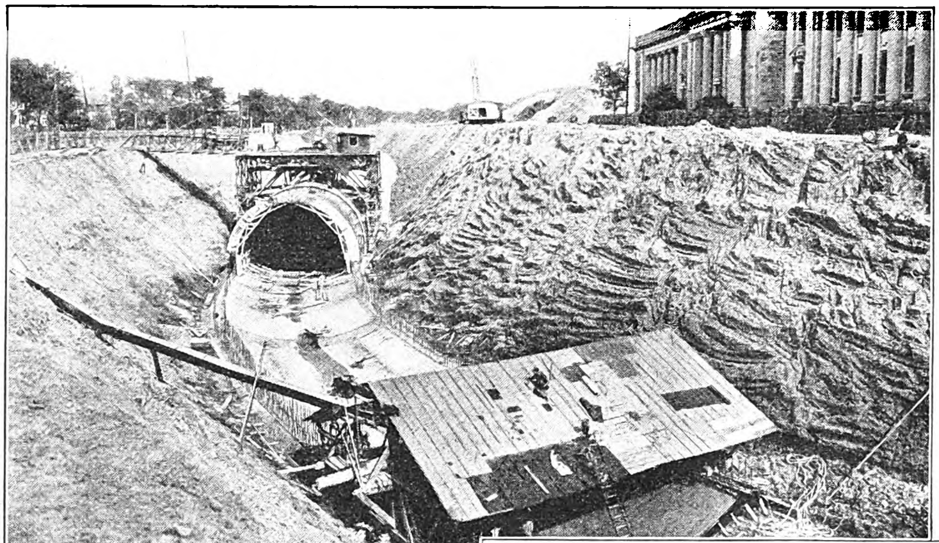
The size of sewers required on this project required us to use arches that are in a peculiar class. They are greater than the sewers originally involved in the city system and are smaller and of a different type from those ordinarily entering into concrete bridge design. Consequently there was little precedent for the engineering work to be done on them. It is not commonly known, outside the group of specialists who deal with this problem, that one of the dark spots in engineering knowledge is concerned with the pressures which earth places against such structures at the backs of retaining walls and the buried tops and sides of sewers and culverts.

ONLY in the last 20 years has any really scientific work been done in this field and most of this has been to determine the earth loads coming on small sewers either in narrow trenches or on culverts under highway fills. The result of this research work on small sewers was of some value in choosing the loads for which the Des Peres arches were to be designed, but the factors which the research had produced had to be exterpolated to such an extent as to be somewhat unsatisfying.

The arches are of reinforced concrete. The stresses were determined by an application of the elastic theory of arch design, the thicknesses were proportioned by an assumption that the compressive stress in the concrete



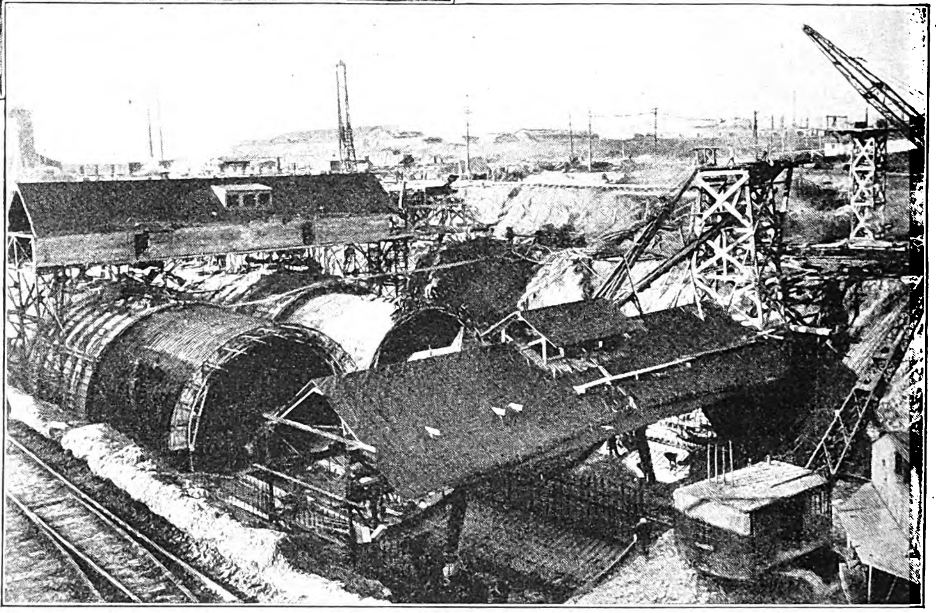
The change brought about by the improvement at a point east of Knox Avenue. The illustration above shows the undisturbed condition of the old river bed, and that at the left shows the completed work at the same point. It was necessary to demolish the concrete arch bridge of the Frisco Railroad and replace it with the steel structure shown at left



The single 32-foot sewer in process of construction in front of the Jefferson Memorial Building

would not exceed 800 pounds to the square inch and the tension from the steel bars would not exceed 22,000 pounds to the square inch.

It was critical to the progress of the work that the great steel centers on which the concrete was poured should be loosened and moved ahead for reuse as quickly as possible. It was decided that this support could be removed whenever the strength of the concrete reached 1200 pounds per square inch, and to determine this time, standard test cylinders were prepared out of the concrete as it was poured into the arch.



The double 29-foot sewer. In the right foreground is the 300-ton shovel with which the main excavation was done. Its arm has a reach of 90 feet

HAVING had to design these structures without as much satisfactory fundamental data as was desired, we felt it to be part of our duty to develop some of this data on this project for use in future structures. Accordingly a complete series of tests was developed in an effort to determine what the actual earth loads are and what the pressures under the footings are by building into the sewer a large number of Goldbeck pressure cells. These cells are interesting little machines in which the pressure of the earth against the face of a diaphragm is weighed by balancing this pressure with air pressure introduced behind the diaphragm. When the air pressure exceeds the earth pressure, a slight movement takes place, electrical contact is broken and the pressure may be read on an air gage.

Readings of earth pressures were begun as soon as the fresh backfill was placed over the sewer in September, 1928, and have been continued. It is very interesting to find that the actual measured pressures on the tops of the arches at the present time are equal to 50 percent more than the actual weight of the earth over these points would cause. One would be doubtful of the correctness of this result had not a similar condition developed on certain culvert tests made elsewhere. It appears that this is possibly because the settlement at the bottom of the deep fills on each side of the arches leaves the upper part of the fills relatively unsupported. A shearing stress is developed in the soil which transmits a part of the weight of the earth at one side of the arch on to the arch proper. This possibility was not realized at the time the arches were designed and it is fortunate that a large factor of safety has been provided.

The horizontal pressures are quite close to the assumptions used in the design, but we can see that these might not be true if the sewer had been constructed in the narrow trench instead of in a wide sloping cut.

The reactions under the footing are very peculiar. They seem to indicate that the inverted arch is supporting the center wall almost free of the ground, but we do not dare adopt this assumption, as some of the soil pressure cells occasionally fail to record when placed on shale or fireclay of hard quality as was the case here. This condition of reaction, however, is not impossible and leads to some interesting speculations.

The construction of the drainage works has been under way since 1924, when the first of the open channels was started. From the very beginning it involved unusual features not common in municipal sewerage.

As the new works lay in the valley and the site was closely restricted by both residential and industrial developments, a great part of the open channel and low level sanitary sewer had to be built in the creek bed or in such a way as to be continually crossing the creek. Construction operations were accordingly at the mercy of the weather and were subject to sudden interruptions by freshets which would sweep over the site and cover the equipment.

It soon became apparent that the success of the operation must lie in so over-equipping the job both as to capacity of the machines and as to the power used, that great progress could be made in the short periods between the rains. This led to the use of large draglines kept as far as possible out of the creek beds, assisted by small equipment in the stream to do the final trimming, this last equipment of a type that would not be seriously injured by continual immersion. In spite of the careful choice of equipment in this way, the work executed under such flood hazards was necessarily very expensive and proceeded somewhat more slowly than was expected when the project was first started.

Whatever loss of time and unusual cost entered into the first three miles of open channel was about balanced by the great savings which it was found could be introduced into the quantity production methods used on the construction of the big concrete sewers. These contracts, like the earlier ones, were equipped with extremely large and powerful excavating units. The high cost of having the work flooded was learned early in the progress and thereafter considerable expenditures to protect the site from floods yielded good returns.

Concrete for most of the work has been manufactured in central station plants of large capacity, completely equipped with machine handling devices and automatic controls of materials and of water. It was hauled to the site of the work in one case by industrial trains and in another in dump trucks. These central concrete plants not only proved to be very effective in lessening the cost of the product but were extremely valuable in producing uniformly well-proportioned mixtures. This last result was brought about not only through the efficiency of the mechanical control apparatus but also through the necessity of securing the result, as the concrete not so accurately proportioned was not subject to long haul without segregation.

The value of these quantity production methods and of protecting the work from interruption by floods is shown by the progress records actually attained. In the month of September, 1929, each of the contractors produced 30 units of sewer on 30 consecutive days. As these units were either 30 or 35 feet in length, nearly 1000 feet of sewer were built on contract that month.

Where the last contract of the big 32-foot sewer is just now being started, most of the construction must take place in a narrow gorge through which the river runs, as there is very little working room on either side. The contractor here, Stiers Brothers, has developed a totally different type of equipment consisting of duplicate electrically-driven tramways of about 1800-foot spans to haul the material in and out, and small shovels and draglines in the river bed loading skips.

ONE of the things that every worker in the ground has come to fear is the encountering of wet running soils, sometimes called muck, sometimes quicksand, depending on the amount of clay present. It has almost gotten to be a tradition among sewer contractors that when quicksand is encountered, all ordinary plans must be abandoned and enormous costs are involved in holding back the running earth with sheet piling, timber, and other effective barriers.

In recent years engineers and the more understanding operators have learned that this material is essentially the same as any other soil except for the presence of an excessive amount of water, sometimes under pressure. Systems have been devised for removing this water through pipes driven into the ground and, where the sands are sufficiently coarse, stable soils are produced.

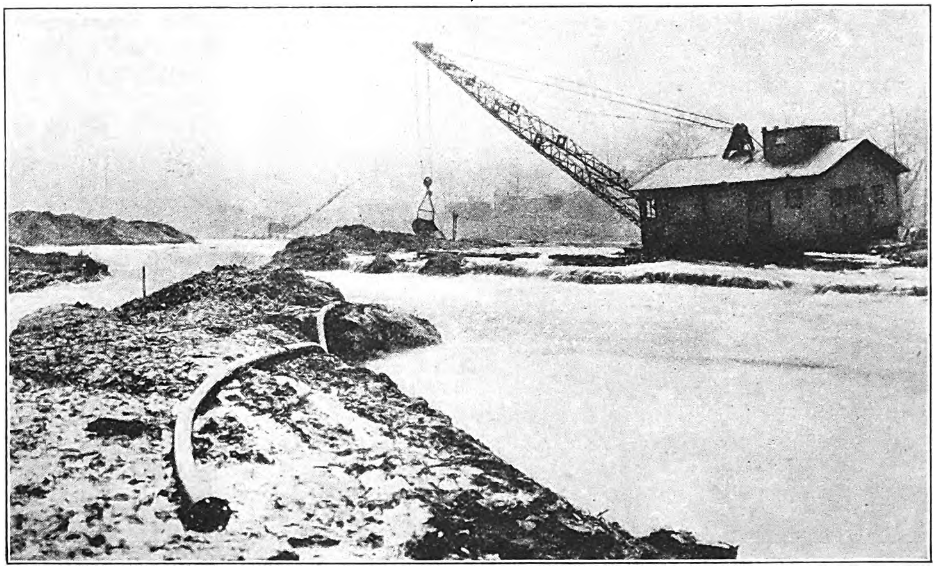
A very interesting problem of this general kind entered into the building of the Des Peres works. This problem arose because the new improvements were to give the same standards of drainage as did the city sewer system and accordingly these works must carry the floods at levels of eight feet or more below the improved ground surface. With the flood water levels so fixed, the bottoms of the channels or sewers were at a great depth below the old creek bed, sometimes as much as 25 feet.

When work on these deep excavations was started in the middle of the natural valleys, the first operation was to open a hole or excavation to the new depth. The natural result of this was that all the soil moisture in the surrounding area tended to flow to the low level outlet. In passing through the soil adjacent to the trench, the pores of the soil were filled under pressure, instability resulted and there was a continual tendency for the banks of the excavation to slide or slough in.

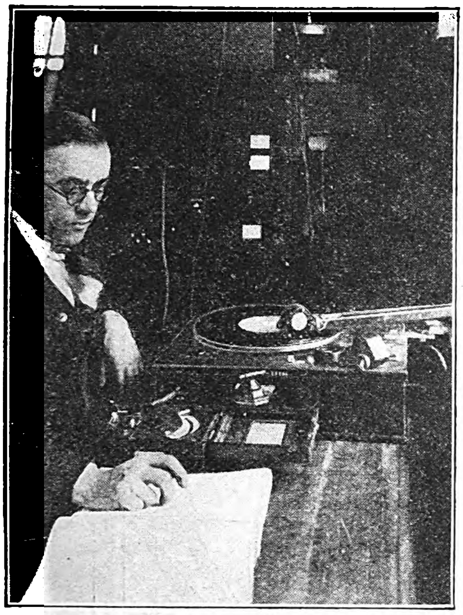
At the beginning of the work, this condition horrified the operators and they were quite sure for a time that the low level structure could never be built, or, if built, that the banks would be continually sliding and that the concrete or rip rap paving laid on the banks would be crumpled up and demolished. They advised, instead, that heavy reinforced linings be placed capable of holding back the terrific soil pressure. A small amount of such lining was actually placed as an example only, for we were convinced that the soil would become stable once the excess moisture had drained out and the pressure of the water in the pores was relieved. Accordingly, we arranged for the rough excavation to proceed and for the trimming of the banks and the placing of the lining to be deferred. A slow outseeping of moisture followed, the ground water level in the valley was gradually lowered and within six months after the original excavation the banks had become re-stabilized throughout. Of the first 30,000 feet of channel bank so treated only 300 feet gave trouble after completion and that was at a point where the bank had been supercharged with a fill of wet clay.

So effective was this means of securing stable soil by natural seepage that when one section had to be started without an outlet, it was decided to simulate this condition artificially. Six months before the beginning of the work a pumping well was sunk to the level of the proposed excavation, drain tiles were run out along the site of the work for several hundred feet and the ground water was continually pumped until the time the work began. When the big machines actually arrived and the new cut was opened the soil was found to be quite stable and no difficulty whatever arose. It was further found that once a stable condition of this sort was created, the soil moisture would drain effectively to the excavation at about the rate at which the work was able to progress up the valley so that difficulties of this kind only occurred where a new depression was opened.

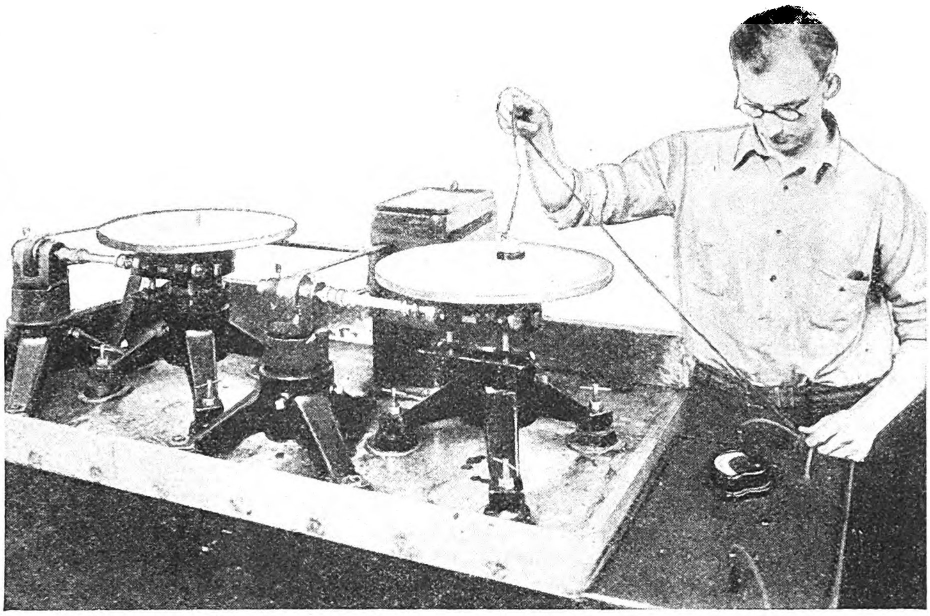
SEWER construction has for a long time been in the hands of practical men who have been accustomed to fight their way out of difficulties and it is very interesting to find how often an adaptation of some relatively simple law of science can make easy the progress of work of this kind.



A section of the job showing one of the heavier floods passing over the construction work. The crests of these floods usually were of a few hours' duration



The electro-magnetic reproducer for disks is tested for operation



An "electric ear" is placed on the record turn-table as it whirls around on the test bench. A sensitive meter tells the operator of any noise-making faults

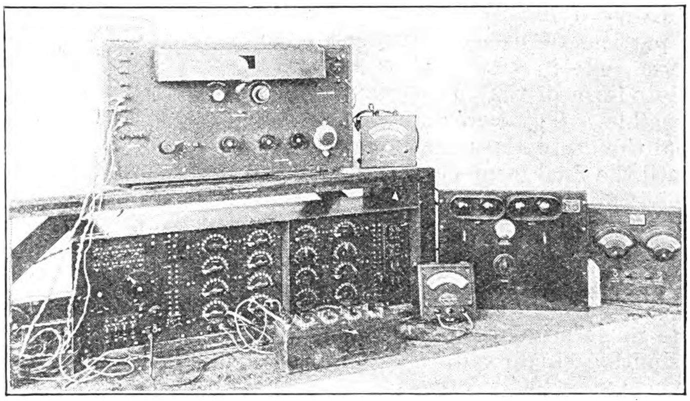
On this elaborate test table, the transformers of the amplifiers are tested for their electrical characteristics



The assembled amplifiers are subjected to tests more rigorous than actual operating conditions in theaters

Accuracy In 'Talkie' Equipment

ACCEPTANCE of talking motion pictures as a permanent part of the entertainment field has imposed on the manufacturers of motion-picture projectors a standard for their mechanical work that rivals that set by the makers of the finest watches. Not only must the machine project perfect motion pictures, but it must also be the source of accurately synchronized sound and voice effects.

It is doubtful if there is any other delicate machine of which more is required than a motion-picture reproducer. It must be rugged enough in construction to stand the rough usage and steady grind of every-day operation, yet parts of it must be so delicately constructed that they can handle without distortion minute voice currents so small that only the most sensitive meters will measure them. A universal type of machine can transform almost microscopic marks on the film into the most delicate shadings of sound or it can be run with disk records to reproduce from tiny scratches in the grooves on the disk. At the same time, the projection mechanism must be functioning, passing the film before the aperture where it is brought to a dead standstill 24 times a second. Yet, about 14½ inches from the point where the film is started and stopped, it must be flowing smoothly past the sound-light aperture without the slightest pause or jerk.

IT is small wonder, then, that the manufacture of sound-picture projectors requires a huge staff of inspectors. The machines must be so perfect when they leave the factory that, when they are installed in a theater, they will operate properly from the first turn of the switch. There can be no breaking-in period in the theater, such as the automobile owner gives his car, for the first performance of a projector is usually judged more critically than any other. Therefore the machines are carefully tested before they leave the shop, and the gear drives are run-in, under load, for periods varying up to 24 hours. This operation removes any burrs and irregularities from the gears, and insures that the final tests for noise and irregular operation will show whether all of the parts are meeting the exacting requirements of theater conditions.

In the photographs on this and the opposite pages we show some of the many intricate tests and inspections that are made before the projector is finally considered up to standard and is shipped to the theater. Here also it is constantly tested in preparation for each daily grind, to insure that the performance will go through without mechanical or electrical failure.

Zoogenesis

The New Theory of Evolution

By AUSTIN H. CLARK
United States National Museum

FROM the very earliest times the absorbing mystery presented by the multitudes of different forms of animal life has attracted the attention of the studious among all human races.

We know that all living things are derived from other living things—life can not arise spontaneously. So in the extremely remote past all forms of life must have had a common origin. No one with any knowledge of biology doubts this, and those with no knowledge of biology are in no position to deny it.

Every living thing is evolved from a particle of living matter—a single germ cell—in which no trace of the adult form of that living thing is discernible. This cell divides into two and the derivatives continue to divide until the final form—cow, insect, crab, jelly-fish or something else—eventually is attained.

Since every animal, no matter what it is, originates as a single cell, we are safe in saying that all types of animal life must be explained in terms of a primitive single cell.

THE course of the development of animals from a single cell to multitudes of different kinds we know today is explained by what is commonly known as the theory of evolution.

Evolution assumes the gradual development step by step of all the widely varying forms of animal life from an original form of simple structure.

But the developmental course which has been followed by animal life from its first beginnings down to the present time can not be reduced to any such simple formula. There are three separate sets of facts to be considered, and any acceptable theory of animal development must harmonize and correlate all three.

Galago, similar to the supposed common ancestor of man and the monkeys

In the first place, within each of the so-called phyla or major groups of animals, as is well seen in the vertebrates, particularly in the mammals and the reptiles, there are many well marked, obvious, and undeniable evolutionary lines or "trees" which, beginning with a relatively simple form of creature, run by easy stages to a specialized and highly complex form.

In the second place, very few of these evolutionary lines are perfectly continuous. Practically all of them are more or less frequently interrupted by gaps of various widths, and these gaps are often very broad. Especially is it true that these evolutionary lines tend to be separated from each other throughout their entire course, running parallel clear through to their earliest beginnings and not converging to a common type of animal as we would expect. For instance the cat line and the dog line are always separate. No forms intermediate between cats and dogs are known, although both cats and dogs are collateral members of the great group of carnivorous mammals called the Carnivora and must have had a common ancestor.

SIMILARLY there are no intermediates between turtles and snakes, both types belonging to the reptiles, or between squid and oysters, though both types are mollusks.

In the third place, no animals are known even from the very earliest rocks which can not at once be assigned to the proper phylum or major group on the basis of the definition of that group as drawn up from a study of living animals alone. A backboned animal is always unmistakably a backboned animal, a starfish is always a starfish, a mollusk is always a mollusk, and an insect is always an insect, no matter whether we find it as a fossil in the rocks or catch it alive at the present day.

There can be only one interpretation of this entire lack of any intermediates between the major groups of animals, as for example between the backboned animals, the starfishes, the mollusks, and the insects. If we are willing to accept the facts at their face value, which would seem to be the only thing to do, we must believe that there never were such intermediates; in other words that these major groups from the very first all bore quite the same general relationship to each other that they do at the present time.

Tree of the evolution of living forms. The lower (pre-Cambrian) part is an assumption, like some of the unbroken branches

Is this creationism? Not at all. It simply means that from the single cell life, at its very first beginnings, developed simultaneously and at once in every possible direction. All of the phyla or major groups seem to be of simultaneous development. From each one of them a separate evolutionary tree arose, growing upward through the ages.

The numerous developmental lines are explained by the process of evolution as that term is commonly understood. This descriptive word should be restricted to these developmental lines.

THE gaps within these lines, and between related lines which run more or less parallel, are explained by the theory of mutation.

The complete absence of any intermediate forms between the major groups of animals, which is one of the most striking and most significant phenomena brought out by the study of zoology, has hitherto been overlooked, or at least ignored. This condition may readily be explained, from an application of the facts gained from a study of embryology, by a theory which may be called the "theory of eogenesis."

Restriction or expansion of the meaning of a well-known word results always in confusion. The term evolution has been used to cover the entire developmental history of animals. But the theory of evolution is based upon, or at least was drawn up from, only a portion of the facts to be explained. It was formulated from data taken from only a partial survey of the field. A better understanding of the whole subject of the development of animals will result if we call it "zoogenesis" and consider zoogenesis to embrace three interrelated phases, (1) evolution, (2) mutation, and (3) eogenesis.

WITH regard to evolution, the first of these three phases: To illustrate evolution as here restricted let us briefly review the history of the mammals and the reptiles, bearing in mind that similar histories are found in many other less familiar forms of life.

The reptiles first appeared in that very ancient time which is known to geologists as the Carboniferous, and gradually increased in diversity and in maximum size. The largest land animals of which we have any knowledge are the largest of the dinosaurs, which flourished in those periods known as the Jurassic and Cretaceous.

At the end of the Cretaceous period most of the larger and more spectacular of the reptiles suddenly disappeared, but many reptilian types, as turtles, lizards, snakes and crocodilians, continued right through to the present day.

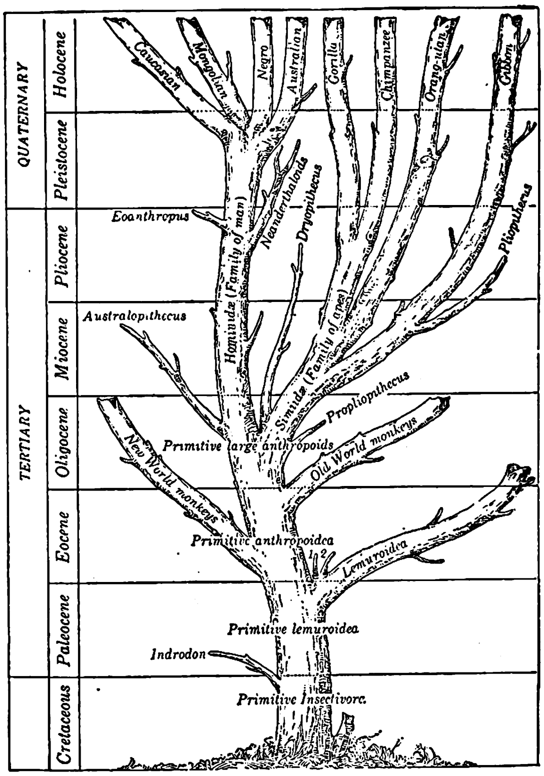
The mammals first appeared in the form of very small and insignificant creatures at the time when the great reptiles were the dominating giants of the land and sea. After the sudden disappearance of the giant reptiles the mammals increased greatly in diversity and somewhat in size, though in the earlier portion of the following epoch the largest mammal was not so large even as a sheep.

These mammals of the earlier portion of the "dawn period" (Eocene) soon disappeared; but as they disappeared their place was taken by other types which were more or less comparable to the sorts we know today. Gradually as time went on these mammals became more and more diversified. Various extraordinary types, some of huge size, appeared and not long afterwards disappeared, while together with these came others which we have no difficulty in recognizing as the direct predecessors of the types we know at the present day.

In order to make the picture clearer, let us narrow our perspective and focus our attention on the horses. In the "dawn age" we find a curious little creature no bigger than a fox called the "dawn horse"—*Eohippus*. This had four toes on the front and three on the hind feet, and a relatively short head with the eyes about half way between the ears and the tip of the nose, instead of nearer the ears as in the later horses.

Following the "dawn horse" we find a number of different kinds of horses, mostly about the size of a shepherd dog or a little larger, all of which had three toes. Like the "dawn horse" and its relatives they had low-crowned teeth which were affixed to the jaw by means of roots.

Still later there were horses which as colts had low-crowned teeth but when fully grown had teeth with fairly high crowns. With these lived others in which the teeth had high crowns at all ages. These horses had shorter muzzles and rather less deep jaws than the modern horse and, while they had a single rounded hoof, there was a toe on either side of it. These lateral toes varied from small ones which did not reach the ground to larger ones which reached the ground. Though these were larger than their predecessors, they were not so large as the later horses of the modern type.



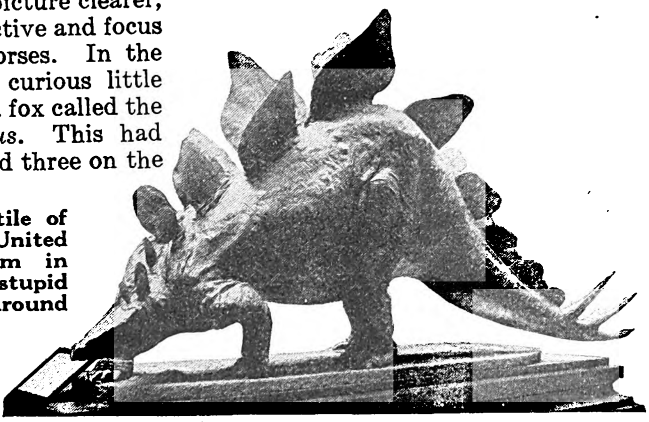
From Shimer's "Evolution and Man." Courtesy Ginn & Co.

Evolution of the primates. The author accepts man's ultimate relationship with the apes but points out that there is no intermediate type, either living or extinct

In the Ice Age we had in North America many different kinds of horses which were all of the modern type with long high-crowned teeth and deep jaws. They ranged in size from little ones no bigger than the smallest Shetland pony to some which were larger than the largest draft horse.

Before the discovery of America by the Europeans all of these disappeared, for what reason we do not know at the present time.

THIS brings us to mutation, the second of the three interrelated phases of zoogenesis mentioned above. In many other animal types we are able to trace, as in the horses, a gradual evolution from a form simple and generalized in structure to one or many forms which are highly specialized. But this is by no means always so. Indeed, it is the exception rather than the rule.



Stegosaurus, extinct reptile of the Cretaceous period, United States National Museum in Washington. When this stupid big brute was lumbering around in Wyoming in the Cretaceous period the ancestor of all the modern mammals was no larger than a rat

Most lines are broken by curious gaps which may be small and insignificant, or broad and striking. It is commonly assumed that these various gaps are due to our lack of knowledge of the animals concerned, and especially of their fossil record. No doubt in very many cases this is true, but in most cases these gaps probably are real and were never bridged by "missing links."

In the light of our present knowledge we can not doubt that all living things are the children of other living things, and that life has been continuous from parent to child from its earliest beginnings. How is it possible to harmonize this fact with the occurrence of broad and unbridged gaps in the evolutionary lines?

THE answer is, that continuity of life does not necessarily imply continuity of the bodily form in which that life is manifested. In other words, children may be very different from their parents. As an illustration of continuity of life coupled with abrupt and striking discontinuity in form, and also in mental traits, let us consider the dogs.

According to the best authorities all of the nearly 200 different breeds of domesticated dogs are descended from a single type of ancestor, which is a wolf closely resembling our native wolf. The domestic dogs may be grouped, following Gibson, into wolf-dogs, greyhounds, spaniels, hounds, mastiffs and terriers.

Some of the wolf-dogs, like the dogs

of the Esquimaux and the Kamchadales, show a more or less close resemblance to wolves, while others, like the collies, Newfoundlands and St. Bernards, are much less wolf-like. But the wolf-dogs may be arranged in a fairly continuous series from the most to the least wolf-like. This series of dog forms is parallel to many of the evolutionary lines which are seen in the geological history of the mammals, as for example, in the horses. It is a series of types passing by almost imperceptible gradations from one extreme to another which is very different.

Of the other types of dogs we may select the greyhounds, hounds, bull-dogs and pugs, the last two from the mastiff stock, as representative types known to every one.

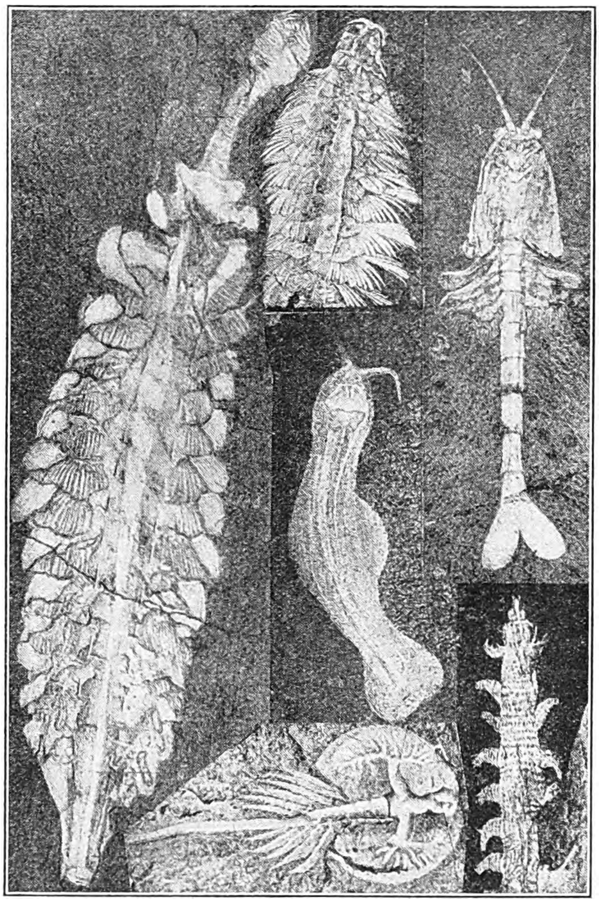
THE greyhounds or, as they are sometimes called, the "gaze-hounds" have deficient powers of scent, but unusually keen eyes. They hunt entirely by sight. There are many different forms of greyhounds. The hounds, having poor sight, hunt by scent, and are also divided into many different forms. Bull-dogs are deficient both in sight and scent, and are stupid and ferocious, displaying but little affection. Pugs, which are much like bull-dogs and are equally stupid, differ markedly from them in being timid and affectionate.

There are no intergrading types between the greyhounds, the hounds, the bull-dogs and the pugs, and there are no intergrades between any of these and wolves. If we did not know their ancestry we would never suspect that these types of dogs had anything to do with each other, or with wolves. They illustrate unbroken continuity of descent coupled with wide and abrupt changes in form and in mental attributes.

An understanding and appreciation of the conditions found among the dogs enables us to approach the problem of the relation of man to the animal world.

Structurally and anatomically man is very close to the man-like or anthropoid apes. This is a readily demonstrable fact which is quite beyond dispute. But it is also beyond dispute that there is a sharp, clean cut, and very marked difference between man and the apes. Every bone in the body of a man is at once distinguishable from the corresponding bone in the body of any of the apes.

Furthermore, man differs very widely from the apes in the possession of articulate speech which enables him to accumulate knowledge in successive generations. He also differs in his use of fire and in his use of tools which, as is shown by the fossil record, have been human attributes from the very first. Besides this, so far as history and the study of modern races enables us to judge, he differs in his use of clothing and of ornaments.



Some remarkably well preserved fossils from the Cambrian period of British Columbia, nearly a billion years ago, almost our oldest fossils, yet doubtless not half as old as life. Even in the Cambrian, the author states, the major phyla were as distinct as today, with no intermediate forms

The most important difference, however, is correlated with the fact that in man the ministrations of both parents are necessary in raising a family. A woman can not raise a family unaided. Interdependent with this we find in man a socially effective sentiment of love which creates and makes a unit of the family. The existence in all human races of taboos and laws directed toward the maintenance of the family would seem conclusively to show that family life was from the first a fundamental human institution. For laws and taboos are not, so far as we know, invented to mold society into a new and preconceived form, but on the contrary to correct the evils recognized as possessing disruptive or destructive tendencies which from time to time appear.

All monkeys, so far as we know, live together in promiscuous hordes or troupes in which each female raises her own young unaided. Family attachments are not necessary and do not occur.

While man obviously belongs to the same division of the mammals as the apes, yet the differences between man and the apes seem to be too great ever to have been bridged by intermediate types, and of all the fossils that have been found not a single one represents indubitably a "missing link."

Man appeared suddenly as a collateral line from the same general complex as the apes, but he was never one of them. Between man and the apes there is a gap, structural and psychological, of the same general nature as that between the greyhounds, hounds, bull-dogs and pugs. But while we know that the domesticated dogs are all descended from a wolf, a creature differing from all of them, and very widely from most types, we have no definite clue to the immediate ancestor of man.

The general features of human structure and anatomy were inherited, in accordance with the unbroken continuity of descent from parent to child, from some unknown ancestor common to all the primates but so far as we have been able to discover, not through an ape. The details of his structure and his mentality are his alone.

Continuity of descent coupled with abrupt discontinuities or changes in form is a common, striking, and well known phenomenon in most types of animal life. We must accord it a proper place in any theory dealing with zoogenesis.

FINALLY, with regard to eogenesis, the third phase: As we look over a series of fossils from the very earliest rocks, those of the Cambrian, we notice sponges, mollusks, crustaceans, echinoderms, and various other types of invertebrate life. Among the divisions of these groups we recognize pteropods and gastropods, crinoids, sea-cucumbers or holothurians, gephyreans, polynoids, and many other sorts.

How is it that we are able to recognize these so promptly? The reason is that these earliest animals all fall within the several phyla or major groups as these phyla are defined on the basis of the living types alone. We do not have to expand our definitions of the phyla to include all the fossil forms of whatever age.

The very earliest vertebrates, crustaceans, insects, or mollusks were just as unmistakably vertebrates, crustaceans, insects, or mollusks as are the representatives of those groups which we find living at the present day.

What is the significance of this? It

can have only one meaning, and that is, that so far back as Cambrian times, at least, the major groups of animals bore the same relationships to each other that they do today.

This is an established fact concerning which there can be no doubt whatever. In spite of the numerous and profound changes that have taken place in the various sorts of animals included *within* each phylum, the interrelationships *between* the phyla themselves have undergone no change at all. No intergrading forms occur between any two of the major groups, and so far as we know no intergrading forms ever have occurred.

WHILE the fossils in the Cambrian rocks are the very earliest fossils that are adequately known, yet it is undoubtedly true that the Cambrian is much nearer to the present epoch than it was to the far distant time when life on earth began, so that conditions in the Cambrian are not necessarily those which obtained at the time of the origin of life.

The answer to this objection is that since we know that the interrelationships between the phyla or major groups run back without the slightest change to the Cambrian, it is more logical to assume a continuation of these interrelationships into the indefinite past than it is to assume, somewhere in the unknown pre-Cambrian ages, a change in the interrelationships, for which last assumption there is not the slightest evidence.

Since there is nothing to be learned bearing on the interrelationships of the phyla from a study of the fossils, in order to solve the problem we must rely on the data supplied by the study of the special science of embryology.

The details of the process by which all of the phyla or major groups presumably arose simultaneously, or practically so, from a primitive single cell are very complicated and too technical for repetition here. They are given at length in a paper entitled "The Origin of the Vertebrates" (*Journal of the Washington Academy of Science*, Volume 13, No. 7, April 4, 1923, pages 129–138) to which the interested reader is referred for these details.

Thus, by a process which has been designated as eogenesis, all of the phyla or major groups of animals appeared simultaneously or nearly so. Although this sudden and simultaneous origin gives them the appearance of having arisen through special creation, *the origin of each may be traced back to the primitive single cell.* However, there is no evidence that single celled animals—the protozoans—are more primitive than other types, or preceded them.

By this process of eogenesis the phyla or major groups came into being, and each of these stands at the base of a separate and distinct evolutionary tree which rises upward through the ages.

THE branches, branchlets and twigs of these evolutionary trees are indicated by interrupted lines, the interruptions or gaps representing mutations whereby discontinuities in form and structure occurred between parent and child.

This is the picture of the development of animal life—of zoogenesis—which is to be drawn from the facts as we know them, and it is the only possible picture which is in accordance with those facts.

This new concept of evolution differs from the old chiefly in the assumption that the basic type in each of the major groups (phyla) arose through following a special developmental path from the primitive cell, the divergence for the most part beginning in the so-called gastrula, a developmental stage common to all animals except the sponges and the protozoans.

Exterior of dining car. Much of the air-cooling and air-conditioning apparatus is concealed underneath the car. The curved hood along the top of the car at the farther end contains the air passages connecting with the louvres

Dining in a Refrigerator!

SUMMER rail travel is rendered uncomfortable by heat, dust, cinders, smoke, and noise. Engineers have been working for many years to mitigate these evils but the problem has been a most difficult one, for the air must be freed from all foreign matter before it can be dehumidified and cooled. A refrigerated car would be a great boon in traversing the great deserts of the southwest. Natural ice has been tried, but the expense was too great.

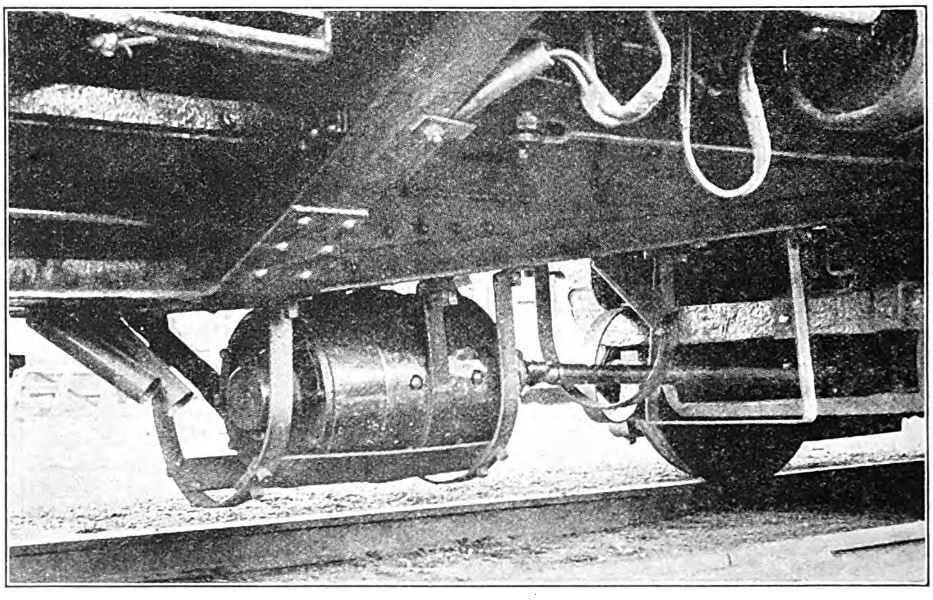
Now, however, the riddle apparently has been solved. The design and installation of the special equipment required was co-operatively worked up by the Baltimore and Ohio and the Carrier Engineering Corporation and the complete installation was made at the Mount Clare shops at Baltimore.

A run was made, with the full winter heating capacity of the car turned on. This was intensified by the heat of the kitchen and the warm weather outside. When the temperature reached 93 degrees, Fahrenheit, the new system was put in operation and in 20 minutes the temperature had dropped to 70 degrees, or more than a degree a minute. It was also shown that the temperature could be lowered considerably further but this would not often be necessary or desirable.

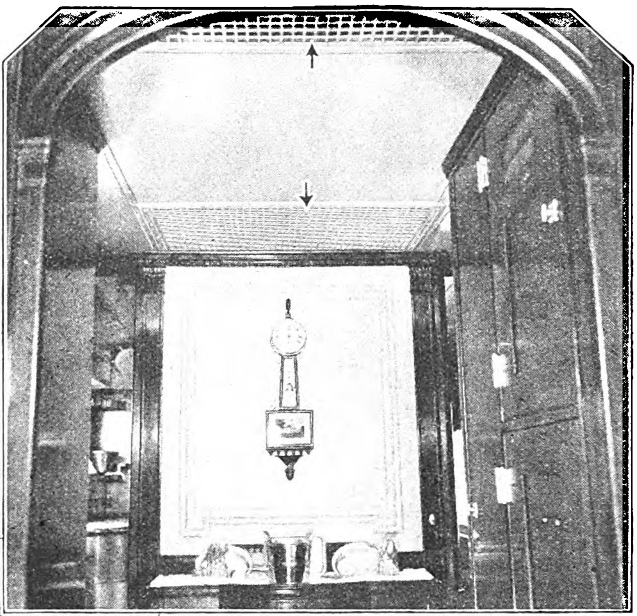
THE automatic control of the air-conditioning and cooling apparatus can be set by the steward or whoever is in charge of the car. The cooling equipment as well as the running gear of the car is so insulated with rubber cushions that vibration and noise are very largely eliminated. The car is also equipped with roller bearings.

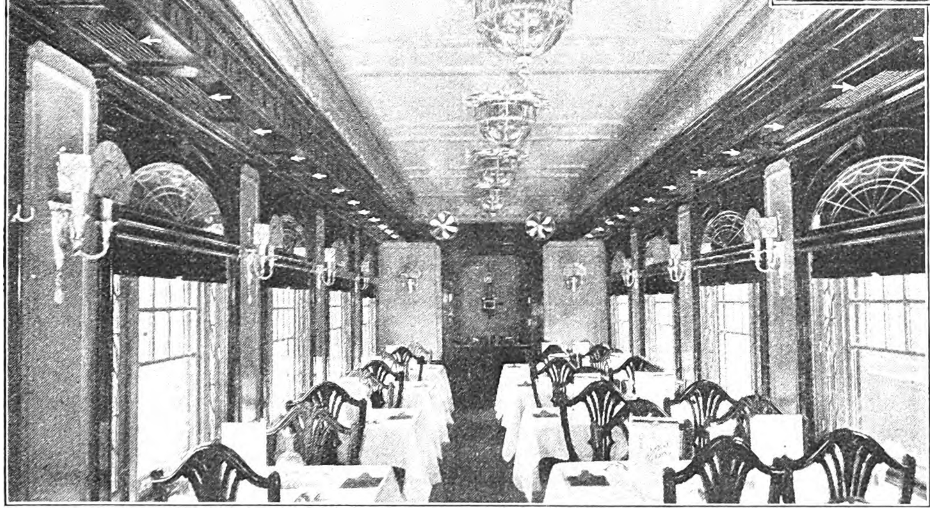
The cycle of operations will be understood by reference to the schematic diagram. The car is equipped with double sash windows which are kept closed at all times and the doors are opened and closed only to allow for the entrance and exit of the passengers and the train crew. The outside air is admitted through air filters located at the roof line. All the dust and cinders are removed from the air by mechanical filtration. The air is then cooled to the proper temperatures by passing over cooling coils. It is then carried throughout the car by overhead insulated ducts. There are no drafts created and the cool dehumidified air is distributed through louvres.

The equipment is electrically operated and as the requirements are in excess of the ordinary axle generator for lighting purposes, a special 10-kilowatt generator has been provided to supply direct current of 110 volts. The water used in the condenser is delivered by a motor-driven pump to a "cooling tower" or "spray unit" at the end opposite the kitchen where fresh air drawn from the outside is passed



The 10-K.W., 110-volt direct current gear-driven generator supplies the electrical energy for the operation of the air conditioning and cooling plant





Interior of the *Martha Washington*. Most of the apparatus is underneath the car and that part of it which is inside is concealed or worked into the decorations. Arrows indicate the louvres for air delivery. *At top:* Re-circulation vents at kitchen end. The air passes over cooling coils and is re-delivered

through the water spray, and thus the temperature of the condensing cooling water is brought back to approximately that of the outside air after which the water is available for re-circulation. The water which is lost by evaporation is taken from an overhead supply tank.

The temperature of the conditioned air which is delivered through the overhead louvres is dependent upon the chilled water in the cooling coils located overhead at the pantry end. This in turn is automatically regulated to suit the conditions by a temperature control device which through an arrangement of movable louvres so directs the re-circulated air as to prevent too low a temperature in the car. This is under the control of the steward of the car so that a comfortable temperature will be maintained at all times. If the temperature of the cooling water becomes too low, freezing of water in the evaporator may occur. To prevent this the back-pressure valve in the ammonia system will automatically cut off the supply of ammonia, thus preventing a further lowering of the temperature. The relative humidity can be controlled within certain limits depending on outside atmospheric conditions and the temperature maintained within the car.

At terminals and layover points, the equipment will be in operation sufficiently long in advance so that the car will have a comfortable temperature before being attached to a train. The system automatically begins operation when the train attains a normal speed under ordinary conditions. The time when the equipment is not functioning because of low speed, or while standing at stations, is so small that the loss would be negligible, and comfortable conditions can be maintained at all times.

Early in July, 1929, tests were carried out by the Baltimore and Ohio Railroad and the Carrier Engineering Corporation with a coach. It is believed that this was the first railway passenger car ever so equipped for air conditioning and cooling. The equipment was applied about the first of July and the tests made during the hot summer months indicated that comfortable conditions can be maintained within cars whether fully or partially occupied by passengers under the worst conditions of temperature and humidity which are likely to prevail. The *Martha Washington* was the next step forward.

The tests of the *Martha Washington* were made by Col. Geo. H. Emerson, chief of motive power and equipment, J. H. Davis, chief of electric traction of the Baltimore and Ohio Railroad, and officials of the engineering company. This was the first car in service on any railroad to be so equipped.

The next problem which should be attacked is the air conditioned and refrigerated sleeping car. This is a much greater engineering problem than the dining car for the reason that the cubical space to be treated is much larger, as quite a bit of the diner is taken up with kitchen, pantry, and passageways. There is an abundant field for the ingenuity of the engineer along this line of endeavor.

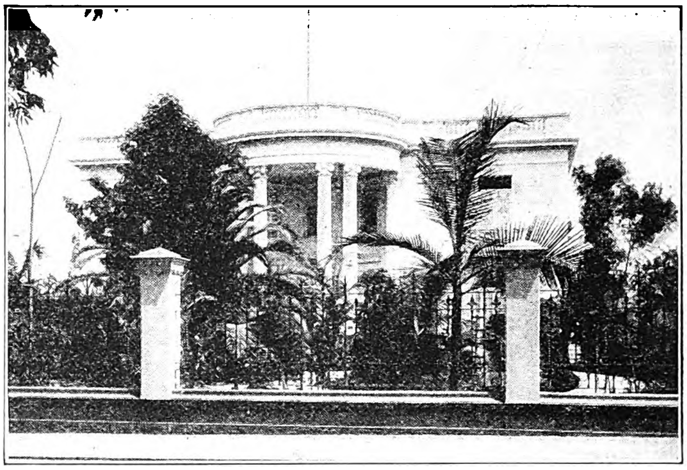
First glance at this Moorish type adobe house in Lima, Peru, would give the impression that it is of plaster



A home in Miraflores in the American colonial style. It is of adobe and might melt away in a heavy rain

Built of Mud

By A. HYATT VERRILL

WHEN we think of a mud house we usually visualize a mere hut or shanty, but in many portions of the world, mud, or adobe, is the principal building material. In the Orient, in sections of Europe, and particularly in Spanish America, buildings of adobe construction are the rule rather than the exception. Quite pretentious houses and other edifices are built of mud and, when stuccoed, whitewashed, or gaily painted, give no hint of the material of which they are composed.

In no other part of the world, however, has adobe construction reached such a state of development and attained to such heights as in Peru. Long ages before the Spaniards first set foot on Peruvian soil, the Incans and the pre-Incan tribes had learned the use of mud as a building material. Enormous walls, great mounds, countless dwellings, vast temples, and massive forts were built of the sun-dried mud bricks and blocks, and many of these still remain, little altered by time and the elements.

THE Dons followed their example and used the cheap and easily obtainable adobe in erecting their buildings. Their palaces, forts, homes, and churches were made entirely of adobe mud, and through the centuries these have endured and remain today as imposing and as beautiful as in the days of Pizarro.

It was left to the modern inhabitants of Peru, however, to carry mud adobe construction to the *n*th degree and literally to glorify mud. In and about the capital, Lima, is this particularly true. Of course, today, many of the business buildings, as well as residences, are of concrete or brick, but adobe still holds its own, and by far the greater number of Lima's homes, as well as a large proportion of its larger edifices, are entirely of mud.

In the days of the Conquistadors, the adobe bricks were merely piled one upon another to form the building walls, but today the usual method is to erect a light wooden framework and build the adobe upon this. In some cases metal frameworks have been used in connection with adobe. This method was employed in erecting the beautiful Rimac Building, perhaps the most elaborate mud building in the world. On the other hand, the world's largest mud building, the old Lima Cathedral, is built of adobe blocks without reinforcement of any kind.

Apparently there are no limits to what may be accomplished with mud in Peru. There are charming, one-storied bungalows with wide verandas, Moorish palaces, imposing colonial mansions, Elizabethan cottages, Spanish mission homes, and even turreted castles, all built of the same sun-dried mud dug from the land on which the edifice is built. So great is the demand for adobe that everywhere, 'round and about Lima, one sees endless piles and high walls of the mud bricks. At first one thinks these merely boundary walls between properties, but it will be noticed that in nearly every case these walls are marked: *"Este pared no es medianera"*—"This wall is not a boundary."

A mud building that has stood for over three centuries. The Torre Tagle Palace

ALSO, wherever there is available mud, one will see the natives industriously engaged in making adobe bricks.

The mud, dug from any convenient spot, is mixed with sand and usually with some chopped straw or dried manure. The resultant pasty mass is then pressed into wooden forms or frames. The shaped blocks are then removed and placed in the sun to dry and in a day or two are ready to use.

Brick making is a most

economical and inexpensive business for a man of limited means, or of no means at all. Provided he can secure permission to make use of the land, or a portion of its surface, for brick making—usually an easy matter, for the rental is taken out in completed bricks—the penniless brick-maker needs little more than his bare hands. With his wife and children, and all his worldly goods—which usually amount to nothing more than a few battered tins, and some hand-made stools—he camps upon the selected site. An ancient kerosene tin of water and a dilapidated shovel are produced. The dry earth is trod, dug, stirred, and worked into a thick paste; then some dry manure, gathered anywhere along the road, is added, and with all members of the little family helping, the bricks begin to take form. As soon as they dry they are piled in tiers.

In a few days the brickmaker and his family are surrounded by brick walls and are living quite comfortably and snugly in a little cavity left purposely for their accommodation. Here they remain as long as bricks can be made and sold on the land. And when an adobe building is in process of erection, the laborers invariably dwell within recesses in the piles of accumulated bricks—thus saving house rent—and tramp back and forth to their work.

WHEREVER a Cholo can find a mud-brick wall and employment, is "Home Sweet Home" to him, and often one may find a dozen or more families all dwelling in perfect contentment in their burrows in the piles of bricks where building is in progress.

In a damp or rainy climate, these dried mud-bricks would, of course, be worse than useless; and, should Lima be subjected to a few days of really heavy rains, most of the city and its suburbs would be reduced to the original, elemental mud. Several times within the past few years, various portions of Peru have been visited by unprecedented rains during the winter months, and great has been the havoc wrought. Around and about Trujillo, houses and churches melted like snow exposed to sunshine, and even the prehistoric ruins of the Chimu city of Chan Chan, which has stood unaltered for countless centuries, slumped and dissolved.

The fine old Cathedral in Lima, the largest adobe building in the world, built in the Sixteenth Century

To protect buildings from the drip from the eaves, practically all modern adobe buildings have several feet of the wall covered with concrete, while others have the lower portions of the walls built of stone, or stone and concrete. Even the old cathedral, which is not only the largest but one of the finest adobe buildings in the world, has been safeguarded with a concrete coating about the base of its walls.

Originally, too, the adobe buildings were all very much alike. They were massive, thick-walled, square, and usually of moderate height, were typically Spanish with iron-grilled windows, out-jutting carved cedar miradors, immense iron-studded and elaborately carved doors, and open patios. But with the modern improvements in adobe constructive methods, architecture appears to have run wild, and there is scarcely a type or style of buildings known to any part of the world the counterpart of which cannot be seen in or about the Peruvian capital.

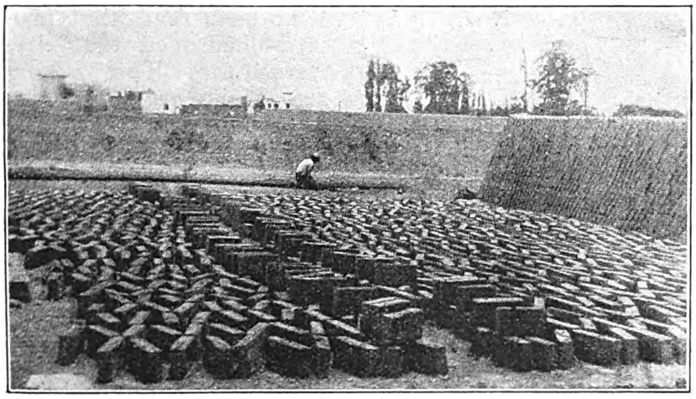
Apparently the average Peruvian never has a definite plan in view when he starts building a house. He may start with a Spanish colonial form and by the time the first story is complete, he decides that the English style is better. He then adds a second story with exposed timbers, leaded glass windows, and stucco walls. Then to the steeply-pitched roof, he adds Spanish tiles, and among the chimney-pots erects a cupola where he can loll away many a hot evening.

HIS front door may be a graceful Moorish arch, but to put a finishing touch to the whole he adds the lofty pillars and severe portico of some Virginia mansion, and builds a *porte cochere* in Japanese style.

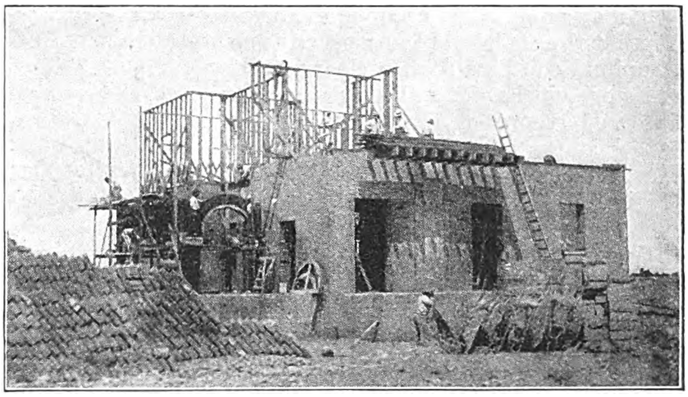
But with all his architectural failings, he loves color, and so paints his home in brilliant ultramarine, rose-pink, canary-yellow, or a combination of all. And, strange as it may seem, these architectural monstrosities do not strike a discordant note in the scheme of things. Surrounded by glorious flower gardens and magnificent pines and luxuriant palms, their bright hues are delightful, and one forgets their faults in admiration of the masses of roses and geraniums which clamber over walls and droop from the eaves.

And there are countless dwellings which are as charming and as perfect in their architectural features as one could wish.

Truly, the Peruvians have glorified mud, and by the same token, they have attained the utmost in building economy, for what could be more economical than to build one's home from the crude material dug from the land when excavating foundations or grading one's garden?



"Not a boundary wall." Piles of bricks ready for use and others drying in the sun at a native brick "factory"



Building an adobe house with a wooden frame. Construction is quite simple but the structure is substantial

Basic Patents in Evolution—I

By WILLIAM K. GREGORY

Professor of Vertebrate Paleontology, Columbia University. Curator, Departments of Anatomy and Ichthyology, American Museum of Natural History. Member, National Academy of Sciences

THE latest airship, crowded with powerful motors and directed by means of numerous instruments of precision, at first sight seems bewildering in its complexity; yet with a little assistance from the experts, one readily comprehends at least the general purpose and arrangement of its principal parts. The human body is vastly more complex than any airship, both in its locomotor machinery and in its instruments of precision; but at least the leading features of its construction and operation may be outlined with but little resort to the technical jargon of the anatomist and the physiologist.

In the case of the airship every mechanism and device doubtless has been developed from some earlier and simpler predecessor, which in turn rests eventually on one or more "basic patents," or primary inventions. An expert willing to search the records of the Patent Office could easily trace the steps in this evolution. Unfortunately, during the long ages when the "basic patents" of the engines of the human body were being tried out in Nature's testing grounds, no patent office records were being made. Nevertheless, the labors of several generations of comparative anatomists, paleontologists, and embryologists have enabled us to piece together the probable history of the human body by comparative methods, which do not differ essentially in principle from those that have been employed successfully by the archeologists or the Egyptologists in reconstructing the main sequence of historical events during long periods of time.

IT may be affirmed on good evidence that the skeleton of any given type of animal contains both a clear record of its present habits and a more or less obscured record of the habits of the earlier stages that led up to it. For example, the skeleton of a penguin (Figure 1, A) reveals many features, such as the paddle-like form of the wing bones, that are obviously connected with this bird's peculiar habit of "flying" under water. Yet many other features, such as the keeled breastbone, testify that the highly specialized and now flightless penguin traces its remote origin to birds that used their wings for flight in the air in the normal way. Again, the skeleton of a vulture (Figure 1, B) is beautifully adapted in very many ways for the habits of this bird of strong flight and predatory instincts. But it also abounds in other characters that have been inherited from the earliest reptiles that first began to skim down from the trees and flap their large skinny arms in the first feeble attempts at flight.

Examples could be multiplied of similar instances in which the "basic patents" acquired by earlier generations are transmitted, even though much disguised in external appearance, to remote descendants. In more technical language, the "habitus" (or totality of characters that adapt an animal to any given mode of life) may, under changed environments and habits, persist in part as the "heritage" of later times.

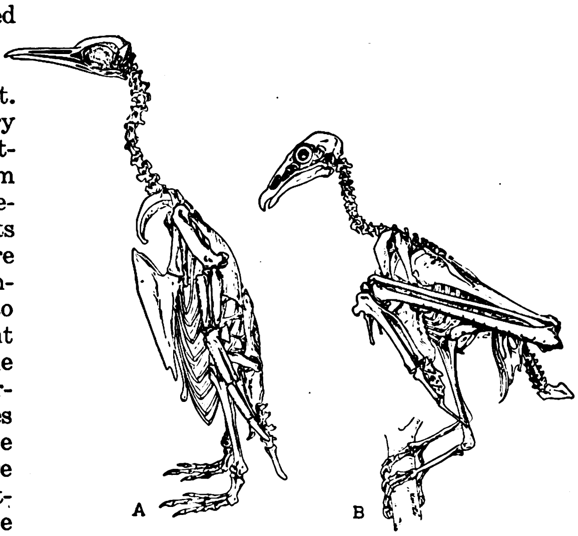


Figure 1: **Skeletons of penguin (left) and of vulture (right), showing swimming "habitus" of the penguin and strong-flying "habitus" of the vulture. Both retain many features in common, which constitute the primary "heritage" of birds**

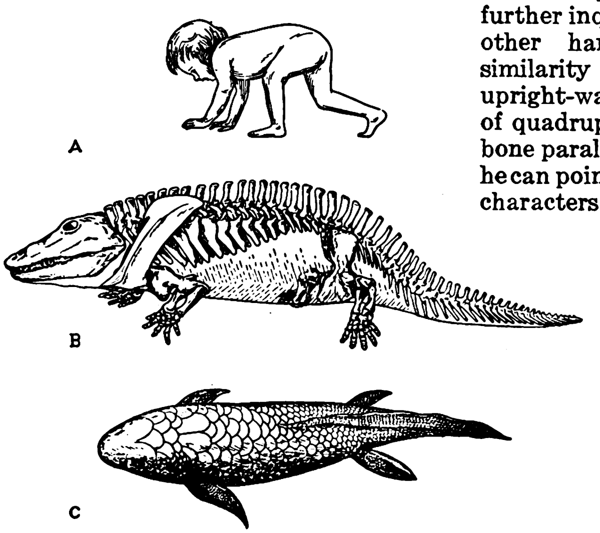

Figure 2: **Man's heritage from quadrupedal ancestors. *A* is a human infant running on all fours (after Hrdlicka). *B* is an ancient quadruped (*Eryops*) from the Permian age of Texas. *C* is an air-breathing fish (*Ceratodus*) with paired paddles corresponding to our arms and legs (oblique view from above) (after Dean)**

With this well established principle in mind, let us make a preliminary comparison (Figure 3) of the human skeleton with those of other animals for the purpose of determining its present "habitus" and of uncovering its prehuman "heritage." As to the "habitus" characters, even a cursory inspection of the human skeleton reveals the fact that it is beautifully adapted to support the body in the erect position, with the center of gravity a little above the points of support at the hip joints, immediately above the limbs. The human pelvis (the hip bones) is likewise fitted in many other ways to act as a bony anchor for the muscles that tie in the abdominal viscera, and as a base for the powerful thigh and back muscles that hold the body erect.

THOSE who believe in the sudden creation of Adam from the dust of the ground usually go no further than to say that such adaptations are part of the Divine Plan, and that the origin of this plan is one of the inscrutable mysteries of creation. But in practice such a philosophy usually blocks further inquiry. The naturalist, on the other hand, points to the basic similarity of the entire skeleton of upright-walking man to the skeletons of quadrupeds that run with the backbone parallel to the ground. Moreover, he can point to a long series of "heritage" characters in the human skeleton which appear to be inexplicable on any other scientific hypothesis than that man is a quadruped that has learned to walk on his hind legs (Figure 2). In the anatomical sense man is still a quadruped, since his fore limbs clearly correspond, bone for bone and muscle for muscle, with those of his nearest quadrupedal and semiquadrupedal relatives, the apes and monkeys.

To review even the main steps in the long ascent from fish to man would be too extensive an undertaking for our available space, as the technical papers bearing on the subject run into many hundreds; but nevertheless let us attempt to notice a few of the many "basic patents" along the way.

There is not much use in inquiring here where the fish itself came from, for professional opinion hesitates between the "jellyfish" and the earliest sea-scorpions or eurypterids. But wherever he came from, the shark is already far nearer to man in his anatomical ground-plan than he is to any known animal that completely lacks a backbone. For this reason the humble dogfish, or small shark, is recognized everywhere as a veritable epitome of human anatomy, and all properly qualified pre-medical students find that dissection of the dogfish gives them a welcome clue to the anatomical intricacies of their future patients.

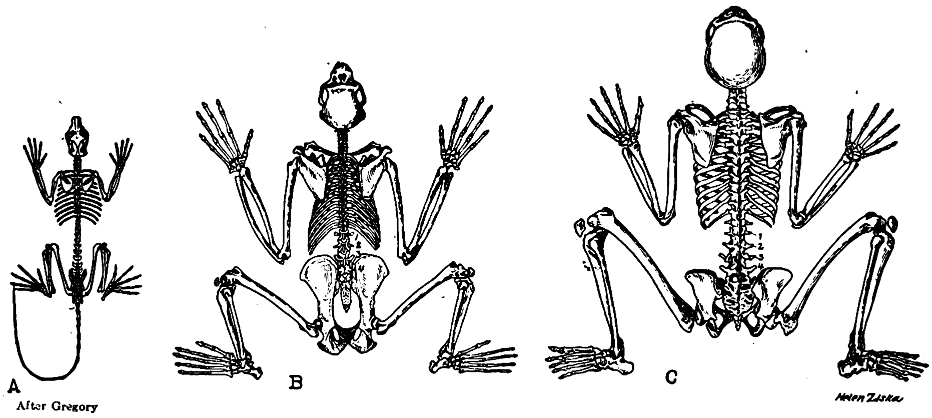

Figure 3: **Man's heritage from his anthropoid ancestors. *A* is a skeleton of an ancient fossil primate from the Eocene age. *B* is a skeleton of a chimpanzee. *C* is a skeleton of man, placed in the same position as *A* and *B***

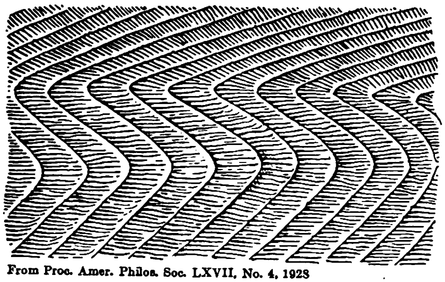
LET us consider first the shark's locomotor machinery and then inquire what parts of it are still recognizable in human anatomy. The "basic patent" of the entire locomotor machinery of the shark is the striped, or voluntary, muscle fiber (Figure 4). The mechanism of this simple-looking little thread is slowly yielding its secrets to the siege of the physiologists. The muscle fiber has been broadly characterized as a "tiny gas engine," but it differs from an ordinary gas engine in using its oxygen in the recovery stage rather than in the work-producing stage. Vast numbers of the red muscle fibers of the shark are grouped in broad zigzag zones called myomeres, or muscle segments, arranged in tightly packed rows along the sides of the body. The ends of the muscle fibers are fastened to the connective tissue partitions that both separate and connect adjacent myomeres. By means of the delicate nerve fibrils that run to each red muscle cell the contraction of the myomeres is timed so that a wave of contraction runs along the side of the body from front to rear. But soon after the first wave starts along the body, a second begins on the opposite side, then a third on the same side, and so forth. By this very simple device the body of a long-bodied fish is itself thrown into a series of backwardly-passing waves, which by their reaction against the water, drive the fish forward.



From Proc. Amer. Philos. Soc. LXVII, No. 4, 1928

Figure 4: **Diagram of arrangement of muscle fibers as shown on the inside of a piece of dried shark's skin. In this "basic patent" of the locomotor machinery of all vertebrates from shark to man, the horizontal red muscle fibers are attached to zigzag connective tissue partitions, or "myosepta," the whole W-shaped muscle segment forming a "myomere"**

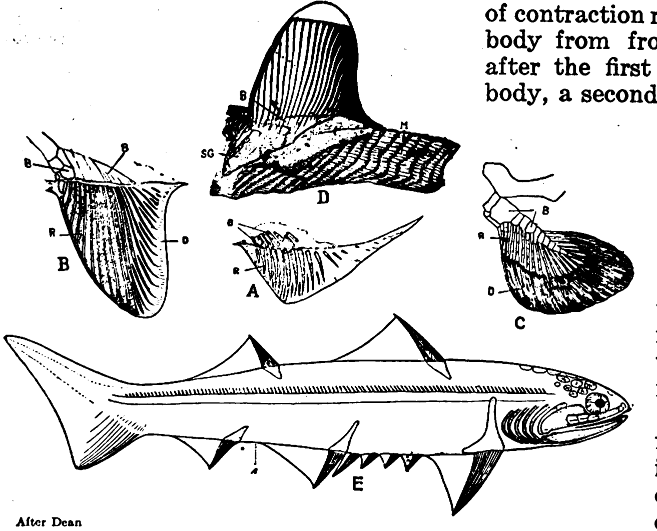


Figure 5: **Origin of fins from fin folds. *A:* Ventral fin of Devonian shark (*Cladoselache*), showing separate rod-like supports of "fin-fold" fin. *B:* Pectoral fin of the same, showing pectoral girdle and basal pieces presumably derived from fusion of separate rods. *C:* Pectoral fin of Permian shark (*Pleuracanthus*), showing fully developed paddle-like fin with jointed axis. *D:* Pectoral fin of Devonian shark (*Cladoselache*), partly covered by preserved myomeres. *E:* Restoration of generalized shark**

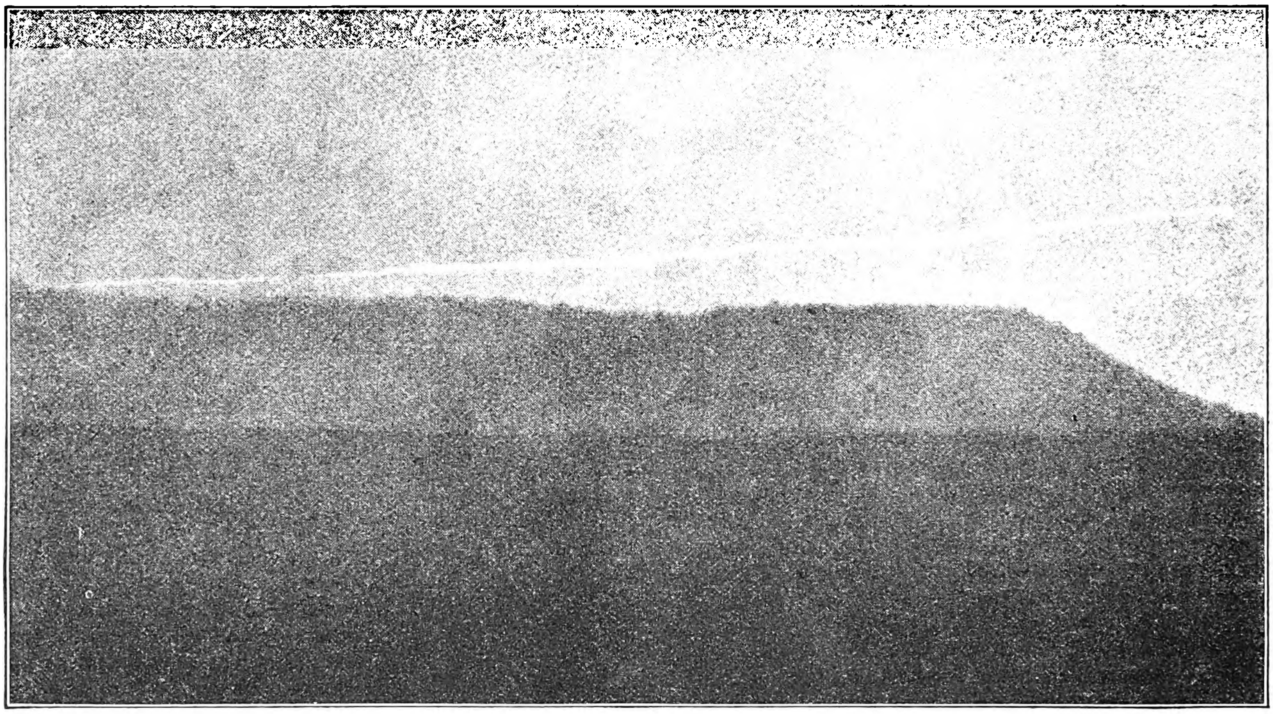
This simple arrangement was also the starting-point for the most complex locomotor machinery of the higher vertebrates. The zigzags of the myomeres soon lose their primitive simplicity. In some sharks, as we pass along the side of the body toward the tail, the tips of the zigzags become greatly prolonged and the connective tissue sheaths of corresponding tips of successive zigzags tend to adhere and unite so as to produce tendons that transmit to the tail the pull of the less modified muscle segments farther forward. And in higher fishes those parts of the muscle zigzags that control the movements of the pectoral fins often fuse into compound muscles that clearly suggest the muscles that move the limbs in the higher vertebrates.

The fins in the most ancient and primitive known fishes, the sharks of the Devonian period (Figure 5), were merely stiff folds of skin which were slightly warped by the zigzag muscles of the flanks, and mainly served as keels and rudders to steady and direct the forward progress of the fish. In some of the higher fishes, on the other hand, the bony rods that supported the paired fins fused into a skeleton that appears to have been the starting-point of the complex shoulder-girdle and fore limbs of land-living vertebrates. The pelvic fins of fishes bear even clearer traces of their derivation from keel-like fin-folds, the bases of which became invaded by outgrowths from the segmental muscles of the body (Figure 5, A).

DURING the embryonic development of all higher vertebrates, including man, the fore and hind limbs develop from bud-like outgrowths involving folds of skin from the body wall and an extension of the segmental muscles of the flanks.

In short, the detailed evidence of comparative anatomy leaves no substantial doubt that upright-walking man has derived all four of his limbs from the corresponding organs of some early four-footed animals, that these quadrupeds derived their limbs from the paired paddles of certain types of air-breathing, lobe-finned fishes, and that they in turn derived their paddles from the simple fin-folds of still earlier shark-like fishes. Such were the "basic patents" of our motor system.

(*To be continued*)



It is a commonplace that we "see the sun after it actually has set," due to the bending of its rays (atmospheric refraction) by the earth's atmosphere. Above is a photograph of the trail of the star *Alpha Centauri*, made by time exposure in a 24-inch fixed telescopic camera by Professor W. J. Luyten of Harvard's South African observatory. The star dips behind the theoretical horizon by as much as the diameter of the moon, yet is visible above it due to refraction. The telescope, of course, is not moved

The "Green Flash" and Other Odd Phenomena

By HENRY NORRIS RUSSELL, Ph.D.

Chairman of the Department of Astronomy and Director of the Observatory at Princeton University
Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

As one watches the setting sun, it sometimes takes strange forms. Always when it is low on the horizon it appears flattened, with its vertical diameter considerably shorter than the horizontal, and just before the lowest point of the rim disappears it may be noticed that the lower half of the disk appears more flattened than the upper. These are normal phenomena which can be seen whenever clear weather and the free horizon permit, but not infrequently—especially when the sun goes down into the sea—its shape may seem strangely distorted. At times the lower half may look larger vertically than the upper, so that the partly set sun looks like a Chinese lantern. The likeness often is emphasized by the appearance of little corrugations in the outline of the upper dome-like half. On other occasions the top of the sinking sun, instead of disappearing quickly, seems to hang on the horizon as a fine horizontal line of light.

It is not the sun alone which shows these strange vagaries. A distant coastline may look distorted. Low sand banks sometimes seem expanded into high cliffs or a long line of distant coast which normally runs out at the horizon, may seem to end in the air with a narrow line looking like sky, separating it from the sea surface below. Ships on the horizon or beyond it, too, are often absurdly distorted, so that only the experienced sailor long familiar with the effects of what he calls "looming" has any real idea of what sort of craft it may be at which he is looking.

Most remarkable of all are the things that are seen upon the desert.* A level stretch of hot sand may appear to be covered with water, reflecting not only the sky but the barren hills beyond and producing a perfect illusion—as the writer has seen it within a few days on the sandy wastes of Nubia.

These more conspicuous phenomena, whether on land or sea, are grouped under the general name of mirage. Though visible and sometimes conspicuous to the unaided eye, they usually show up better with a field glass of low power. But when a high-powered glass is used—much more a telescope—the image is found to be so blurred and trembling that very little can be made out. Just at the edge of the mirage, indeed, the bad definition is often perceptible even by the naked eye.

All this is interesting, surely, to the traveler but what has it to do with astronomy? "Much every way," as Saint Paul once said—it is the most spectacular exhibition of something with which the astronomer has to reckon in all his observations—namely, the refraction of light in the atmosphere.

In empty space all the waves of light travel with the same standard speed but in air they are retarded, and the more so the denser the air. As a result the "rays" of light—that is to say lines drawn at right angles to the waves and indicating in what direction the

---

*Dr. Russell s article was written in Egypt, where he had just seen some of the phenomena described in it.—*The Editor.*

latter are moving—are usually curved when passing through the air, instead of straight as they are outside in space. One simple rule suffices for an understanding of most of the numerous effects of such refraction. The rays of light always curve toward the side on which the air is denser. Why this happens can be seen at once from Figure 1, which represents a number of successive positions aa', bb', and so on, of the crest of a light wave. The air is supposed to be denser toward the bottom of the picture than toward the top, hence the distances ab, bc, and so on, through which the light wave moves, will be greater than a'b', b'c', and so on (the effect is of course vastly exaggerated in the figure). The rays of light XY and X'Y', which are drawn so as to be always at right angles to the waves, will therefore curve downward; that is, toward the denser air.

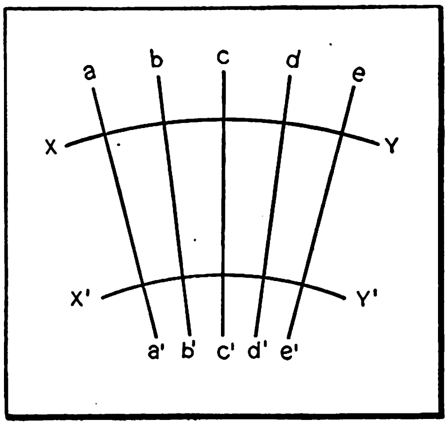


Figure 1: **Explaining the cause of refraction or bending of light. See the explanation in the text**

UNDER normal circumstances the air grows steadily denser downward from great heights to the earth's surface. Hence the rays of light curve downward and the direction in which they enter our telescope or our eyes is altered so that we see the sun, moon and stars higher in the sky than they would appear were there no atmosphere.

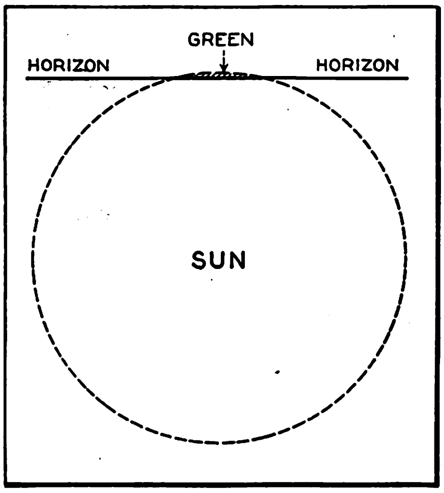
The more obliquely the rays traverse the air the greater is this effect. At considerable altitudes the shift of apparent position by this "astronomical refractor" is not very large—about a minute of arc at 45 degrees altitude. In all accurate observations, of course, it must be carefully allowed for—which is laborious since its amount varies with the pressure and temperature of the air. Near the horizon the refraction becomes large, amounting at rising and setting to more than half a degree. For bodies only a little higher, its amount is considerably reduced. When the sun is setting, therefore, the rays from its lower side are more curved than the less oblique rays from its upper side, the lower limb appears to be raised more than the upper, and the disk seems flattened. It may be noted in passing that refraction makes the sun set later than it would otherwise do, and rise earlier, since it raises the sun in both cases, so that the day gains about 5 minutes in length in temperate latitudes at the expense of the night.

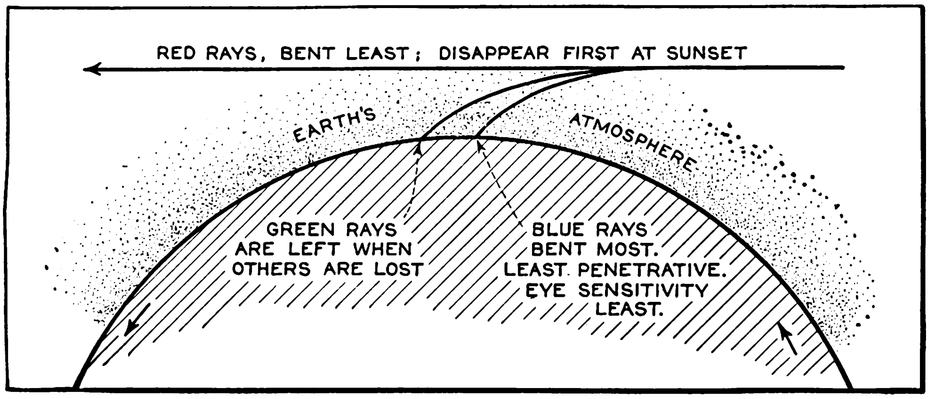
Before leaving this normal refraction we may mention an interesting effect which, though of the "second order" depending on small changes in a quantity which itself is usually small, can be easily observed without instruments.

Shorter waves are more slowed by air than longer ones, and hence the rays of red light are curved least and the violet most. When the sun is low, therefore, it appears to be raised a little higher if seen by green light than by red, and if viewed through a telescope its disk shows a greenish border at the top and a reddish one at the bottom (the violet is always lost in coming through so great a thickness of air). This border is far too narrow to be seen by the unaided eye, but just as the sun sets the green image remains in sight for an instant after the red and yellow have disappeared, so that under favorable conditions the last speck of sunlight can be seen to turn from yellowish red to green.

This "green flash" (Figure 2) is a normal phenomenon and can be seen unless something interferes. Unfortunately a good many things may interfere. The air, of course, must be clear and free from haze. There is little hope of seeing it unless the setting sun looks yellow rather than red, and is too bright to look at without dazzling the eyes. The horizon must be fairly distant, sharp, and at a low altitude. A sea horizon or a low distant range is the best. Finally the eye must not be fatigued by gazing at the brilliant disk before it sets. A mere glance now and then to see how things are going is all that the observer should allow himself until hardly more than a speck of the sun remains. Granting these conditions the green flash is visible under a great variety of conditions. It is better seen with a field glass than without. At sunrise, of course, it is equally well visible, with the advantage that the eye is not tired, and the disadvantage that one must keep a sharp watch not to miss it.

Figure 2: **The phenomenon of the green flash is not especially spectacular; it occurs when less than 1/100 of the disk remains in view (right). Below is the explanation of the effect (diagrammatic)**





RED RAYS, BENT LEAST; DISAPPEAR FIRST AT SUNSET
EARTH'S
ATMOSPHERE
GREEN RAYS ARE LEFT WHEN OTHERS ARE LOST
BLUE RAYS BENT MOST. LEAST PENETRATIVE. EYE SENSITIVITY LEAST.

MIRAGE, including in this term all the protean forms of distorted images of celestial and terrestrial objects, arises from abnormalities of refraction mainly if not entirely due to irregular distribution of temperature within the air. The normal and gradual increase of density downward is due mainly to the increase of atmospheric pressure. To be sure, the air is warmer low down than higher up; and this works the other way, though under ordinary conditions to a much smaller degree than the change in pressure.

When, however, the earth's surface, whether land or water, is considerably hotter than the air at large and the weather is cooler, a thin layer of air just above the surface may be heated so much that it becomes considerably less dense than the overlying cool air, even though it is at a slightly higher pressure. Rays of light passing through this stratum will be curved upward, as illustrated in Figure 3, which shows how the illusion of a sheet of water filling a desert plane will be created. The distant object A is seen by the observer at O, through the upper layer of normal air, by light which follows the path AaO, which is curved very slightly downward. Light rays traversing the layers of hot air near the surface indicated by the lower lines will

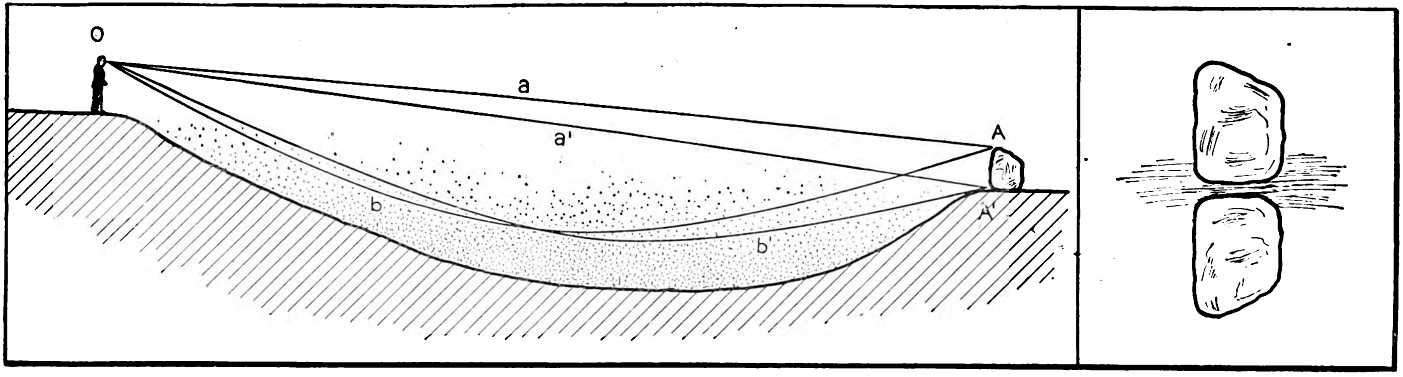


Figure 3: **Explaining the familiar illusion of a lake on a desert, also at right the rock at A is seen doubled, a "superior mirage"; see Humphrey's "Physics of the Air," standard work in which peculiar phenomena are treated**

be curved strongly upward so that the observer may see a second image of A, caused by light which has followed the path AbO. The base A′ of the object will be seen both along the rays A′a′O and A′b′O, so that the observer will see two images, one erect and in its normal position and another inverted and lying below it as if reflected in a sheet of water filling the valley.

Mirages appear most typically under two very different conditions: first, on land where the bare surface of the ground is highly heated by the sun, and secondly at sea where the vicissitudes of the weather bring cooler air over warmer water. The first situation is characteristic of desert regions, but one need not go to the borders of the Sahara nor to Death Valley to find it. Almost any bed of level railroad track on a calm sunny day will suffice, and a stretch of level oiled highway still retaining the heat of the sun though the air above has cooled after nightfall, does even better. Most of us have seen a distant locomotive looking twice as high as it should, and it is a common thing looking from an observation tower to see the space between the rails apparently filled with water. Almost all of us, too, have seen the lights of an approaching car half a mile or so away apparently refracted from the pavement of the road; and all these are as truly examples of mirage as the proverbial "lakes" in the desert.

ALONG our coasts, too, when the autumn days and evenings are cool and the water still retains its summer heat, distant shores seem lifted into the air, ships are strangely distorted, and far-away light-houses show double lights one above the other. No one can live long by the water without seeing these things, but not so many understand them.

Another effect of these anomalies of refraction is that the distance of the horizon at sea, or of the farthest objects that are visible on land, may be very different on different days, or even at different hours of the same day How this happens is again best understood from the diagram. Figure 4 almost explains itself. In the absence of refraction the rays of light are straight and the horizon at A. When there is a stratum of hot air close to the surface the rays curve upward and the horizon is nearer at B, but when the air near the surface is abnormally cold the rays curve downward and the horizon is shifted to C.

It is clear from the figure that not only the distance but the apparent direction of the horizon is altered. As a result the dip of the horizon, for which allowance has been made in all observations, may differ perceptibly from the standard value given on the tables employed by mariners. The error arising from this cause is often a good deal larger than any other which occurs in careful observations with a good sextant, and it sets a limit to the accuracy of determination of longitude and latitude at sea; but fortunately the uncertainty arising from the cause is usually less than the distance which the ship would run while the captain is "working his sights," and so it is not of practical importance.

THE diminished distance of the horizon under mirage conditions is not very noticeable, but the increase when the air is cold close to the ground may be very remarkable. On the Texas prairies, where the ground is as level as the sea, and distant buildings look like ships "hull down," the writer has seen just before sunrise houses and farms which were ordinarily quite invisible. Within a few minutes after the sun's rays warmed the ground these began to settle down into the horizon and before long they had quite disappeared. Under these conditions in clear weather the mariner may see light houses which normally would be far beyond the horizon.

The most remarkable instance of refraction which the writer has seen happened one afternoon in a New England harbor when the sea horizon was clearly visible above the top of a house on an outer beach, although the observer in a small motor boat had his eyes less than six feet above the water. In this case the downward curvature of the rays must have been so great that, although passing above the house (fully 30 feet above sea level), they bent down to the water within a few miles on each side.

IF the layers of warmer air were horizontal and absolutely calm the reflected or distorted images of a mirage would be sharp and clear, but even in the stillest weather there is always more or less stirring of the air, if only by currents arising from the hot ground, and this turbulence confuses and disturbs the images so that they bear at best only a low magnifying power. This is but an extreme instance of the "bad seeing" which is always more or less present and is so troublesome to the telescopic observer. If the atmosphere were visible like water, its turbulence then would be far more impressive than it is. In comparison the wild turbulence of Niagara Rapids would seem quite tame.

All the phenomena of atmospheric refraction, whether normal or abnormal, are an unmitigated nuisance to the astronomer but they are so varied, so curious, and so easily to be seen if one is on the watch for them that some knowledge of them may add interest and pleasure to a summer vacation.—*Luxor, Egypt.*

The electrical photographing mechanism is automatic. The photograph is taken through a screen and it, in turn, is viewed through a screen

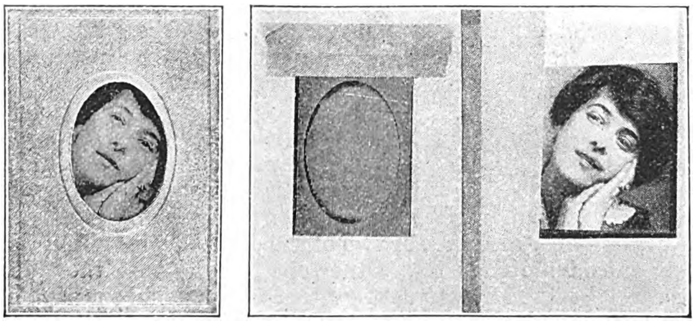
Film Yourself for a Quarter

THE theatrical business is precarious at best and "flops" are common so that there is little wonder in a producer taking a flyer on stocks or in an invention, particularly in something which has a very popular appeal. Mr. A. H. Woods is one of these producers who is backing a very clever device that makes simulated motion pictures of subjects while they wait. Mr. Woods obtained the rights in an English invention a few years ago but the time required to produce the picture was inordinately long. For the past two years Mr. Stanley J. Pask, a practical camera man, has been making the device commercially marketable. The pictures may be radically different—thus you may smoke, use a telephone, or take a group of a family of three, and each can be animated in turn.

The would-be movie star sits in the booth and the face is well lighted

The new camera is very complicated and only a brief outline of the cycle of operations will be given. Three (or more) pictures are taken on one plate film through a screen composed in part of transparent material and in other parts, of opaque material. The screen is positioned directly in front of and resting against the sensitized film and with the object to be photographed focused properly in front and illuminated by a powerful electric light, so that at least three exposures may be made. The screen is shifted at each exposure, the person being photographed changing position. The person sits on a stool in a booth fixed up like a dressing room. The idea is to take the photographs so that they will give some idea of how he or she will "screen."

ONCE in position the attendant presses a plunger and the cycle of operations begins. After the three exposures are made, the sensitized film is developed automatically in the machine in 12 seconds and we have what appears to be an ordinary photograph except that it is ruled with almost invisible vertical lines. This is mounted in a pasteboard frame 2⅜ by 4 inches and a cover of the same material is provided with a cut out window to which is attached a vertically ruled film. The two pieces of cardboard, one holding the photograph and the other the film, are loosely attached so that there can be lateral movement. If the sides of the mount are pinched slightly, the picture is "animated" giving the effect of a moving picture, which is most amusing. These booths will soon take their places where amusement devices are shown, and in theater lobbies.



At left is picture ready to be "animated." In center is the cover with the ruled screen and to right the photo

Gathering petals for perfume in the Balkans. Egypt, too, produces fine flower oils to a growing extent

Perfume

By MARTIN MEYER, Ph.D.

Assistant Professor of Chemistry, College of the City of New York

THE sense of smell is one of the human functions which not only has failed to advance with evolution but which in many respects has actually deteriorated with the increase of civilization. The dog distinguishes friend from enemy by the smell, and can track a man over a long period from the mere recollection of the odor of one of his articles of clothing. Wild animals scent danger at incredible distances where no explanation save smell or intuition is forthcoming.

The human animal no longer possesses this delicate perception. He can distinguish agreeable odors from disagreeable ones, but the very language itself expresses the atrophy that has occurred. One does not have to be exceptionally well skilled in the use of words to be able to describe a scene so accurately that another who has seen it will recognize it or, not having seen it, would later feel familiar with it. With a smell, however, this is quite impossible. Try to depict in words the most familiar fragrance, that of the rose, for example, so that a hearer will know it, without employing words such as "rose-like," which suggest the object described. Your effort will certainly be a failure.

Perfumes are solutions of essential oils and other fragrant materials in slightly diluted alcohol or spirits, while those of the ancients were merely the odoriferous materials themselves.

Essential oils are interesting substances indeed. They are all obtained from vegetable sources, occurring in the flowers, leaves, stems, and roots of plants, and are extracted by highly ingenious methods. They derive their general name from the fact that all are oily materials in the sense that they are usually lighter than water and float on its surface but do not mix with it. They also resemble other oils in that they will form a greasy spot on a piece of paper, but they differ from the so-called fixed oils, in that this spot disappears or evaporates completely on standing, whereas the others do not. Not all have pleasant or even agreeable odors.

OTHER perfumery materials, and some of the most expensive, are obtained from animals. Ambergris, a highly prized perfumery component, is found occasionally in large lumps on the seashore, washed in by the waves. It is a material emitted by sick whales. Musk is obtained from a variety of oriental deer, now nearly extinct, because of the merciless hunt for it, and civet, another valued fragrant essence, from a member of the cat family, in ways that have nearly exterminated the species.

Some of the flowers yield their essential oils simply by pressing the petals, but the yield is extremely small. A ton of flowers may give only an ounce or two of the desired perfume material. Other oils may be obtained by extracting them with alcohol or other solvents.

Steam distillation is yet another method employed in coaxing flowers to yield the secret of their gorgeous fragrance. The flowers are macerated with water, and then steam is passed through the mixture and the escaping vapors are condensed. The essential oil floats upon the surface and can be separated and used in making perfumes, while the residual water itself retains enough of the oil in solution to be highly fragrant and has commercial value. Oil of roses can be made in this way, and the remaining liquid is sold as rose-water. In France they employ an interesting process termed *enfleurage.* In that land, growing flowers is a branch of agriculture conducted on a scale comparable with the raising of the cereal grains. One of the greatest beauties of southern France is the large flower fields in bloom. Fats and oils possess the property of absorbing odors to a marked degree; every housewife knows the result of placing butter in the icebox with fish, and in *enfleurage* the petals of the flowers in full bloom are packed in a box on shelves between pans of a very pure fat which slowly absorbs this fragrance. The essential oil then may be extracted from the fat and used for perfumes, or the fat itself may be made into pomade. The yield of essence by this method is extremely small but its quality is very high.

ESSENTIAL oils and perfumery materials are high-priced articles of commerce but they rarely reach the retail trade. They are made or purchased by the manufacturer of perfumes. In price they vary from a few dollars an ounce to hundreds of dollars a pound, and many of them are literally worth more than their weight in gold. Perfumes are made by dissolving them in alcohol, and as a rule a perfume does not contain more than 10 percent by volume of essential oil.

Usually perfumes do not consist of a single essential oil dissolved in alcohol. Therein lies the secret of their manufacture, for the blending of the oils to make the commercial odors is a delicate art and a closely guarded secret of the firms which have become world-famous. Some of the formulas, such as the famous German Cologne water, have been in the sole possession of single families for generations and to obtain them is impossible. They are available neither in the interests of science nor for any price.

A chemist named Piess once devised the interesting scheme of likening the odors to the musical scale, and made up a keyboard on which the lower notes were represented by the heavy oriental odors such as patchouli, ylang-

ylang, and sandalwood, rising to the lighter and more evanescent ones like rose and heliotrope. On this fascinating scale one could play odor symphonies like a musician, for musical accords represented agreeable combinations, and discords incompatible mixtures. The device was, of course, purely of academic interest for there is no mechanical rule by which perfume formulas can be originated. Mixing of essential oils to form fragrances which will strike the popular fancy is an art requiring a delicacy of perception that doubtless can be acquired only by long experience.

The manufacture of perfumes is a field in which the chemist finds a very agreeable opportunity to display his talent and his ingenuity, and he already has done so with a marked degree of success. Usually the chemical laboratory is a place distinguished by odors that are proverbially vile beyond description. The perfume laboratory is truly a garden of roses, for practically every material which enters into their manufacture, as well as the perfumes themselves, have highly aromatic agreeable odors.

WITHOUT the chemist, perfumes would still be far too expensive to be used as generally as they are, even though they are still relatively costly. The cheapest of them which contain any considerable quantity of natural essences sell for three to five dollars an ounce, and 25 dollars is not unusual.

In the case of the most expensive of all, the rôle of the chemist is best illustrated. Natural violet perfume is the rarest and most costly of all the fragrances in the perfumer's bouquet. An acre of violets yields only a few drops of the essential oil which is this essence, and it is exceedingly difficult to obtain and keep. By careful analysis it has been determined that the chief component of violet oil is a chemical substance called ionone. When pure, this material is so powerfully fragrant that it paralyzes the sense of smell completely and seems odorless, a phenomenon which is not unusual with strong solutions of highly odoriferous substances. Synthetic organic chemistry has shown how to make ionone very cheaply and violet perfume so made is now among the cheapest of all. This is so true that natural violet perfume scarcely can be obtained, for it can not compete with the five-and-ten-cent-store variety with which the untrained taste, or rather, smell, so easily confuses it.

Among the other triumphs of the chemist of a similar nature have been methyl salicylate, identical with the chief component of natural oil of wintergreen; coumarin; geraniol, characteristic of roses; citral; musk; and many others. The products of the chemists' laboratory can not, however, be used alone in any but the cheapest perfumes. While they have very powerful odors identical in many cases with the principal substances in the natural essential oil, the discriminating sense can easily distinguish the many other components which shade so delicately the perfume made from a natural flower.

THESE do, however, make perfumes cheaper to manufacture because they can be used to replace part of the true essential oil, which then gives the bouquet which surrounds and enriches the principal odor. Practically no perfumes as sold today are without synthetic organic products, yet on the other hand, none, save the very cheapest, is completely synthetic.

Relatively few people seem to enjoy the fragrance of a perfume with the true appreciation of a connoisseur yet, like the taste of tobacco or the fine bouquet of a wine, the appreciation of which is almost a lost art in America, it is easy with care to perceive the extremely nice shades of odor which distinguish the higher grades of perfume from each other. This is especially uncommon and enjoyable in the case of popular odors which are blends not characteristic of any one flower. Frequently I have experimented with women who have used the same and expensive odor of perfume for many years. After modifying the perfume so that the chief odor remains the same, as well as the color, though the difference was easily perceptible to one who had carefully observed, I have presented it to them in the expected package and bottle, and they often not only fail to detect the deception, but compliment me upon the fact that it appears fresher because it is stronger and more lasting. With age perfumes do change in color and in odor.

IT is interesting to note that here, too, as in the case of any rare and expensive commodity, the practice of bootlegging flourishes and is very profitable. Rare ingenuity is sometimes exhibited, running from the comparatively crude device of diluting the original perfumes with alcohol and cheaper perfumery materials, to complete and spurious imitation of the original product. In the case of two or three internationally known perfume manufacturers, especially in purported re-bottled perfumes, this has been perpetrated so extensively and unconscionably that it has damaged considerably the widely advertised and wholly deserved name.

Careful chemical study established the nature of the devices used and strenuous methods have been adopted to stop the deception, but if the public which, in general, detected it only where the perfume became so dilute as to be not at all lasting, would cultivate a more refined sense of smell, this would be much more difficult. One would think that this would be done by people who are willing to pay 25 dollars for an ounce of material, the use of which, without such artistic perception, is like casting pearls before swine.

¶ This is the third and last of Dr. Meyer's very interesting and instructive series of articles. It is hoped that at some future date other popular articles, equally interesting, may be written by this author.—*The Editor.*

The Eight-Inch Gun Cruiser

By CAPTAIN W. D. PULESTON, U.S.N.

At the close of the Revolutionary War the Continental Navy was disbanded. Due to attacks of the Barbary pirates on our commerce in 1794, Washington recommended and Congress authorized the construction of six frigates. This was our first building program as an independent state. General Knox, Secretary of War and Navy, decided that these frigates "should combine such qualities of strength, durability, swiftness of sailing, and force as to render them equal if not superior" to any European frigates. The results of the battles between frigates during our wars with France and England indicated that American designers measurably succeeded in their object. President Roosevelt voiced the same idea in his demand that the American Navy "ship for ship" must be better than any other in the world.

The era of wooden ships culminated in two principal naval vessels—ships of the line displacing 1300 to 3100 tons, carrying 60 to 120 guns, and maximum speed of 12 to 13 knots; and frigates displacing from 650 to 1300 tons, carrying 32 to 50 guns and capable of outsailing the ships of the line, except in heavy weather. In addition to these were sloops of war and fire-ships corresponding to our light cruisers and destroyers, and bomb-ketches especially designed for use against shore defenses.

The advent of the steam engine, the paddle-wheel, and the screw propeller gradually gave a reliability to naval motive power entirely lacking in the sailing vessels. The iron and steel industry furnished the naval designer with material that permitted greater freedom in design than wood.

The great advantages of seapower were early known to Europeans, and modern European states, particularly from 1870 onward, demanded navies, and gave an increasing impetus to naval design that continued to the Washington Conference in 1921-22.

The weapon builders and the armor manufacturers responded to the urge, and the development of the gun, the mine, and the torpedo, and the improvement in armor and compartmentation of ships, proceeded apace. After the Spanish-American War we began to build a fleet. The submarine and the airplane made their appearance to complicate the task of the naval designers further, and the World War accelerated the natural rate of improvements of all naval weapons and vessels as nothing else has ever done.

For over a century of design, naval constructors generally and American particularly, following the idea of General Knox, have struggled to obtain three almost unattainable attributes—invulnerability, omnipotency, and omnipresence. They sought an unsinkable ship, an irresistible ship, and a ubiquitous ship. Together with their ordnance and engineering designers, they strove to create a ship that could resist any other, run down any other, and sink any other ship. In the same plant, the ordnance manufacturer would seek to develop impenetrable armor and an armor-piercing projectile.

This competition led to continued increase of tonnage because designers soon discovered increased size gave them a still greater corresponding increase in offensive and defensive values. There naturally followed a constant increase in size of all types of ships.

Mahan's widely read books on the advantage of command of the sea spurred the great powers, particularly Great Britain and Germany,

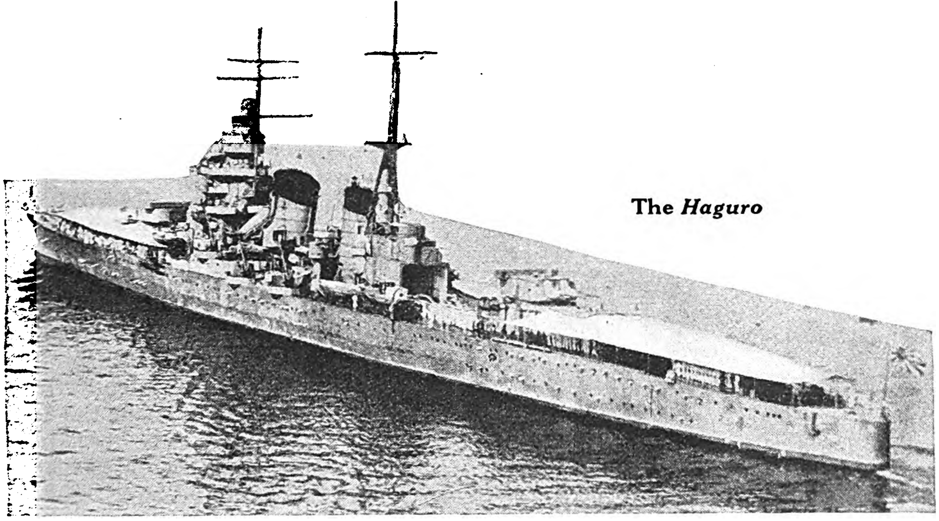
The *Duquesne*



The *Haguro*

to renewed efforts and the first decade of this century saw an enormous development in naval strength. Until Admiral Sir John Fisher became First Sea Lord of the British Admiralty, design proceeded generally on the tentative system, following a step-by-step development. Fisher brought in the dreadnought type of battleship and battle cruiser, and led the world in the pre-war design; other countries quickly followed his example. The British pre-war design culminated in the battleships of the Royal Sovereign class, the battle cruisers of the Tiger class, and the so-called battleships of the Queen Elizabeth class whose 25 knots made them practically battle cruisers. The progressive design of battleship and battle cruiser almost met in the Queen Elizabeth class, as shown by the following table:

	Tons	Speed	Guns	Armor	Protective Deck
Queen Elizabeth..	27,500	25	8-15"	13"	1" to 3"
Tiger..........	28,500	30	8-13.5"	9"	1" to 3"

This table also shows the great cost of the last few knots; thus for five knots extra speed, the battle cruiser *Tiger* conceded the *Queen Elizabeth* 4 inches of armor belt and 15-inch guns instead of 13.5 inches.

In the naval competition between Great Britain and Germany, neither state made much effort to conceal the fact that they were building against each other and expected to fight in the North Sea. In fact, one of the main reasons for Fisher's designing the dreadnought class was that Germany, until she deepened the Kiel Canal, was at a handicap in this deep-draft class.

American designers have to build their vessels for service in all parts of the world; and with no hereditary enemy, they have to design vessels for more than one purpose and fit them for duty in any part of the world.

OUR 1916 naval program provided for ten superdreadnought battleships and six battle cruisers. We kept our battleship types quite distinct from the battle-cruiser type, not attempting the great increase in speed in our battleships attained by Great Britain. So did Japan, although generally speaking, the designed speed of her battleships has exceeded ours.

The first modern limitation on the size of all naval vessels was the dimensions of the locks of the Panama Canal. This fixed absolutely the maximum outside limits of American ships and practically fixed it for other navies that will probably find the Canal useful, if not essential.

The Washington Conference placed the next limitation on naval design by creating a battleship holiday and by limiting cruiser displacement to 10,000 tons and armament to guns of 8-inch caliber. The battleship holiday, recently renewed at London, increased the importance of cruisers, destroyers, and submarines, and naval constructors concentrated their attention on the designs of these and aircraft carriers. The limitation placed on the tonnage and caliber of guns to be carried on cruisers left open to competition within very narrow bounds, the factors of speed, armor, and armament.

IN the previous competitions, designers had learned the great advantage of increased displacement and heavy caliber guns, so most naval constructors went at once to the 10,000-ton, 8-inch gun cruiser, with slight variations in speed and protection, depending upon the ideas of the line officers, the skill of the naval constructors, the efficiency of the establishments furnishing the materials going into the construction, and the available appropriations. It is significant that competition in design was just as sharp as before, except that it was concentrated in certain types, and confined to prescribed displacements.

The art of naval construction had practically reached a parity in the leading naval countries before the Washington Conference suggested a combat parity and ratios instead of unlimited competition in design; and there is small difference in the quality of the shipbuilding materials available in first class countries, so that it is not surprising that the 8-inch gun treaty cruisers of the five leading nations have approximately the same characteristics. This is shown by the similarity in the 8-inch gun treaty

TABLE A

cruisers of the five nations in the accompanying Table A, in which for convenience of further comparison, is also included the German battleship *Ersatz Preussen,* which is limited by the Versailles Treaty to 10,000 tons displacement but the 11-inch guns the Germans used came as a surprise.

Table A indicates that the designers of Great Britain, the United States, and Japan have practically stabilized the speed at 32.5 knots and battery, while France and Italy are building 35-knot cruisers. They all burn oil and use geared turbines except Germany, who depends upon the Diesel internal combustion engine. This table again shows the price paid for the last few knots speed in cruisers; thus the *Ersatz Preussen* carries 11-inch guns, is comparatively heavily armored, and can make 26 knots, only 6½ knots less than the typical treaty cruiser with 8-inch guns and comparatively unarmored. There is a striking parallel in the relationship between the *Ersatz Preussen* and the Queen Elizabeth class of fast battleships, and the treaty cruisers and the Tiger class of battle cruisers.

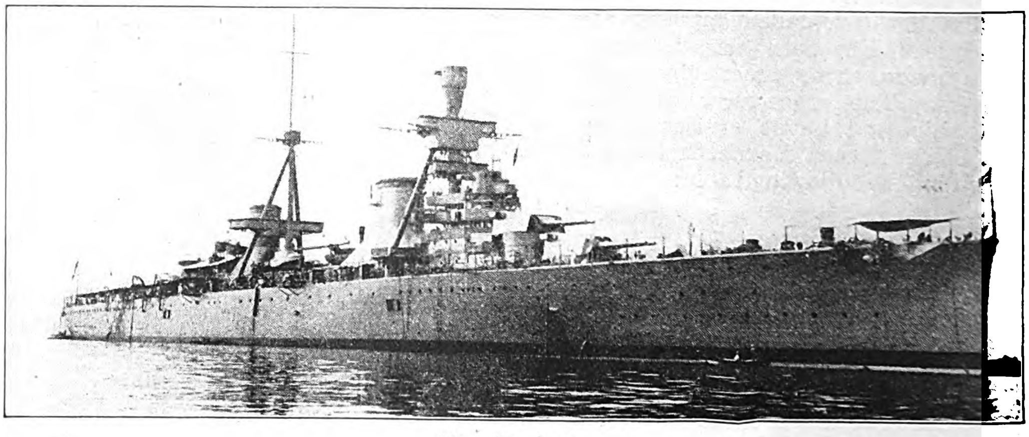
Mahan's test of a ship was: Is she well designed to accomplish her war tasks? This is a principle easier to enunciate than to apply, for its application implies the ability to determine with a fair amount of accuracy the future adversary and the nature the war will take.

At the present time, under the principle of parity, Great Britain and the United States are confronted with the problem of finding parity in cruiser strength when Great Britain believes she needs more 6-inch gun cruisers and the General Board of the Navy believes we need more 8-inch gun cruisers. Both countries trade in all parts of the world; the volume of their foreign trade over a period of five years is approximately the same; while Great Britain has more widely-spread dependencies, they are more strongly linked up by her numerous bases, whereas our water communications, even between our east and west coasts, pass directly in front of numerous foreign countries, so, generally speaking, it can be said that the naval burdens of the two countries in time of war will be approximately equal.

THE vital interests of Japan are much more closely concentrated than either American or British. She is an insular empire with adjacent continental possessions, very similar to England with French possessions under the Plantagenets. In addition to her navy she possesses the second or third largest army in the world. Accordingly, her naval ratio at Washington was made 5 to 3, and in return we agreed to cease fortifying our Far Eastern possessions. At London, substantial concessions were made to Japan, in cruisers and destroyers, and parity was given her in submarines. Members of the General Board have pointed out the additional handicaps the abandonment of the 5:3 ratio with Japan will impose upon our Navy in the event of war in the Pacific.

Naval competitions are certainly expensive and they may become provocative; limitations of naval armament will reduce somewhat the expense and if carefully done, need not jeopardize the legitimate interests of any state. But it should be recognized that *navies are symptoms of the probability of wars,* not their primary causes.

The task confronting world statesmen today should be to obtain a friendly accord between the nations of the world. Until they accomplish this preliminary essential, conferences on the limitations of armaments will continue to disappoint the fine hopes of Americans who have been led to believe that the scrapping of a few warships will banish self-interest from the peoples and ambitious policies from the rulers of the world.



The *Trento*

A Home Made Microscope for the Amateur

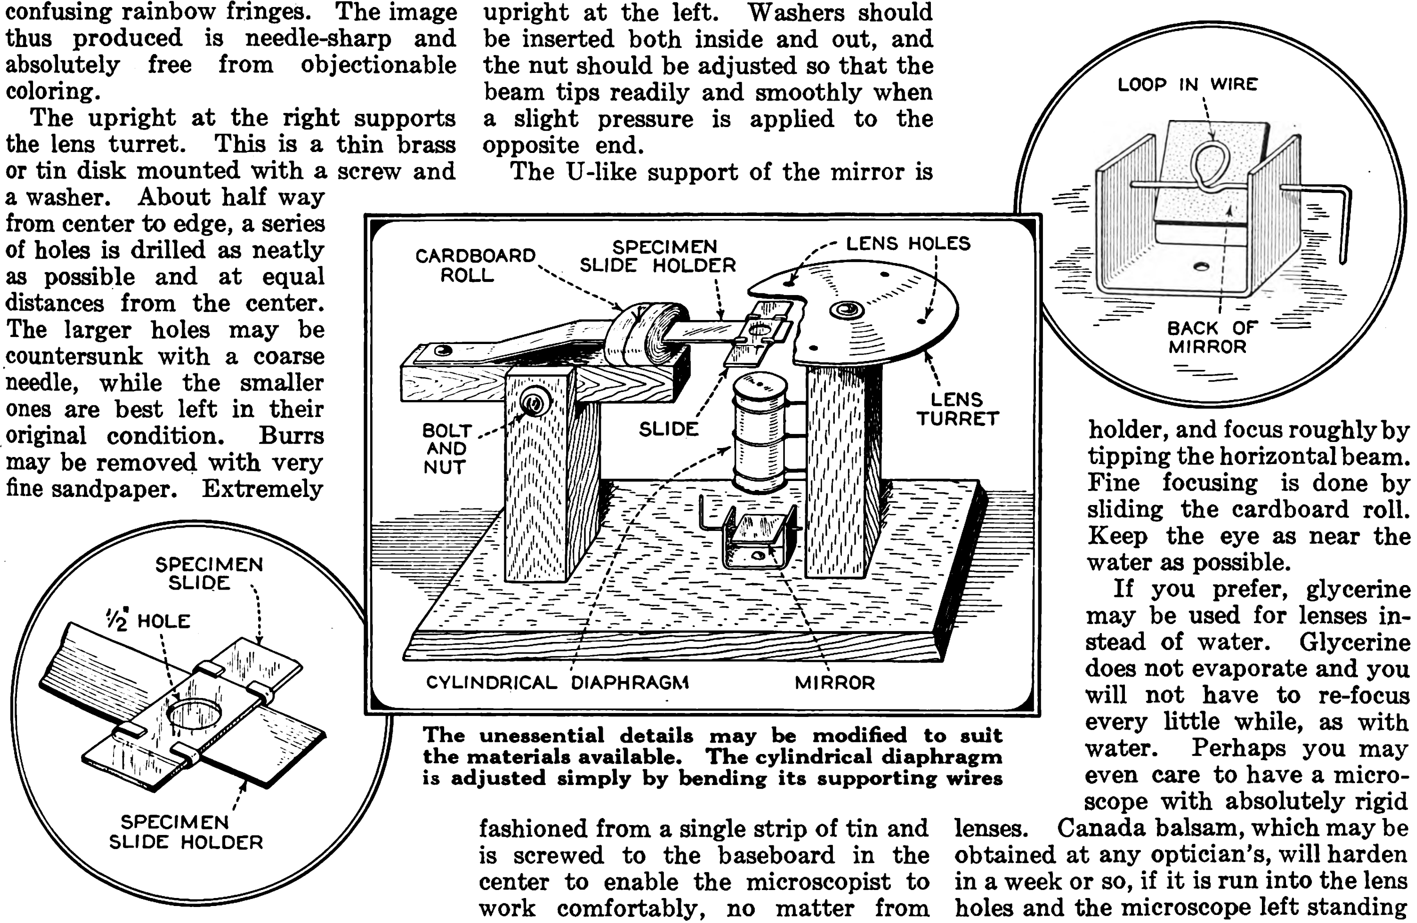
By LEON J. ISRAELOVITCH

Associate Editor Science and Engineering, *Leningrad*

A MICROSCOPE magnifying from 25 to 300 diameters may easily be constructed in the home workshop, with practically no expense. Only the simplest and most ordinary tools are required.

This may sound too good to be true, yet it is a fact. The reason is that small drops of water, which cost nothing, are used instead of expensive powerful glass lenses. A cylindrical diaphragm is also employed, doing away with blurring of the image and confusing rainbow fringes. The image thus produced is needle-sharp and absolutely free from objectionable coloring.

The upright at the right supports the lens turret. This is a thin brass or tin disk mounted with a screw and a washer. About half way from center to edge, a series of holes is drilled as neatly as possible and at equal distances from the center. The larger holes may be countersunk with a coarse needle, while the smaller ones are best left in their original condition. Burrs may be removed with very fine sandpaper. Extremely small holes are made as follows: Use the smallest drill you have and stop drilling when the tool is almost through—when a little "pimple" appears on the other side. Remove the drill, pierce the "pimple" with a fine needle and even up the edges with sandpaper.



The unessential details may be modified to suit the materials available. The cylindrical diaphragm is adjusted simply by bending its supporting wires

The wonder-working cylindrical diaphragm is held in place under the lens turret with three wire supporters. It is merely a small metal or cardboard tube closed on both ends with black cardboard disks and India-inked on the inside. A small hole is made in the bottom disk, while the top one or lid is pierced in the center with a fine needle heated to red heat in a flame, so it will not leave any burr.

A special holder for slips of glass upon which objects to be examined are mounted, is fashioned from a strip of thick tin. Its business end is shown in the left-hand drawing. The other end is securely nailed to the square beam. The holder is slightly bent in the middle, to accommodate a small roll of cardboard secured with glue or a thread and wound loosely enough to slide back and forth easily.

The square beam is drilled exactly in the middle and is held by a bolt and a nut, in a fork sawed out of the thick upright at the left. Washers should be inserted both inside and out, and the nut should be adjusted so that the beam tips readily and smoothly when a slight pressure is applied to the opposite end.

The U-like support of the mirror is fashioned from a single strip of tin and is screwed to the baseboard in the center to enable the microscopist to work comfortably, no matter from which direction the light falls. Liquid glue is used to attach the mirror to its looped-wire support.

No dimensions are given on the drawing, for the very excellent reason that they are of absolutely no importance. There is only one thing to watch for, when assembling the device. The fine pencil of light streaming up from the diaphragm should go squarely through the lens holes in the disk.

There is nothing difficult in the use of the water microscope. Decide which enlargement you need and choose a hole in the lens turret accordingly. The smaller the hole, the more powerful the lens. Rub the hole with your fingers, coating its sides with a thin film of grease, to prevent water from spreading. Dip a sharpened match into clear water and apply the point to the hole. Water retained on the match will flow down and form a nice round drop. Turn the lens turret until light from the diaphragm shows through. Work the mirror about to obtain the best lighting. When high powers are used, say 250 diameters, the source of light must be a strong one, preferably the sun or a powerful electric lamp.

Now insert the specimen slide in the holder, and focus roughly by tipping the horizontal beam. Fine focusing is done by sliding the cardboard roll. Keep the eye as near the water as possible.

If you prefer, glycerine may be used for lenses instead of water. Glycerine does not evaporate and you will not have to re-focus every little while, as with water. Perhaps you may even care to have a microscope with absolutely rigid lenses. Canada balsam, which may be obtained at any optician's, will harden in a week or so, if it is run into the lens holes and the microscope left standing in a warm dry place.

¶ Editor's note: *William Waldeyer, a San Francisco reader of this journal, has made an interesting suggestion. "Let the mechanically inclined amateur expend, say, eight dollars for a 10*x *objective, mount it in a stand of his own design, and add a 5*x *or 10*x *Huygenian eyepiece, also a small lens of short focal length for a condenser. Just as in amateur telescope making a little study will be necessary, but the first qualification for a real hobby is that something must be left to the ingenuity of the amateur." For the study, Gage, "The Microscope" is recommended. No blueprints or instructions are available.*

Work and Fatigue

Industrial Fatigue Is Passing Out of Style

By DONALD A. LAIRD, Ph.D., Sci.D.
Director, Colgate Psychological Laboratory

MEN of science visiting an exhibit arranged by the Genetics Department of the Carnegie Institution, saw a specially developed race of tireless mice which danced all day long. This was a product of careful breeding. Sir Arthur Keith and Ales Hrdlicka, well-known anthropologists of England and America, see evidence that a new type of man is emerging from the biological melting pot in America. Greater resistance to ordinary fatigue may be one of the characteristics of this new biological development in the human race, but none of us, obviously, shall live long enough to see this changed specimen. And it will not help to make us at present more resistant to fatigue.

Fatigue will doubtless be removed pretty thoroughly from the world many decades before the new biological man has emerged. In fact, one who has been keeping in close touch with the progress of fatigue elimination in industry for the last ten years knows definitely that a great deal of fatigue has already been eliminated.

IT is not the invention of labor-saving machinery that is doing most to eliminate fatigue. Such machinery may save the labor of three men, but add to the fatigue of the two men who operate it. The noise and jar and "high speed" attention the new machine demands is often more fatiguing than the brute labor that it is replacing. An invention can be labor saving but fatigue increasing.

Realizing this truism, some years ago the Society of Industrial Engineers organized a special Committee on the Elimination of Unnecessary Fatigue. This committee, to which I have the honor of belonging, serves to stimulate and co-ordinate the work on the conquest of fatigue in America. It has brought together mechanical engineers, physicists, physiologists, and psychologists on a common battle-ground for applying their sciences. In England we find a more formidable and official organization for battling fatigue, in the form of the Industrial Fatigue Research Board, which is a part of His Majesty's Governmental agencies. This board keeps a large group of investigators active in the textile, metal, wood-working, and other industries, searching out new facts about fatigue and new ways of eliminating it.

There are four general sources of fatigue which, fortunately, are being attacked by modern Saint Georges. The most treacherous and insidious source is poor emotional adjustment of the individual. One who is of necessity engaged in work which he does not like, or for which he is otherwise poorly adapted, is especially likely to experience a vague but pernicious fatigue. The rapid growth of vocational guidance in the schools, and the development of psychological tests for determining fairly accurately what work one can do best, are powerful forces for eliminating much emotionally generated fatigue. Monotony is another cause of emotional fatigue. We know that there is no such thing as intrinsically monotonous work; work which is monotonous to one person is fascinatingly interesting to another, but it is highly important that each individual work at a job which is not monotonous to him.

Fatigue of an emotional origin also arises from poor supervision of workers. The roughness of the foreman of the old school caused much fatigue. Today foremen and other supervisors are being given special training in how to handle people. This foremanship training, which is on a state-wide basis in states such as New York, is already eliminating much fatigue which has been caused by reprimanding and ill-chosen supervision of the kind not based on a good comprehension of the nature of human nature.

HUNDREDS of thousands of persons are suffering from fatigue of emotional origin, which however, has no relation to their daily tasks. These are persons with a poor emotional adjustment to life in general. They are persons who "enjoy being tired," just as about the same number "enjoy poor health." These thousands who awaken feeling tired after eight to ten hours of sleep need a general probing of their inner emotional lives. Psychiatrists and mental specialists are undertaking this on a grand scale throughout the country, largely as a result of the work of the National Committee for Mental Hygiene. Specialists have been trained for this work, and wholesale clinics

Courtesy of Harrington and King (Chicago)

A ceiling designed to absorb noise; adequate artificial lighting; restful wall colors; and venetian shades, free this office from environmental fatigue

have been established in a dozen large cities. Some larger firms have their own specialists who are engaged full time in guiding their workers to emotional readjustments which have not been caused by their work, but which are nevertheless a fatigue handicap.

The following typical case of this type of fatigue has been reported by Dr. V. V. Anderson who is engaged in this work with R. H. Macy and Company in New York. This case may be taken as illustrative not only of the pernicious hidden emotional causes of fatigue, but also of the highly socialized "long view" many employers are now taking of the problems of fatigue elimination.

Mary T. was a successful sales clerk, 35 years old. For half a dozen years she had been complaining of being tired and needing a rest. From time to time she had been given short leave from work with pay, and finally took six months with pay. The family doctor reported that she "must have a complete rest."

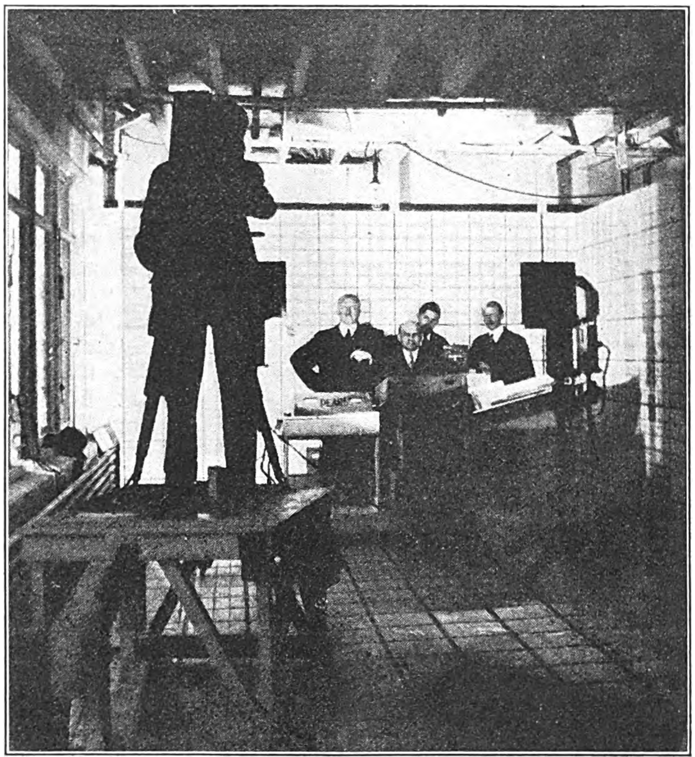
UPON Mary's return to work the store psychiatrist gave her state of chronic fatigue skilled study and found that "she acts very tired, seems exhausted, sits down a lot, leans against the counter, and seems to be a changed girl from what she used to be." Emotional causes for her chronic fatigued state were readily found. She has made but few friends, never goes out, and her only pleasures seem to center in the home of her father and mother, although her father complains a great deal about her not getting married. She is very jealous of her married sister and frequently has trouble at home with her father. When these unpleasant situations develop she indulges in a temper tantrum or appears to become ill, and thus obtains great sympathy from her mother and sister. Her "tired feelings" are another way of gaining sympathy and attention.

The psychiatrist explained her situation to her frankly, planned a scheme of emotional re-education for her, including social and recreational activities to keep her away from home, and arranged for her to have half-time employment. She needed to understand how she had been seeking pity and sympathy through appearing tired, whereas healthy emotions demanded the equivalent outlet through accomplishments and service to others.

Her entire emotional attitude toward herself, her job, her home, and life in general was altered. Her mental health improved vastly and her chronic fatigue disappeared. She is now working full time and topping her department.

According to Dr. Anderson such cases are very common, and develop easily in almost anyone. They are neither normal nor abnormal, but in the broad borderline zone.

A second important general cause of fatigue is the physical condition of the individual. The phenomenal strides now being made in general hygiene and public medicine are accomplishing near-wonders, an example being the elimination of much of the pathological fatigue caused formerly by the hook-worm in vast areas in the southern states. The growing use of routine medical inspections of employes by company physicians is also accomplishing a great deal toward avoiding fatigue which is caused by some organic trouble rather than by the work itself. Some concerns, like the Dennison Manufacturing Company, have their executives undergo complete medical examinations semi-annually.



Studying less fatiguing methods of work by means of the moving-picture camera set up in a manufactory

The activity of the ductless, or endocrine, glands appears to have a profound relationship to one's fatigue, although there is no definite single glandular mixture which is a cure-all for tiredness. This is a field both of great promise and great obscurity.

One of the most interesting aspects of the relation between bodily conditions and fatigue is the chemistry of the fatigue changes brought about by work itself. As physical work is done glycogen is consumed by the muscles, with the production of lactic acid and carbon dioxide as residual by-products. The carbon dioxide liberated is gradually breathed off, although in the case of excessively severe work some excess carbon dioxide may be stored in the adjacent tissues to be breathed away during less active moments. Lactic acid appears to be the definite cause, however, of actual fatigue caused by work. In almost every variety of steady work the lactic acid is produced more rapidly than it can be removed, bringing about a definitely toxic condition. This condition may spread to remote parts of the body. Heavy work with the right arm, for example, can readily produce an excess of lactic acid which spreads to the left arm. Working with one arm may thus tire the other arm; we also can recover from some of the fatigue of the right arm by the action of blood oxygen on the lactic acid in the left arm.

No chemical has yet been discovered which will offset these accumulations in the working body. During the World War, however, German troops were given sodium biophosphate before long marches, on the theory that this would offset the lactic acid formations.

IT is a fact that soldiers given this substance were usually fatigue-resistant, but more recent experiments have shown that the biophosphates did not produce this result by causing the lactic acid to disappear. It does help eliminate fatigue, but just how it works still is a question.

Since the body itself will attempt valiantly to remove the lactid acid, much excess fatigue has been avoided in industry by the introduction of rest periods so that the chemical factories of the body can remove much of the acid before there is such an excess that there will be the possibility of a serious fatigued state. Girls folding handkerchiefs, for instance, are least fatigued when they fold for five minutes and rest one minute. In heavier work, such as carrying pigs of iron weighing 92 pounds each, fatigue is least when each 12 minutes of work is followed by three minutes of rest. It is a paradox of mankind that by resting at the proper times they can do more work with less fatigue.

Some day a substance may be discovered which will take care of the lactic acid accumulation and take the place of rest periods. At present industry knows no such substance, hence each month sees a few thousand more workers being forced by their employers to rest during working hours.

Another paradox which is a result of the accumulation of lactic acid is that the longer workers are at work the less they accomplish. Workers who have been engaged in work eight hours a day, for example, when put on overtime which requires ten hours work a day, will do less after two weeks in the ten hours than they formerly did in the eight hours. The extra two hours work is doubly pernicious in adding to the total production of the acid, and subtracting from the rest hours during which the accummulation can be overcome.

With the shorter work week, as well as the shorter work day, large amounts of human fatigue will be eliminated—provided the worker knows how to use the added leisure time so that there will be no further accumulation of fatigue.

Time exposure record of movements of the hands of a worker. When given expert study this picture will reveal waste effort

The third general direction from which fatigue is being attacked is by adjusting the environment so that less indirect fatigue is caused. The poorly lighted factory and home of a decade or two ago were the cause of much indirect fatigue—not only eye fatigue, but muscular fatigue due to the increased tension of the muscles in giving attention. Muscular tension is a form of work which consumes glycogen and produces carbon dioxide and lactic acid, even though no productive work is accomplished. With the invention of the incandescent bulb half a century ago Edison paved the way for the elimination of much unnecessary and indirect fatigue.

In the past decade a great deal has been accomplished by applying scientific knowledge concerning the relationship between temperature and fatigue. When the temperature goes above 68 degrees, Fahrenheit, fatigue is abnormally increased, unless the cooling power of the air is increased by being set in motion. Thermostats and chemical refrigeration are now being widely used, not merely in those industries which are intrinsically heat-producing, but in offices as well.

Within the past year or two another cause of indirect fatigue has been stalked out into the open—noise. I am naturally proud of the part the Colgate psychological laboratory has had in discovering minimum allowable noise analogous to the optimum temperature of 68 degrees, Fahrenheit. Scarcely a new office or factory is designed now without noise control being given thoughtful consideration, and many old work places are being remodeled so that they approach the minimum allowable noise of 35 decibel units.

The three general causes of fatigue—poor emotional adjustment, bodily condition, and environmental forces—have been discovered and worked out, largely by men of science outside of industry. The fourth general cause has been attacked largely from within industry itself.

This fourth general cause is fatiguing methods of work. Research on this source of loss received its impetus in the United States three decades ago. For the following 20 years the investigation was kept up, largely to gain increased output rather than directly to reduce fatigue. The last decade however, has witnessed a shift in the approach, because it has been demonstrated thoroughly that the greatest output is achieved when the methods of working are least fatiguing. So, in place of trying directly to reach greater output per worker, the approach now is to reduce all possible fatigue in methods of working. Thus the output will take care of itself better than it would if one tried directly to improve the output factor alone. The aim should be to make the work as easy as possible; very greatly in contrast to the primary aim of the "efficiency expert" with his pockets full of colored pencils, who, thank goodness, is going out of fashion along with fatigue. I believe in general that England is more awake to this changed approach than is America.

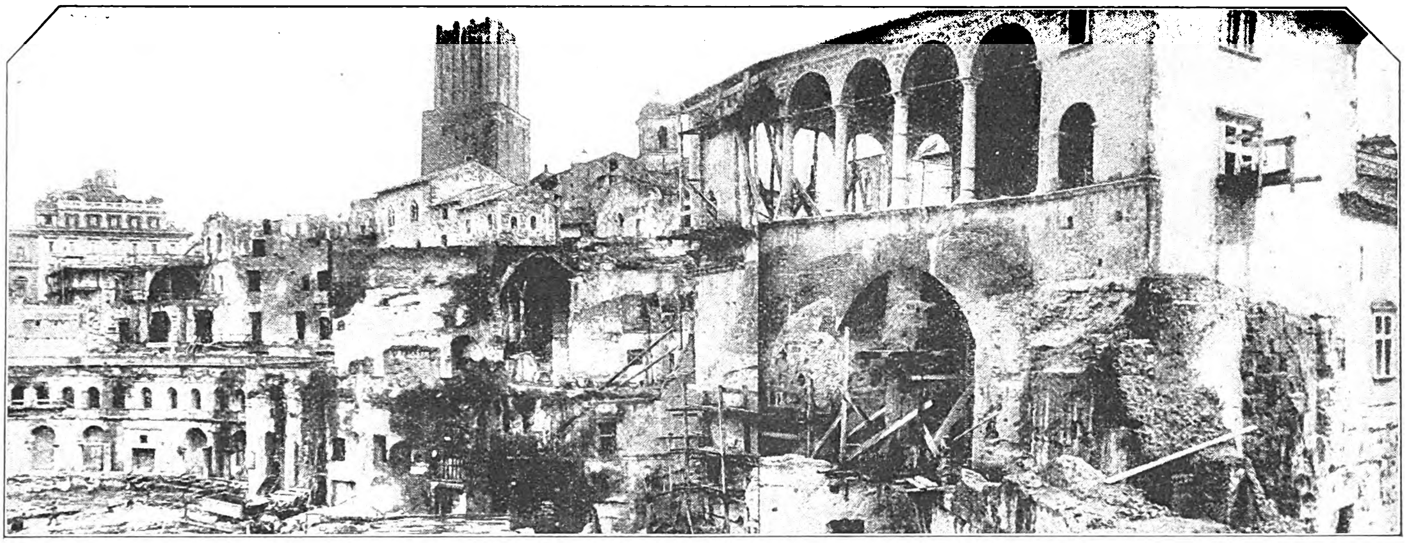
So much of the work that has been done to make working intrinsically easier is so simple and so obvious that it reflects little credit to the human mind that this has not been done years ago. Take, for example, the small metal stand on which hot irons are placed in the laundry. These metal stands are necessary to keep the cloth covering of the ironing board from being scorched while the goods to be ironed is being smoothed out. It has not been unusual for these metal stands to be six inches in height. Lifting a five-pound iron to this height an average of 60 times an hour constitutes 150 foot-pounds of work, and since the human body has an efficiency only of about 20 percent, this means the consumption of bodily energy equivalent to 750 foot-pounds. Today iron racks scarcely an inch high and sloping gently toward the point are in use, so that the iron does not even have to be lifted but is simply slid on to the rack.

In tin-plate and sheet-steel manufacture human effort is being diminished, more perhaps in American than in English mills. In feeding the heavy bars or plates to the rollers which flatten them gradually into sheet form English workers have to lift them from two to three feet. The rolls are conventionally several inches lower in American mills, and thousands of horsepower of human energy are saved daily through this difference of a few inches. An inclined runway with freely idling rollers is now being adopted to bring the sheets or bars all the way to the powered rollers by sliding the plate along rather than lifting it. Thus more fatigue and sore arms are eliminated. Similar application has been made in hand-stoked furnaces, where coal-hole doors are no longer four feet above the floor level.

Lifting, stretching, bending, stooping, sitting all day, standing all day, produce fatigue rather than effective work, and they are being eliminated with amazing rapidity in modern industry. Special departments are being established in large work-places to train new workers how to work most effectively with least waste fatigue. All these pay both financial and human dividends.

Intensive experimentation since this article was first written is now indicating definitely that a diet rich in carbohydrates and especially quick-energy sugar of the common table variety will lessen the fatigue loss which ordinarily comes from the depletion of glycogen and the accumulation of lactic acid. These experiments at Colgate University and at Temple University have shown that less fatigue is experienced when this preparation is made for exertion.

One does not have to be a carping critic to notice that the general pace of life is getting more severe during man's leisure, but one does not have to be a blind optimist to discover that the work of the world is rapidly becoming less fatiguing. Whether the diminished human strain incidental to the work of the world will compensate for the increased human strain during man's idle moments, is a question I can not answer, but is a question of grave significance.



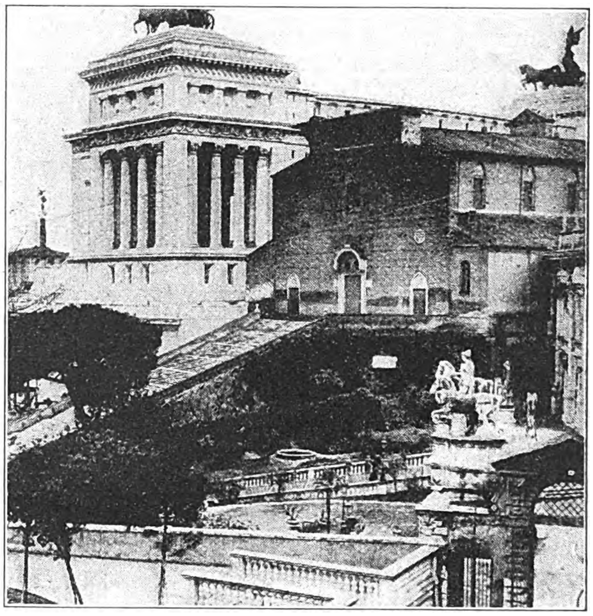
The Rome of the Caesars reappears in the modern Rome of Mussolini: The Fora of Augustus and Trajan

Rome's Slums Reveal Imperial Ruins

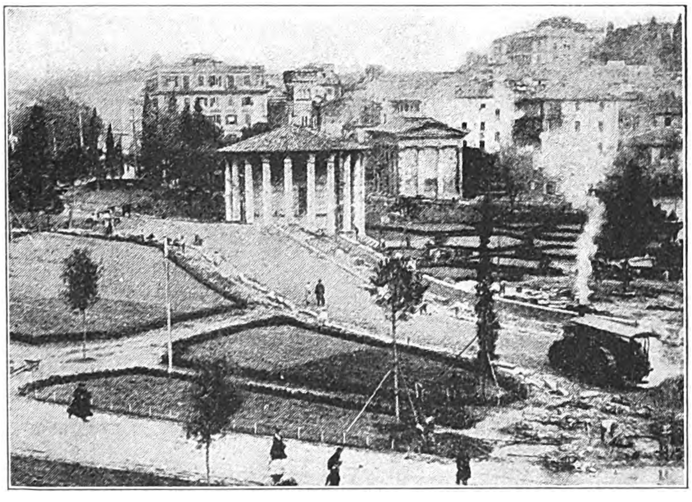
WHATEVER the Fascist government may have done or left undone, one great accomplishment stands to the credit of the great leader "Il Duce." This is the carrying on of excavations on an unprecedented scale. Excavation in a crowded city like Rome under post-war conditions presents grave problems. Where the density of population is very great, the slums can not be destroyed until the people are housed. When the ruins are uncovered they are made available to the scholars of the world, and wherever possible they are given a landscape setting.

In Italy cultural matters are receiving their due. While other countries have allowed important buildings to be sacrificed for utilitarian purposes, Italy has always looked askance at the tempter and resisted, which is hard when it is necessary to contend with national poverty.

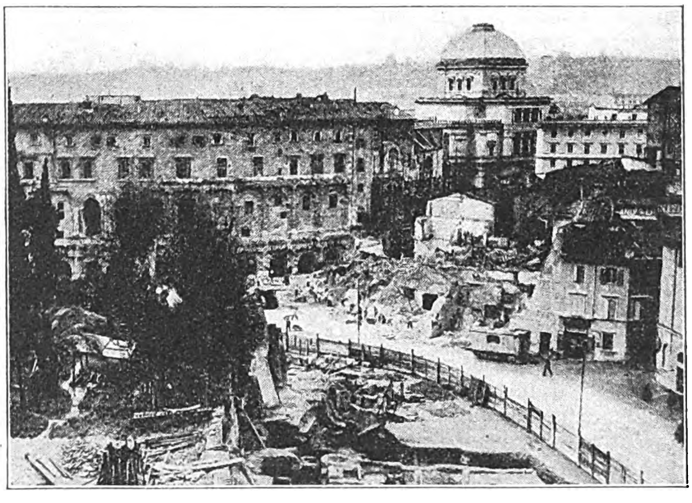
Our illustrations show how the beauty of the ancient structures has been revealed after demolition of ugly modern buildings. The Fora of Augustus and Trajan, which for centuries have been covered by later buildings, are now emerging in a remarkable state of preservation. The tower shown in the photograph above is the so-called "Tower of Nero" from which he observed the burning of Rome. Unfortunately for the story it was built in 1200 A.D. Adjacent, a great covered market with 150 shops in the Oriental style has been discovered. The "Theater of Marcellus" has been laid bare down to the foundations. The temples of Vesta and the Vestal Virgins have been freed from buildings.



A new vista opened in modern Rome, displaying the Victor Emmanuel monument towering above the Aracoeli church after demolitions



The Temples of Vesta and the Vestal Virgins now entirely cleared of old obstructions of later buildings



The Theater of Marcellus reappearing after being concealed for centuries by squalid structures now removed

The Imperious Sycamore

By WILLIAM
ALPHONSO MURRILL

> "Clear are the depths where the eddies play,
> And the dimples deepen and hurl away;
> And the plane tree's speckled arms o'ershoot
> The swifter current that mines its root."
>
> *Bryant*

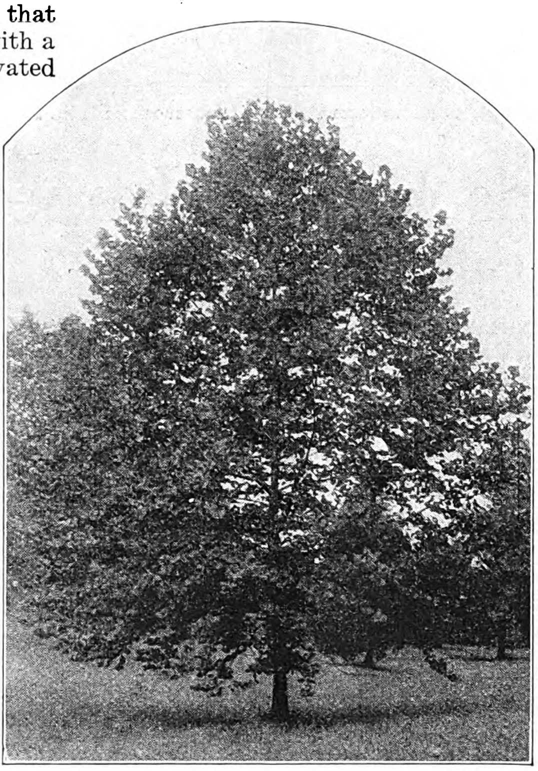
WHO has not at some time rested serenely in the shade of a big sycamore tree with scaly, white trunk and wide-spreading branches? I well remember one of these giant trees that stood alone in a fertile meadow, with a cool spring nearby and cultivated fields all about it. At noon the men would come with their horses and wagons—there was room for all and to spare—and eat their dinners while the horses finished their oats or corn and chewed contentedly at wisps of grass.

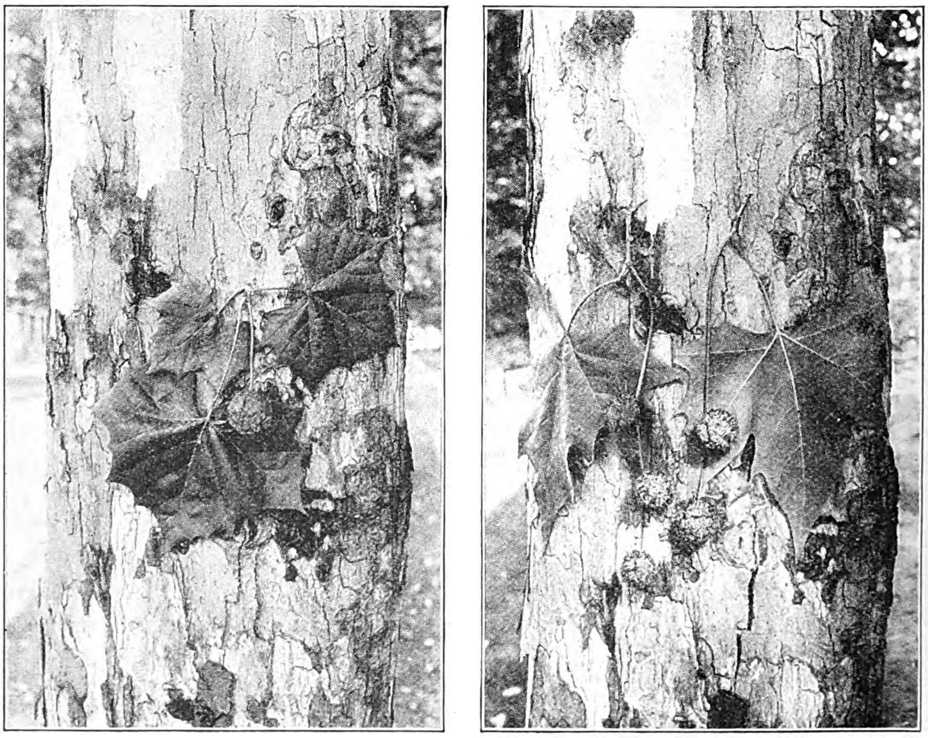
At wheat harvest and threshing time, the women-folk would meet the men at the tree and spread good things from big baskets on tablecloths laid upon the grass. Appetites sharpened by hard work would take on a razor edge at the sight, and soon a few of the older men would be taking little cat-naps while their stomachs wrestled with unusual responbilities.

THEN the "boss" would get up and squint at the sun, or peep at his big silver watch, and say, "Well, men, I reckon we've rested long enough; let's get busy."

With this scene in mind, it is not difficult for me to imagine the religious ceremonies held beneath the oriental sycamore on the plains of Persia, when splendid rugs were spread upon the ground, the roots of the tree wet with libations of fine wine, and the branches bedecked with jewels and gold. It is said that Xerxes halted his army for days just to behold a single tree of this species, which was so imperious and shapely that he had its form stamped upon a medal in order to have it before him the rest of his life.

The Greeks also venerated this noble tree and planted it in groves and about their dwellings. The botanical name *Platanus* is derived from the classic Greek name, which refers to the broad leaves. In Europe, it is known as the plane tree, while the name sycamore is always applied to a maple with leaves resembling those of the plane. In still earlier times, the name sycamore was applied to a fig tree, the wood of which was used for mummy cases. The tree which Zaccheus climbed for a better view was Pharaoh's fig, *Ficus Sykomorus*, a native of northeastern Africa. Fig, maple, plane—all sycamore; but in America it is still sycamore, in spite of the wise ones.





In low, rich land, the sycamore thrives and makes a beautiful shade tree such as the one shown in the meadow at the left. Below at left are shown bark, fruit, and leaves of the western plane or American sycamore. Below at right, of the London plane tree

The American sycamore, or western plane, is the largest hardwood tree in North America, sometimes reaching a height of 170 feet and a trunk diameter of 11 feet. A specimen at Sunderland, Massachusetts, measured 22 feet in circumference and over 100 feet in height when it was three hundred years old.

A sycamore of the Wyandotte Indians, at Sandusky, Ohio, was once the largest tree between the Alleghanies and the Rockies, four acres of ground being shaded by its immense top. After the Indians ceased their pow-wows, it became a favorite place for picnics, and then a group of young men made it a Sunday rendezvous for drinking and card-playing. The owner appealed to them to quit the place but they refused, so he burned the tree. Unfortunately, its age was never computed, but its trunk was fully 11 feet or more in diameter.

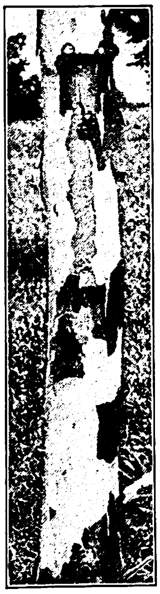
Specimens of the oriental plane have been known to have lived 4000 years. On the Greek island of Cos there is one so old and ponderous that its branches had to be supported with marble columns. It stands in a public square and is held in great veneration by the inhabitants.

Our American sycamore tree occurs wild from Ontario to Florida and westward to Minnesota and Texas, preferring open meadow land or low woods. The bark is very characteristic. On the young trunk it is smooth and greenish gray. The outer bark flakes off annually in large patches, exposing the white under bark. Near the base of old trees, the bark becomes thick, deeply furrowed, and dark brown. The trunk appears at times like an old warrior covered with battle scars.

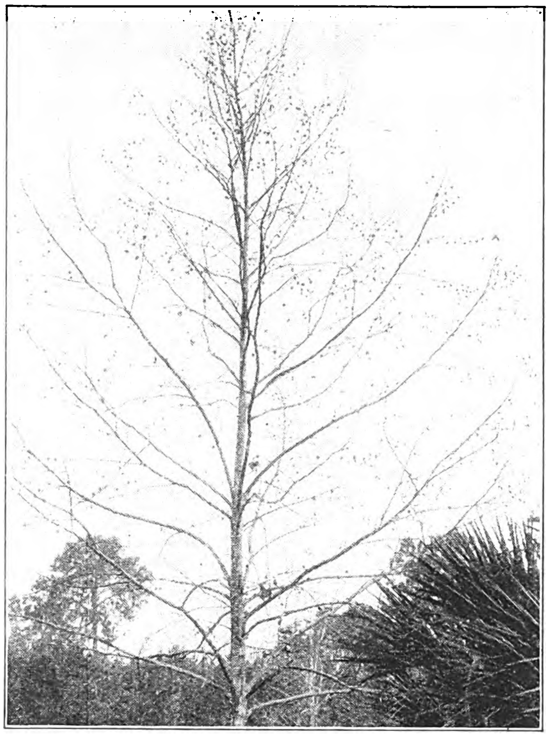
The large, simple, somewhat star-shaped leaves are sometimes seven inches broad; and the fruit is a ball an inch in diameter hanging by a slender stem during the winter and breaking up in the spring, when the small seeds are widely scattered by the wind.

THE wood is rather strong but decays rapidly in contact with the ground. It is used for butchers' blocks, tobacco boxes, furniture, interior finish, crates, tools, and rollers. The reddish-brown color is attractive, but the logs are "mighty hard to split."

The plane trees form a family all by themselves with only eight species, natives of the north temperate zone. We have one native species in the eastern United States while there are two others in the west and three in Mexico.



***At right:* peeling bark of the American sycamore. The bark that is exposed is a creamy white**

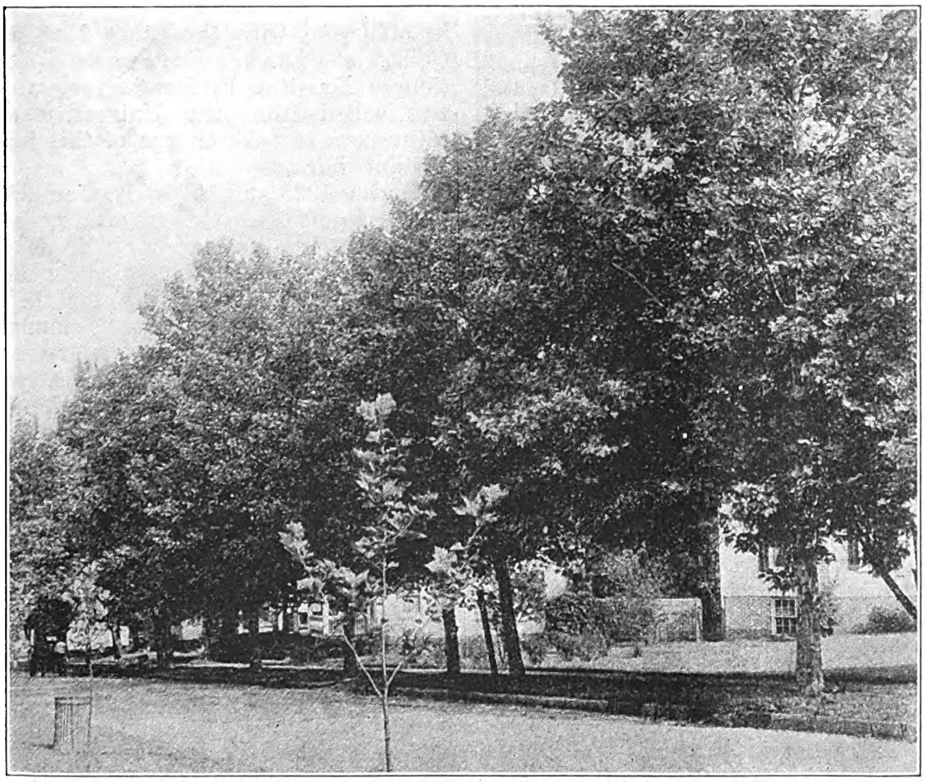


The American sycamore in winter presents an appearance of sleekness and fruitfulnes

The oriental plane was brought to Europe by the Romans from its home in southern Asia and has been abundantly planted as a shade tree in cities. A hybrid between it and our western plane, known as the London plane, is the most abundant and thrifty tree on the London streets and is very popular in this country. Our tree was introduced into England early in the 1600's and at one time the French were quite fond of it.

The sycamores, or plane trees, are all more valuable for shade and ornament than for lumber. They rank next to the oaks as street-trees, and are preferred by many. With the annual scaling of the bark, the tree rids itself of the smoke and dust of cities. The branches may be cut back as often and as freely as desired without permanent injury to the tree. The sycamore blight disfigures our tree in the spring, as well as the London plane, but the leaves come out again in time to keep off the hot summer sun.

In Paris, at least one third of all the street trees are planes. With plenty of good soil and water, these trees keep vigorous in spite of the severe conditions of city life. They are large enough for wide avenues, and they can be cut to fit the narrow streets on which they are often planted.



Either the American sycamore or the London plane makes a sturdy street tree. Often they are trimmed and shaped somewhat in the manner of hedges

For the benefit of those who find it difficult to distinguish between our native western plane and the London plane—which is still called the oriental plane by most of our nurserymen—I would say that the two trees differ in their bark, leaves, and fruits, as well as in their general form; but a glance at the bark and fruits of any doubtful tree will at once decide the question. When the London plane sheds its bark, the patches beneath are pale greenish, instead of white as in our species. The fruits of the western plane are usually borne singly, while those of the London plane are in clusters of two to four, with the balls often arranged one above another.

THE long, tapering single seeds are tightly compacted within these balls, radiating out from a hard core. The minute flowers are borne in pendulous heads containing either male or female flowers.

The leaves of the oriental plane are five-lobed, hairless, of a bright green color, and are arranged alternately on the twigs. The leaves of the London plane are usually three-lobed. The western plane—the American sycamore which is also sometimes called the buttonwood—has leaves that are more leathery and less deeply lobed than the oriental plane. Other common varieties under cultivation are the maple-leaved plane and the *variegata*, which has variegated foliage.

Vegetables That Defeat Goiter

By M. BISHOP ALEXANDER

"IODINE." This word stands out prominently on the labels attached to shipments of fresh and canned vegetables from the state of South Carolina to all parts of the nation. We are frankly puzzled. What does it mean? Why iodine? The answer is found in the wording on the label. We scan it closely and find thereon the statement that:

"South Carolina fruits, vegetables, and milk naturally contain sufficient iodine to provide for the requirements of nutrition."

The explanation of the answer and its importance is readily seen in the authoritative statement from scientific and medical sources that all animals require certain amounts of iodine to prevent goiter. The importance of the discovery and announcement that South Carolina grown products contain iodine, which in proper quantities is a goiter preventative and cure, is further indicated by the following official statement:

"THERE are 30 million persons in the United States who have an iodine deficiency and two thirds of the states are in the iodine deficiency area."

Dr. Weston, a prominent physician and baby specialist of Columbia, is credited with discovering and calling attention to the mineral value of South Carolina grown products. Observing in his practice that goiter was exceedingly rare in South Carolina and being familiar with the work of American and European investigators on the relationship of iodine to this malady, he conceived the idea early in 1923 that the foods grown and consumed in South Carolina must be responsible for the very low percentage of goiter in that state. He discussed this idea with several of his friends and finally prevailed on the General Assembly of the state to provide for a commission to study the mineral elements in foods grown or produced in the state. Thus came into being the South Carolina Food Research Commission.

GOITER is an abnormal condition of the thyroid gland caused by iodine deficiency. And since the substances secreted by the thyroid govern the growth of all cells, promote metabolism, and perform many other useful functions in the body, it is vitally important to maintain this gland in healthy condition.

In an article in our April, 1926, issue, Dr. J. W. Turrentine pointed out that America is a goitrous nation and urged the use in foods of marine algae as a preventative and cure. The present article is, therefore, a fitting follow-up, and especially since it indicates a more palatable food cure.—*The Editor.*

This commission consists of Dr. D. M. Douglas, President of the University of South Carolina, Dr. E. W. Sikes, President of Clemson College, Dr. Robert Wilson, Dean of the Medical College of the State of South Carolina, Dr. J. A. Hayne, Secretary of the State Board of Health, and two others: Dr. Weston, who acts as chairman, and Dr. R. R. Walker, Secretary, appointed by the Governor.

The South Carolina Food Research Commission established its laboratory in affiliation with the State Medical College at Charleston and under direction of Dr. Roe E. Remington, who was called from the University of Minnesota to take charge of this important work.

During 1928 and 1929, Dr. Remington examined in the laboratory at Charleston hundreds upon hundreds of samples of vegetables grown in all sections of South Carolina, for their iodine content. He found the amounts of iodine in them enormously greater than those reported by other laboratory workers in vegetables from northern, western, and, in fact, any other states.

THIS discovery in conjunction with the goiter survey made by the Field Force of the South Carolina State Board of Health, in which it was found that goiter was practically non-existent in the state, led to the definite conclusion that goiter will not occur if foods that naturally contain a sufficient amount of iodine are regularly eaten.

The results of the analyses of South Carolina foods for iodine content were broadly summarized by Dr. Mazyck P. Ravenel, in the *American Journal of*

Public Health, September, 1929, issue, as follows:

"While similar data (analyses) for the entire country are not available for comparison, it can be said that the vegetables grown in South Carolina contain from 20 to 30 times as much iodine as those produced in . . . . and . . . [two great vegetable-growing states—*The Editor.*] * * * * * It has already been pointed out that the vegetables which are richest in iodine are also richest in vitamins and iron."

The amount of iodine necessary in the daily ration in order to maintain iodine balance is variously estimated. The only careful experiment is that of Dr. von Fellenberg, of Switzerland, who was able to maintain iodine equilibrium over a period of four weeks in a man on a diet which contained 0.0143 milligrams per day (equivalent to 5.22 milligrams per year).

DR. REMINGTON has calculated the weight in ounces of some fresh vegetables from South Carolina which will yield this amount of iodine.

LEAFY VEGETABLES

Cabbage, average of 8 samples	7 ounces
Lettuce, average of 9 samples	8 ounces
Spinach, average of 14 samples	7 ounces
Turnip tops, average of 5 samples	10 ounces

POTATOES

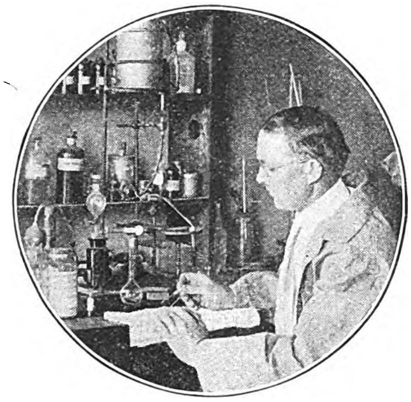
Potatoes, average of 76 samples	11 ounces
Sweet potatoes, average of 70 samples	16 ounces

ROOTS

Beets, average of 4 samples	24 ounces
Carrots, average of 8 samples	21 ounces
Turnips, average of 12 samples	23 ounces
Asparagus, average of 22 samples	27 ounces

On this basis, a diet containing four ounces of green vegetable, eight ounces of potatoes, and four ounces of root vegetable would yield 0.021 milligrams of iodine per day which is about 150 percent of the value set by von Fellenberg. Since this quantity can be, and frequently is, eaten at a single meal, it is felt that these vegetables are adequate for goiter prevention when eaten regularly.

"A sufficient amount of iodine in the food supply," Dr. Weston says, "is essential to the well-being of every individual, and if deficient there results enlargement of the thyroid gland in the neck, lowering of mental and physical ability, and ofttimes sterility.



Dr. Roe E. Remington, who directs the food research at the laboratory in Charleston

"We have learned that some foods are more valuable than others in regard to their content of chemical elements. Among the best are lettuce, spinach, cabbage, carrots, beet tops, turnip tops, kale, and broccoli." He said also that "modern methods of canning do not seriously impair, if at all, the chemical elements of fruits and vegetables."

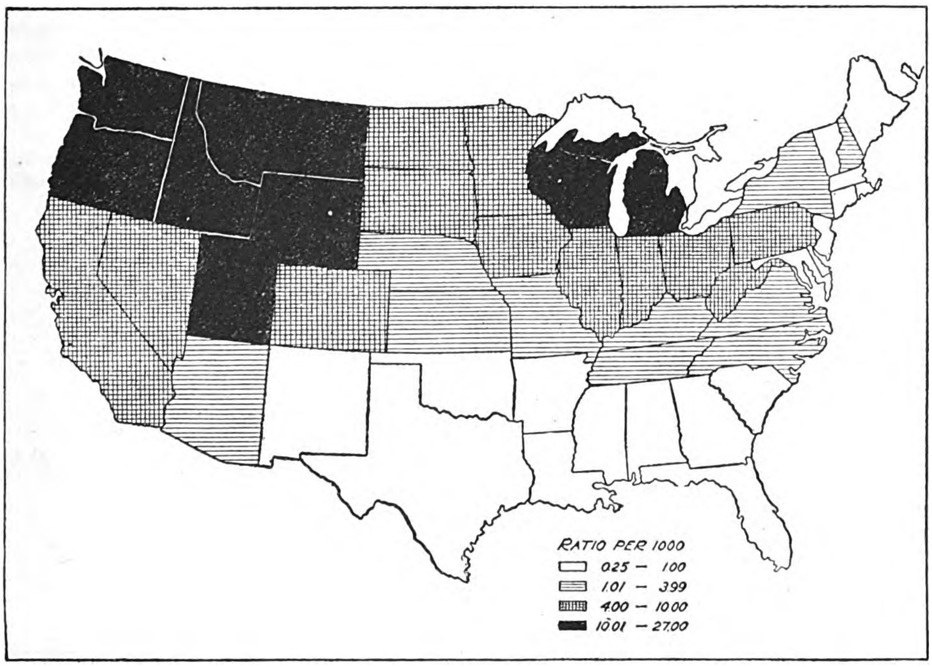
Figures compiled by the United States Public Health Service show that the goiter incidence is high and is a serious problem in large sections of California, Connecticut, Colorado, Kentucky, Illinois, Indiana, Idaho, Kansas, Louisiana, Minnesota, Michigan, Massachusetts, Missouri, Montana, Maine, New York, Oregon, Pennsylvania, Utah, Virginia, West Virginia, Washington, and Wyoming. The northwest has a high incidence.

From an historical standpoint, goiter is one of the most ancient and interesting diseases. It was a health problem in China 15 centuries before Christ, and it was then a custom among the Chinese to feed thyroid substances from animals and the ash from burnt sponges and other materials, now known to contain iodine, in the treatment of goiter.

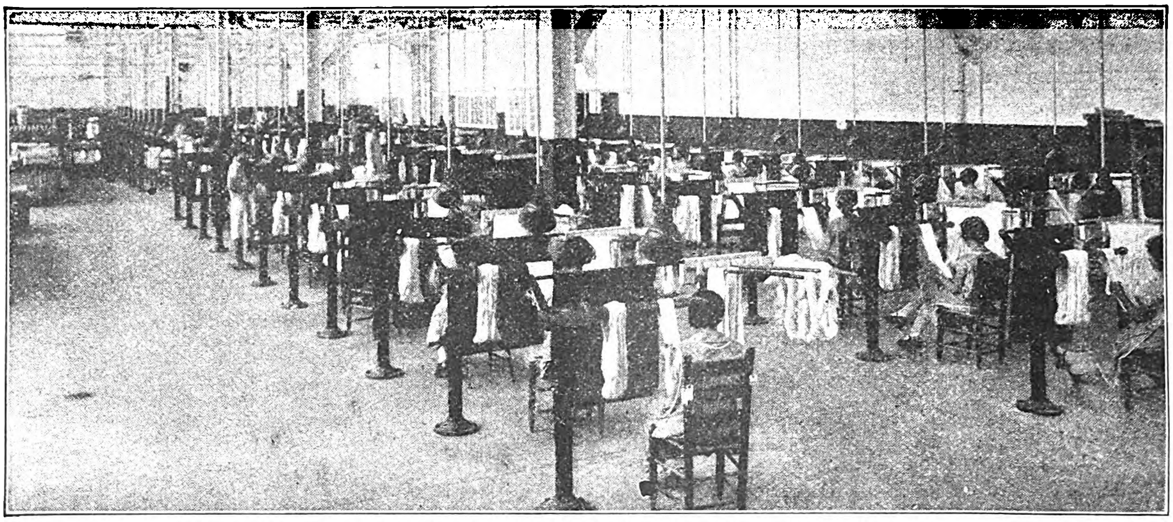
Iodine first was discovered in 1811 by Courtois, a saltpeter manufacturer of Paris, and its first deliberate use as an element in the treatment of goiter was by Coindet, a physician of Geneva, in 1820. Thirty-two years later, Chatin directed attention to the fact that goiter was more prevalent in regions where soil and water were low in iodine content. Between 1922 and 1927, Dr. J. F. McClendon, Professor of Physiological Chemistry in the University of Minnesota, published a series of articles which were largely responsible for definitely crystallizing the relation between a deficiency of iodine in the food supply and the incidence of goiter.

THE South Carolina Food Research Laboratory was made ready in 1928 and after a number of analyses had been made it was decided to seek expert advice as to checking the equipment, methods, and laboratory results. In a conference in Chicago between Morris Fishbein, M. D., editor of the *Journal of the American Medical Association* and a Contributing Editor of the SCIENTIFIC AMERICAN, Dr. Clifford Grulee of the University of Chicago, and Dr. Weston, all agreed that, because of his international reputation and high standing among chemists, Dr. McClendon was the man for the task. Negotiations were entered into with him and later he visited the laboratory. After carefully checking the apparatus, methods of analysis, and the results, he enthusiastically stated that he believed the solution to the serious goiter problem had been found. In 1929, he spent his summer vacation in the laboratory and again freely confirmed the results obtained there.

Since the endorsement of Dr. McClendon, the reports made by the laboratory under Dr. Remington have been accepted without question by the American Medical Association and the American Chemical Society. Dr. Mazyck P. Ravenel, Chairman of the editorial committee of the *American Journal of Public Health*, has also expressed the opinion that the laboratory has "found the solution of the gravest health problem confronting the people of the United States."



Ratio of simple goiter found in men examined for service during the World War, based on 2,510,701 examinations. From U. S. Public Health reports



Inspecting hanks of artificial silk in a large American plant

Mechanical Silkworms

By GRACE LOCKHART

"WILL you walk into my parlor?" said the spider—and man walked in! Ever seeking new worlds to conquer, he carefully examined "the prettiest little parlor that ever he did spy." And then he walked out—to compete with his spider-host.

Silk is a liquid substance secreted from their food by various insects, of different families, but principally by the spider and the silkworm family. The silk of the spider family is of most exquisite quality, and is the finest spun filament produced in nature. From time to time it has been used to make fragile silken articles. But the small amount of the product and the difficulty of controlling spiders have made its commercial use in large quantities impractical.

YEARS of patient experiment followed by many practical tests resulted recently in perfection in the scientific laboratories of the American Bemberg Corporation at Elizabethton, Tennessee, of the closest approximation yet made by man to spider filament.

The diameter of spider filament measures 0.00023 of an inch, the diameter of the man-made filament 0.0004 of an inch. An ordinary newspaper sheet is nine times the thickness of a single filament of the man-made product, and in a single pound there are 4227.5 miles of filament. Out of it are being woven the filmiest of laces, the sheerest of chiffons, exquisite fabrics for modern womankind—at once beautiful and enduring.

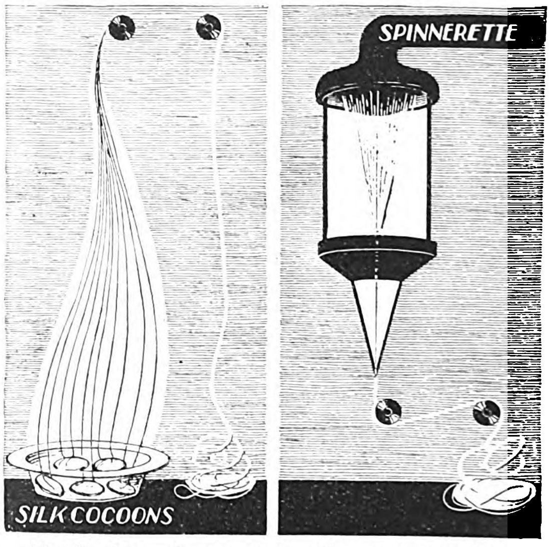
The size of yarn is designated by the term "denier," this yarn being 15 denier. The inventive mind, however, is seldom content to rest on the laurels of past achievements, and it is said that a 5-denier yarn was successfully spun in the Elizabethton laboratories to the astonishment even of the spinners themselves. It was so fine that those who watched could not see it. The hand could feel it, but the filament was invisible to the unaided eye.

THE basic raw material used in the manufacture of the yarn is cotton linters, that very unprepossessing gray fuzz that clings to the cotton seed after ginning. By a stretch-spinning cuprammonium process of manufacture, unnumbered tons of linters, formerly a waste product, are now being transformed into soft, shimmering multi-filament strands of Bemberg. So similar to silk thread, both in internal structure and external appearance is the produced yarn, that, woven into hosiery or into fabrics, experts cannot by sight or touch distinguish between the man-made fiber and the product of the silkworm.

Curiously, an order was recently received, the first of its kind recorded in history, for man-made spider webs. They were woven by hand with infinite patience in the laboratories of the American Bemberg Corporation and used for decorative purposes in "Old Algiers," first unit of a new chain of restaurants at Broadway and 102nd Street, by the well known restaurateur, William Childs. The interior reproduces an old Algerian village and in this very interesting manner modern scientific skill was called upon to heighten the illusion of antiquity by supplying artificial spider webs with which to decorate odd corners of the restaurant.

The cuprammonium process of manufacturing these ultra fine filaments was perfected after patient investigation of the interior of the silkworm and careful study of his spinning technique. The silkworm's product is made from the cellulose of mulberry leaves, the man-made fiber from cellulose of cotton linters. The dissolved cellulose of linters is drawn through tiny perforations in the mechanical "spinnerette" exactly as it is drawn through minute orifices called "spinnerettes" in the neck of the silkworm.

From the point of view of volume, however, the machine distinctly has



Similarity of natural silk and artificial silk: a number of fibers make one thread the advantage. One silkworm during its lifetime can produce from two to six filaments of silk thread about 1000 yards in length, whereas the machine produces 112 filaments at one time and in a thread that is endless. Cuprammonium yarn produced last year throughout the world would more than reach from the earth to the moon —a mean distance of 238,857 miles.

In the chemical process by which these miles of glistening filaments are produced, the linters are washed, bleached, and then dissolved in a solution of ammonium copper oxide. After being aged, the solution is filtered and pumped to the spinning machine. As it passes through the spinnerette into a fixing bath the surplus stretch is taken out of the filaments before they unify so that they emerge in a thread of unusual strength and pliability.

DUE to the minute accuracy of the machine, it has been possible to improve upon nature's product. Microscopic cross-sections of silk threads and threads made of Bemberg show an amazing similarity of structure, with greater uniformity of filament structure in the man-made fiber. Fiber and fabric have the same appearance, the "hand," texture and bloom, the scroop and crunch, and the subdued luster of pure silk.

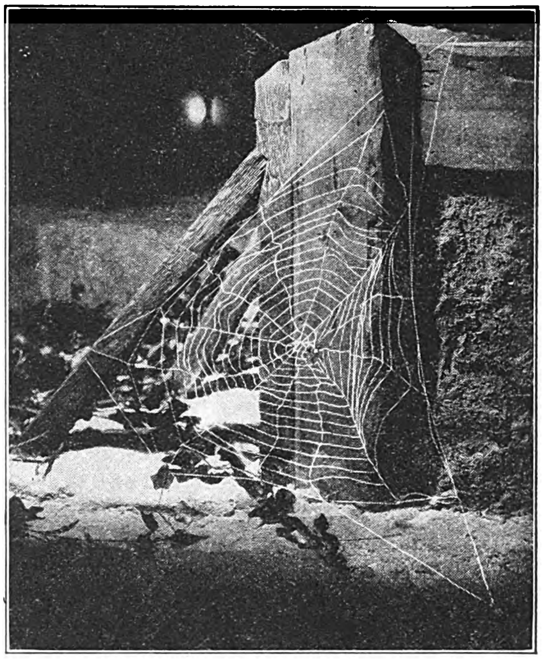
Besides the cuprammonium method there are three other important processes of manufacture used today for making these yarns. They are known as the viscose, cellulose acetate, and nitro-cellulose processes. The resultant fibers and fabrics woven from them differ considerably from each other in characteristics and qualities. The volume output, known generally to the public as rayon, is made by the viscose process, sometimes of wood pulp, sometimes of linters. About 85 percent of the chemical yarns manufactured in the United States are made by this process.

The United States has invested more than 120 million dollars in plants for the manufacture of synthetic yarns, while the world investment is estimated to be one and a quarter billion dollars. The total world production last year was over 468 million pounds, of which the United States, both the largest producer and the largest consumer of chemical yarns, produced more than 100 million pounds. Less than half a century old, man-made yarns have been developed and perfected until today they rank in importance with the ages-old silks, cottons, woolens, and linens.

Looking backwards, we find, in the year 1734, an ingenious Frenchman named Bon making hosiery and gloves out of spider web; not, however, with spectacular success and not, certainly, for mass consumption. A century later one George Audemars of Lausanne, Switzerland, obtained a patent for transforming dissolved nitrocellulose into filaments which he called, descriptively, "artificial silk."

Efforts to produce this material, however, did not assume commercial importance until 1884, when Count Hilaire de Chardonnet, called the "father of the rayon industry," perfected a practicable process for manufacture. His achievements were viewed by the public for the first time at the great Paris Exposition of 1889, and excited much interest.

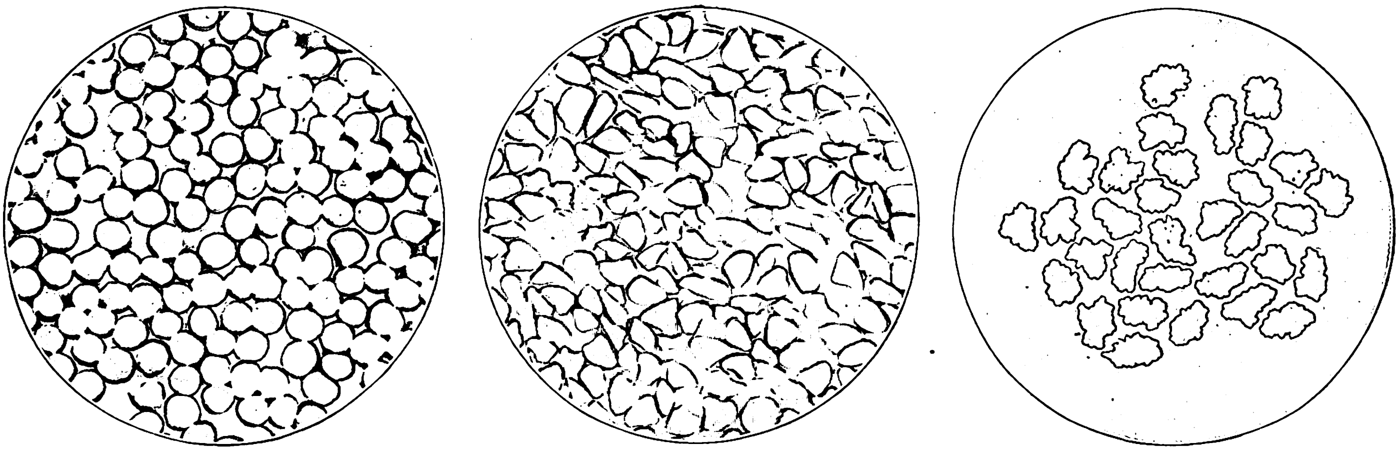
COMMERCIAL production of synthetic yarn was begun in Germany, in France, and in Great Britain at the opening of the 20th Century. Plants were established in Italy in 1908, in Holland in 1912, and in the United States in 1910. During the last five years constant experiment with resultant improvement in technique and the rapid development of new uses for chemical yarns has resulted in a spectacular increase in their production. In 1927 the world production was 269,822,000 pounds. In 1929 it had increased to 467,330,000 pounds.



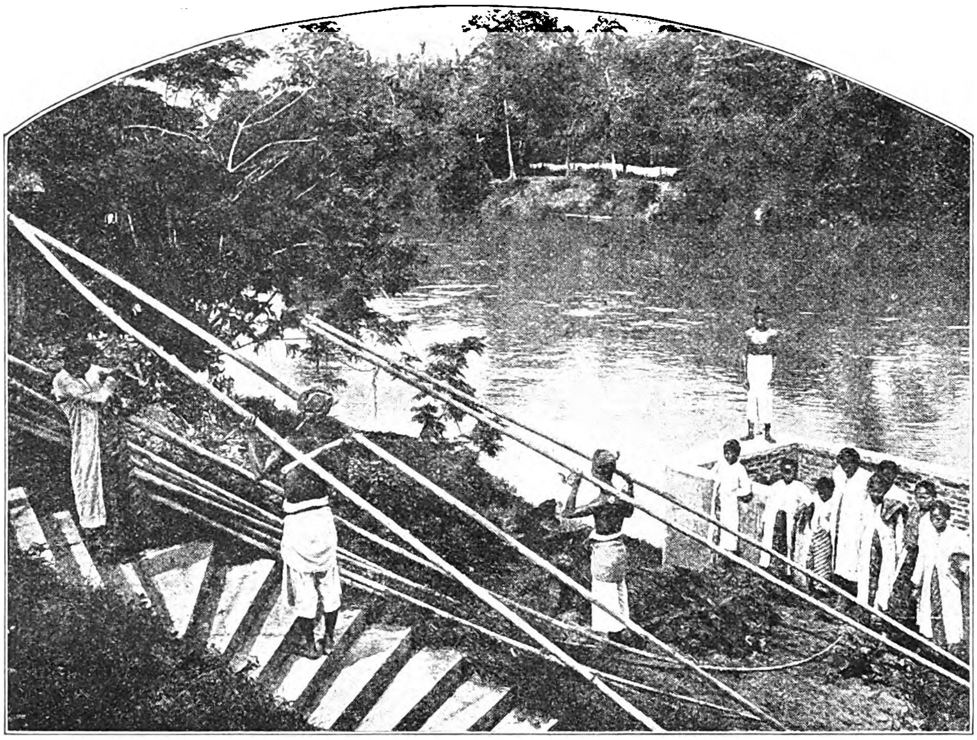
Spider web of man-made filament in the courtyard of a New York restaurant

The establishment of the American Bemberg Corporation plant in 1927 in Elizabethton, within two years time transformed a sleepy little village of 2400 inhabitants into a flourishing industrial town of 12,000. Thousands of mountain folk on foot, on mule, and on horseback followed in the wake of science. Thousands of men and women set themselves the task of feeding and tending the giant mechanical silkworks. Thousands who had watched the spider spin his silver web in the blue-green shadows of southern hills, engaged in the task of spinning, with steel fingers, the same infinitely fine filaments at the foot of Smoky Mountain.

The spider toils on, weaving nets to trap his prey. The industrial chemist also toils on, weaving silken garments for the Colonel's Lady and Judy O'Grady, displacing the old with the new, displacing spider and silkworm with men and machines.



Inspection under the microscope of the internal structure of natural and artificial silks shows the filament contours. At the left is Bemberg filament; in center, natural silk; and at right, viscose rayon—all magnified 300 times



Transporting bamboo to the market. Often it is floated down the river, then carried by the natives

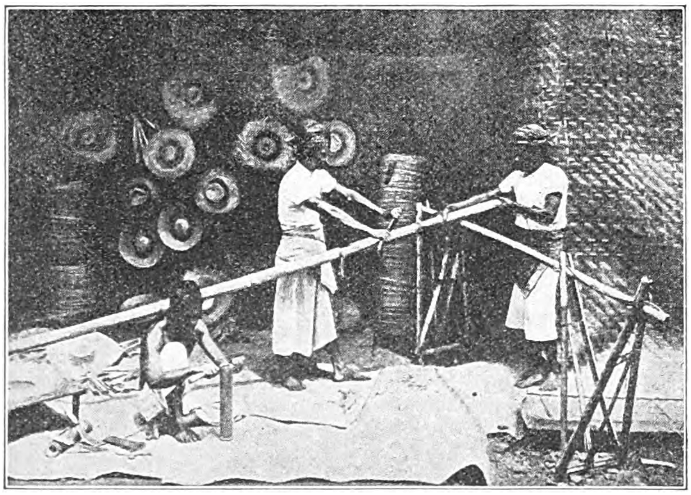
By HENDRIK de LEEUW

'Panama' Hats From the Pacific

THE American farmer who uses the old-fashioned floppy "straw" hat does not realize that he is perhaps indebted to the deftness of slim brown hands in the far off Dutch East Indies for the sunshade that protects him from the blistering sun. Likewise, milady of New York, London, or Paris may not be aware of the fact that her blocked, or basket-weave, or rough "straw" is from the same source. Hats of many different shades and colors, in almost countless models and shapes, and of a variety of materials—15 to 20 millions of them—are made yearly in these distant islands for the markets of the world. The United States purchased over 8,000,000 of one kind in 1927.

The Dutch East Indies are richly endowed by nature with the materials of which these hats are made. Bamboo in many varieties is found in Java, Madura, Bali, and Lombok; rattan in the outer islands; pandanus in Sumatra; lontar palm in the eastern archipelago; and various grasses in many localities. Pandanus grass has long, strong leaves and is famous for its use in the Sumatra solid plaiting. Lontar leaves have long been used by the natives as writing paper, while in the Celebes and in Borneo, the natives have used *foeja*, or beaten bark, in their crude cloth and hat manufacture. In fact, the various fibers and growths of the jungle play an important role in the lives of the natives. The young roots of the sago palm and twigs of the liana serve as material for baskets, mats, and crude harvest hats; unopened leaves of a wild banana are used in making garments; and other fibers, leaves, and bamboo strips are fashioned into fishing nets, cages, ornaments, war garb, old-fashioned payongs (umbrellas), and so forth.

The hat industry, so the story goes,



Bamboo is harvested before the branches bud, cut into lengths of six or seven joints each, and then scraped

The natives cut the bamboo into blades and these are split again and again until divided into thin strips dates back to the 1850's when a Chinese migrated to the Dutch East Indies from the Philippines, at that time the center of the hat industry. He settled in Tangeran, in Java, about 14 miles from Batavia, and started in a small way the manufacture of so-called Panama hats. As the new industry showed signs of a lucrative future, a Frenchman named Petitjean took it up on a larger scale. Rivalry ensued and the competition stimulated the growth of the business until it had spread to all the islands.

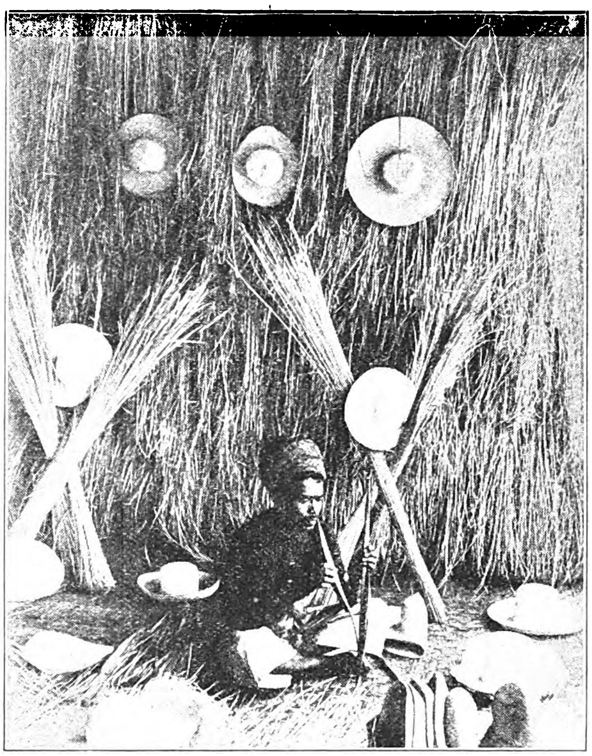
THE hats originally produced were rather crude, but as the industry developed, more up-to-date methods were adopted although the greatest part of the work is still carried out in the homes of the natives. The whole family assists in the work, the men usually preparing the material while the women and children do the plaiting of hats. The men do the final stitching and ironing.

In making hats of bamboo strips, the bamboo stalks are cut before the branches bud and are carefully handled, since bruising causes red spots. Those that are floated down the river are used for inferior hats because they reeive many injuries. And although bamboo is plentiful in the islands, most plaiters buy it in the markets.

In preparing bamboo for plaiting, the stalks are first cut into pieces six or seven joints long and the green rind is removed. These pieces are exposed to the sun and the dew of night to whiten them. The following day they are split into blades three or four inches wide. These, in turn, are split into laths about one inch wide and the splitting is continued until finally five to nine strips are obtained from one piece. After a further exposure to the sun and dew—to make the strips flexible—they are divided into "straws" by means of a wooden or a bone knife.

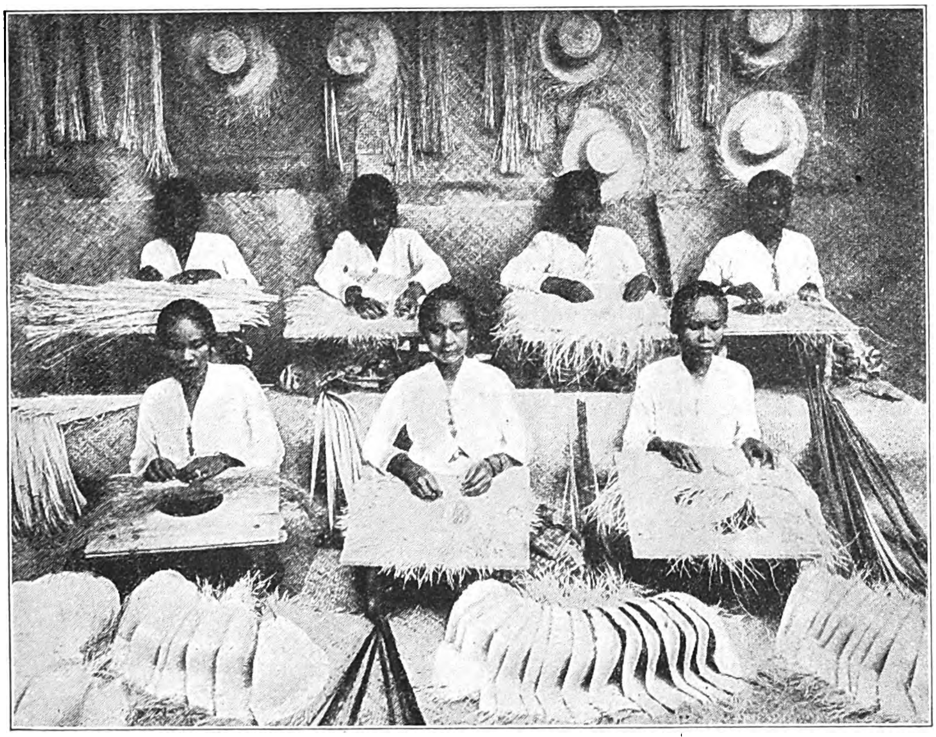
At this stage, a peculiar thing happens. The prepared bamboo "straws" are sent to Europe for bleaching by a jealously guarded secret process, and are then returned to the islands for plaiting.

The pandanus grass leaf is prepared for plaiting by removing the midrib, cutting the halves thus formed into strips, and removing the outer surface of the leaf. The strips are then boiled for a night, dried, and also sent on a trip to Europe for bleaching. The grayish fibrous leaves resemble raffia at first, but when finally ready for plaiting, they assume the creamy white color of the Panama hat.



Further splitting. Prepared material, together with several finished and one unfinished hat

A hat of ordinary quality generally takes about two days to manufacture. One of higher quality may require four days or even longer. In plaiting them, the crown is begun first on a round board in which a flat-headed nail has been driven as the central starting point. Only the most experienced plaiters do the work on the apex of the crown. As the plaiting progresses, the hat is placed upside down on a board through which there is a hole large enough to receive the crown. The "barrel" of the crown is then plaited within this hole, which acts as a pattern or guide for the size. When this is finished, the brim is plaited flat or curled, as may be desired. Finally the hats are washed, air dried, and packed for shipment.



Native women doing the intricate work of plaiting, at which they are very proficient. Their hands move so fast that one can hardly see their movements

Besides going to countries of the western world, hats from the Dutch East Indies are sold to Australia for the fruit pickers—in this case being one yard in diameter, to the Orient in fez shape, to Singapore for children, and to many other places in the form of topees, blocked, unblocked, bleached, or colored hats. Many of them are lined with inserted hats of coarser variety, the brims being woven together at the edge.

IN the Dutch East Indies, there are as many styles of home-made hats as there are tribes. One finds in some localities, hats with beaded borders; in others, hats beautifully embroidered with gold or other precious metals and used by native princes. Some of the Dajak tribes make plaited hats with intricate decorative patterns worked into them. Some of these are worn only by persons of high standing or are given the dead to take with them to "Apo Kasan," the Dajak hereafter. The *songko,* a flat, stiff, bamboo-plaited cap—also sometimes made of lontar fiber—is the original headgear of the certain tribes of Celebes and is worn by grandees and officials. It is often elaborately embroidered with gold and silver braids. Select specimen's of the native hatter's art become heirlooms and are presented to married couples as prized gifts.

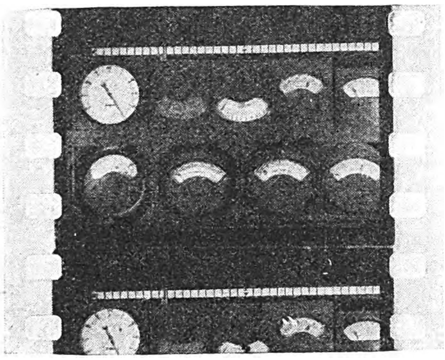
Movie Camera as an Aid in Testing

ENGINEERS, whatever their field of operations, often are required to carry out tests of various kinds where it is necessary to read a number of meters simultaneously. In such cases, several men may have to be employed to do the reading at each recording period but the results obtained are frequently difficult to coordinate. Should the test extend over, say a six-hour run, and five-second or half-minute readings be required, then the observers would probably make trouble.



Section of movie film showing how meters are read by photography

This is the substance of an address presented to the Association of Certificated Mechanical and Electrical Engineers, of South Africa, by Mr. L. B. Woodworth. To overcome the many difficulties, he advocates the use of a camera, preferably a movie camera, for taking the readings. The accompanying illustration, obtained from Mr. Woodworth, will show at a glance the effectiveness of his method, and anyone familiar with tests of this nature can realize its many possibilities. As will be seen, the record obtained in this manner is permanent and may be filed away for reference at any future time. With the addition to the set-up of an ordinary clock or watch and a placard showing the date, so arranged as to be included in the picture, the resulting record would contain all facts necessary to be known, perfectly co-ordinated, and absolutely accurate. And one man can do the job in but a moment at each recording period.

Fire War on Pests

FIGHTING one forest menace with another is the solution for winning the war with bark beetles, according to David Arrivee, assistant supervisor of Targhee National Forest in Northeastern Idaho. Fire was the medium he and the Targhee forest officers used in exterminating the insects which are as deadly to the trees they infest as fire itself. He explains, in *American Forests and Forest Life*, magazine of the American Forestry Association, the method employed and compares its advantages of speed and reduced costs to the tedious felling and burning of infected trees.

Yellowstone National Park itself might have been infected by the insidious enemy had the officers of Targhee National Forest not been successful in their crusade.

"Unlike fire," points out Mr. Arrivee, "insect infestations send up no black and pungent-smelling smoke signals. The myriads of little black beetles, each smaller than a grain of wheat, show themselves only during the short midsummer mating flight, attack a tree at the rate of one pair for each of the hundreds of pitch tubes that usually exude from the entrance holes on the trunk, and then attend strictly to business under cover of the bark."

Bark beetles work swiftly both in killing the tree attacked and in spreading to others in the vicinity, and their damage is often as deadly as fire. In the race for winning the territory back from the enemy the foresters hit on the scheme of fighting with controlled fire.

"In this treatment," says Mr. Arrivee,

In the war against the bark beetle, the man whose job it is to exterminate the pests, is equipped with a small pump tank of kerosene. He sprays this liquid on the tree, lights it, and burns out the insects "oil is sprinkled evenly over the trunk of a tree with a small pressure pump carried on the back. The oil is lighted and the tree trunk is enveloped in a sheath of flame, which chars the bark and cooks the beetles, larvae, and eggs. Directing the oil stream quickly up and down the trunk, the treater gives it an even, thin coating, with an extra dash around the base where the bark is thick. Striking a match, he tosses it at the foot of the tree and with the oil stream carries the flame up and around it, placing an additional amount of the fuel as high as he can reach up tall trees to make the fire 'crown' through to the tip."

That this method is economical as well as efficient is borne out by Mr. Arrivee's statement that, "Computing the cost of equipment, labor, hauling, team hire, fuel, camps and supplies, the 1929 Targhee projects cost forty-six cents a tree, compared to the reported cost of $1.70 a tree on similar projects where the method of cutting, piling, and burning is practiced. Also, the oil-burning treatment takes only about one tenth as much time."

The tree, of course, is killed but the insects would do the job anyway and, were they not checked, would multiply and kill many other trees.

Air Traffic Control Systems

THE Aeronautics Branch of the Department of Commerce has appointed a special committee on standard signal systems for airports, in an endeavor to bring about uniformity in such systems. The results of the inquiry so far have emphasized the facts that the existing systems leave much to be desired and that they lack uniformity.

Sirens are in use at a few of the larger airports and are quite effective in conveying information to ground operators. Sometimes varicolored flags are in use. At a western airport, red and green semaphores are operated from a control tower. The Very pistol, red and green illumination of the wind tee, and blinking of the boundary lights are night-signaling methods.

The majority of those canvassed in the inquiry stressed the value of radio communication.

One authority proposes separate areas for landing and taking off, and stop-and-go lights at the head of the take-off runways. An airport engineer favors a visual system complete in itself and aural and radio signaling as auxiliaries. A system employing steam jets to be illuminated at night will be installed at an eastern airport. At another in the middle west it is proposed to install a panel of lights which will indicate the number of planes in the air at any particular time.

The committee invites suggestions from all persons interested in this topic.—*A. K.*

Elmer A. Sperry

ON June 16, Elmer A. Sperry, who has been ranked second only to Thomas A. Edison in the field of American invention, died in Brooklyn, New York, at the age of 69. During an active life, he had taken out nearly 400 patents. Among these, the most notable, perhaps, is the Gyro-stabilizer for ships, a device which he later modified for use on airplanes and aerial torpedoes.

He invented the Gyro-compass which is used widely on ships of many nations, and "Metal Mike," the automatic steersman which keeps a ship on a set course. He applied the gyroscope to airplanes to give pilots an artificial horizon for flying in fog. Some of his other inventions are: systems of street lighting, lighting system for motion picture projection, high-powered searchlights, and electro-chemical processes.

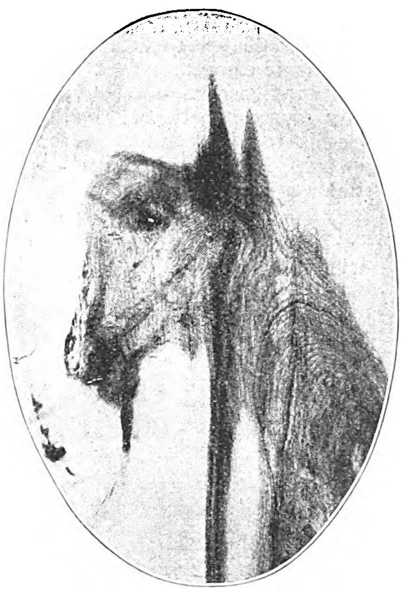
Mr. Sperry was President of the Sperry Gyroscope Company until January, 1929, when he sold out. He was the founder and a charter member of the American Institute of Electrical Engineers and of the American Electro-chemical Society. He was also a member of many of the most important scientific and engineering associations and societies in this country, and had received many awards and medals both at home and abroad.

New Alloy in Plumbing Industry

THE British discovery of a new ternary-lead alloy—with which it will be possible to produce sheets and water pipes superior to and cheaper than those made of pure lead, and having only two thirds of the weight, has been announced. The new alloy, which was discovered by the British Non-Ferrous Metals Research Association in the course of investigations to find the cause of breakdowns in lead cable sheathings, consists of 98.25 percent lead, 1.5 percent tin, and 0.25 per cent cadmium. Tests show that it possesses the following advantages over pure lead: Pipes made from it will be cheaper, having only two thirds the weight; its ultimate tensile strength is 84 percent greater; its resistance to vibration is 217 percent greater; in certain corrosive waters its resistance is superior to lead iself.

A ton of ternary alloy costs 10 percent more than lead, taken on the basis of metal costs, but the ternary alloy will give 33⅓ percent greater length and superior mechanical strength of pipe, for the same weight of lead, so that there is a gross margin of saving amounting to 23 percent. There is a small extra manufacturing cost but the net savings make the alloy pipes considerably cheaper. Another saving will be on carriage charges. Lead sheets are subject to "creeps." The tin-lead alloy, which has a greater resistance to corrosion, is 300 percent less ductile than lead.

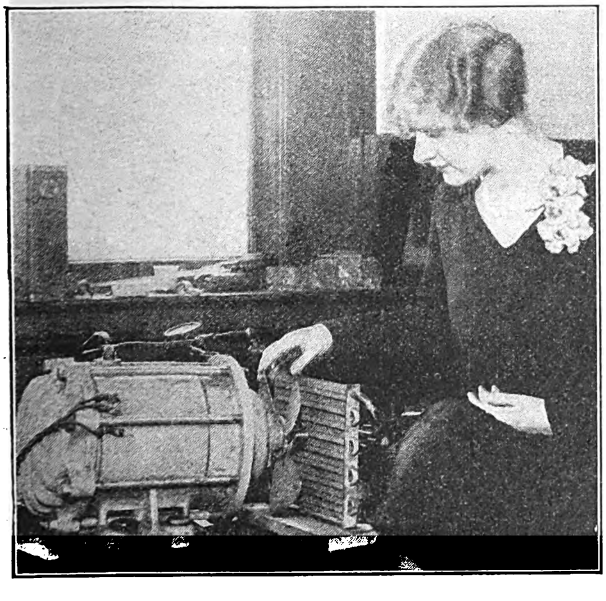
There seems to be good reason to believe that this alloy will take the place of lead pipes and sheets throughout the world.—*A. E. B.*



This curious animal portrait, found on a maple board in a shop of the Forest Products Laboratory, Madison, Wisconsin, was produced solely by a natural discoloration around a cluster of knots. The teeth and the high light around the eye were produced by reflections from the light used by the photographer

Food Poisoning

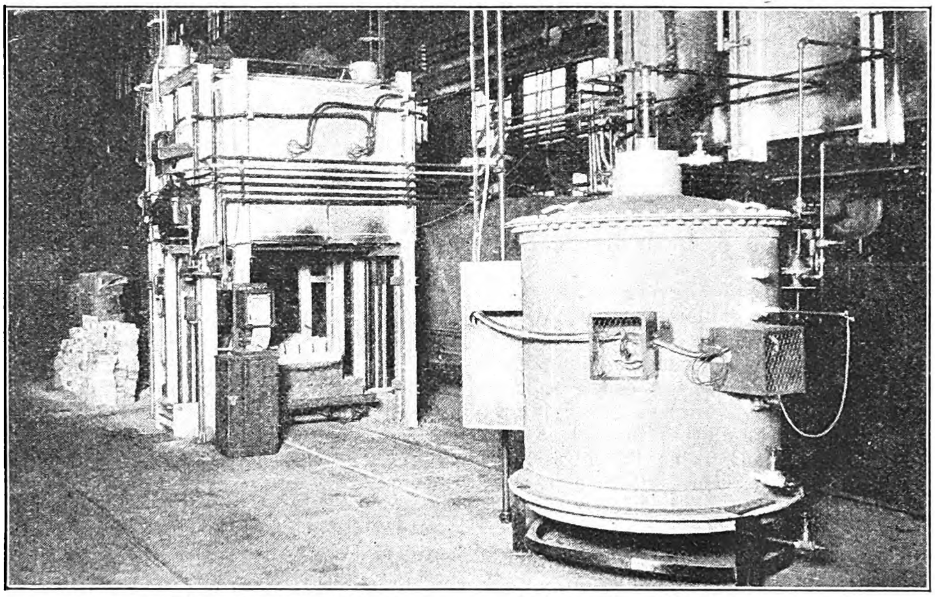
A CONSIDERABLE number of people in Chicago were poisoned after eating cake. It was formerly thought that food poisoning was due to the development of strange chemical substances in the bowel. Recent investigations have proved, however, that the effects are almost invariably due to bacteria or bacterial production. The most serious type of food poisoning is that following the ingestion of the botulism germ or of its poisons. Investigations made by Prof. E. O. Jordan of the University of Chicago have shown that other forms of bacteria likewise produce such



No shaft or belt turns the fan on the new Westinghouse electrical refrigerator. Powerful cobalt steel magnets, a recent development of the company's engineers, whirl the fan around by magnetic induction, through the end bell of the motor housing. The motor armature has no mechanical connection with the outside, as it runs in bearings within the housing. This construction allows the motor housing to be permanently sealed

changes. When samples of the cake were brought to the laboratory and subjected to bacteriologic examination, it was found that a staphylococcus of the type that ordinarily causes infection of the skin had developed a toxic substance in the cake and when a filtrate containing this toxic substance was swallowed by human volunteers they developed nausea, dizziness, and prostration, exactly as did the people who ate the cake.

In this experiment 80 feeding tests were made on 58 male volunteers who were mostly between 20 and 30 years of age.



Electric annealing furnace and Electrolene producer

In an attempt to control the psychology of the situation some of the volunteers were given milk without any of the toxic filtrate. Usually there was slight rise in temperature, then dizziness, loss of appetite, weakness in the legs, headache, pain in the abdomen, nausea, and vomiting. Following this there was looseness in the intestinal action and then gradual recovery. Such conditions emphasize anew the importance of careful sanitation in the preparation of food.—*M. F.*

Seamless, Endless Tube Made by Electrolysis

BY forever pulling off the metal sheath as it is deposited out of solution on an iron alloy core, Prof. Jean Billiter of the University of Vienna makes seamless and endless tubing of copper, zinc, and iron.

But this, his first method, was too slow, he told the American Electro-chemical Society in St. Louis recently; only a few inches of tubing could be made in an hour. Therefore a faster method was devised.

A lead core is now run continuously through the solution and metal is deposited on it as the core moves. Then the soft lead is melted away and the copper, zinc, or iron tubing left. A tube five yards long and nearly one tenth of an inch thick can be made in 24 hours.—*Science Service.*

"Electrolene" to Supply Cheap Hydrogen

ELECTROLENE! There's a new, synthetic name for a brand new arrival in the industrial chemical family. An appropriate name it is too, for electricity is its daddy. Electrolene is the name given by F. P. Wilson, Jr., of the General Electric Company to the new industrial gas produced by the latest ingenious contrivance of the famous Schenectady laboratory. The machine will also produce carbon monoxide or carbon dioxide or a mixture of all of them.

Briefly, the Electrolene producer is an electric furnace in which hydrocarbon gases, with or without steam, are partially decomposed to produce mixtures having carbon monoxide, hydrogen, and carbon dioxide as the main constituents. The relative quantities of these gases in the mixture depend upon: (1) The hydrocarbon being treated; (2) The temperature to which it is heated; (3) The amount of steam used.

The hydrocarbon used as raw material may be butane, propane, ethane, city gas in which methane is the principal hydrocarbon, or a great variety of other gases.

There are dozens of operations in the chemical industry where chemists would use large quantities of hydrogen except for the high cost of the gas that forces them to adopt other expedients. Now comes an electrical device which supplies, not pure hydrogen, it is true, but a gas mixture which will, in many cases, do just as good a job, at about one tenth the cost. If methane is fed into the producer operated at 1400 degrees, Centigrade, the result will be hydrogen and CO; if carbon monoxide and steam are fed into it, the Electrolene will be a mixture of hydrogen and carbon dioxide, the proportion depending on the temperature of the producer. The electric heat supply is automatically controlled to maintain any desired temperature, and the steam supply is also automatically regulated for any rate of output, so that one valve controlling the Electrolene flow from the producer is the only part of the equipment requiring manual attention.

In every case an appreciable increase in volume of raw gas supplied appears as Electrolene. In the case of complete dissociation of coke-oven gas with steam one cubic foot of raw gas becomes approximately two cubic feet of Electrolene, having an approximate analysis of 72 percent hydrogen, 23 percent carbon monoxide, and 5 percent of "inerts." From butane, a volume increase of 13 times is secured, the resulting Electrolene analyzing approximately 69 percent hydrogen and 31 percent carbon monoxide. With methane, the volume increase is four times, and the Electrolene analyzes about 75 percent hydrogen and about 25 percent carbon monoxide.

For a great variety of industrial uses, Electrolene promises to be an effective answer to the chemist's prayer for cheap hydrogen.—*A. E. B.*

Canned Salmon Prevents Disease

CANNED salmon contains the substance which will prevent the frightful hard-times disease, pellagra, the United States Public Health Service has just announced. Canned salmon may therefore be substituted for meat in localities where pellagra is prevalent but where meat is scarce.—*Science Service.*

Detecting Dangerous Sewer Gases

ABOUT a year ago, a series of explosions in a sewer in London ripped up pavements and shattered building fronts over a wide area. Just a few weeks ago, a similar explosion in a sewer on Broadway, New York, caused considerable damage. Such accidents emphasize the ever-present danger, not only of serious property damage but also to the men of maintenance or inspection crews due to the accumulation of various gases such as carbon monoxide, ordinary sewer gases, and the fumes from oil wastes, in manholes or sewers beneath our streets.

To check up on this gas accumulation, the Mine Safety Appliances Company has developed the Jones Gas Detector, an easily portable outfit mounted in a small stand. It consists essentially of a bomb in which a spark plug is inserted and to which a pressure gage is attached. In addition, there are the following component parts: A measuring device, cylinder of propane, water cup, aspirator bulb, two dry cells, an automatic spark coil, ignition switch, necessary valves, and so forth. (One cylinder of propane, in compressed liquid state, is sufficient for making approxi-

Testing for carbon monoxide gas in a manhole with an ampoule

mately 300 tests as described below.)

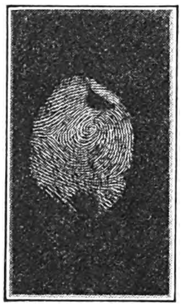
In operating the Jones Gas Detector, a sample of the air to be tested is drawn up from the sewer and forced into the apparatus through a suitable length of sampling line by means of an aspirator bulb. The sampling line is then detached and the aspirator bulb is connected to the rubber inlet tube which traps the sample in a closed system. Stopcocks on each side of the bomb are closed and a spark introduced into the bomb by snapping the ignition switch momentarily to the "on" position and then to the "off" position. In this manner, an explosive gas-air mixture is ignited and the pressure developed by the explosion in the bomb is indicated on a drag needle pressure gage. If no pressure in indicated by this procedure, the sample is enriched by the addition of a measured volume of propane which displaces an equivalent volume of sample. After this propane is thoroughly mixed with the sample by aspirating through the closed system, the stopcocks are closed and a momentary spark is introduced. An explosion in the bomb indicates that the original sample is not less than 75 percent explosive since the measured volume of propane added is equivalent to 25 percent of an explosive propane-air mixture. If no explosion is indicated in the bomb after the first enrichment, it may be necessary to make three more individual additions of propane to the original sample, following the same procedure as with the first to determine if the original sample is approximately 50, 25, or less than 25 percent explosive.

If there is no initial explosion in the bomb and no further explosion upon the addition of a fully explosive concentration of propane, the original sample consists either of an inert atmosphere or explosive gas in concentration above the upper explosive limit. To determine which of these two conditions exists, further simple tests are made according to directions supplied.

To detect the presence of that most treacherous and deady gas, carbon monoxide, the above company produces the M-S-A Carbon Monoxide Detector Ampoule. This consists of palladium chloride in an acetone-water (non-freezing) solution, sealed in a small glass tube which is surrounded with absorbent cotton. The ampoule is first attached to a string, crushed between the fingers until the cotton is fully saturated by the escaping solution, and then suspended in the manhole for 10 minutes. The solution turns the cotton a yellow color. In the presence of carbon monoxide, it turns black. The degree of grayish or black discoloration, compared to a chart, indicates the carbon monoxide concentration. It is claimed that concentrations as low as .03 percent can be determined with this ampoule.

City Trees Often Gassed

SHADE trees need pure air just as people do. Trees are often killed by illuminating gas from leaky pipes in the soil, says the United States Department of Agriculture. Recent experiments show that gassed trees may be saved, if they have not been exposed too long, by forcing air or oxygen under pressure, through a specially constructed nozzle, well into the ground at different points around the tree so as to displace the gas. It will be necessary, of course, to find and stop the gas leak or the procedure will have to be repeated.

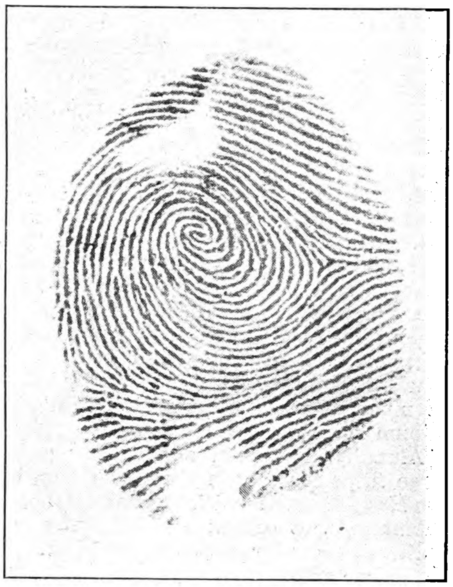


At the left is a fingerprint raised from the irregular neck of a bottle by means of the new fingerprint lifting tape. At the right is the same print (reversed) as it appeared when the lifted print was photographed on bromide paper enlarged for comparison

Fingerprint-Lifting Tape

A SPECIAL tape of black rubber which simplifies the raising of a latent fingerprint, has recently been invented and patented by Major Richard M. Joyce, Superintendent of the Bertillon and Criminal Identification Bureau of the St. Louis Police Department. Latent prints are to be distinguished from those intentionally made on suitable surfaces for record purposes; they are those which are inadvertently left behind by criminals at the scenes of their crimes.

The old photographic method of obtaining permanent records of latent prints has many disadvantages. Prints left on curved, angular, or reflecting surfaces or in restricted recesses are almost impossible to photograph, and when a camera is used the resulting images are distorted or indistinct. By Major Joyce's method, the print is first powdered with aluminum bronze powder, the tape is pressed over this, and the gleaming print is lifted. The image is then covered with a transparent shield which protects it until it may be conveniently photographed.



This new transfer system extends fingerprint recording facilities to small towns or rural districts not able to purchase and operate the usual photographic equipment.

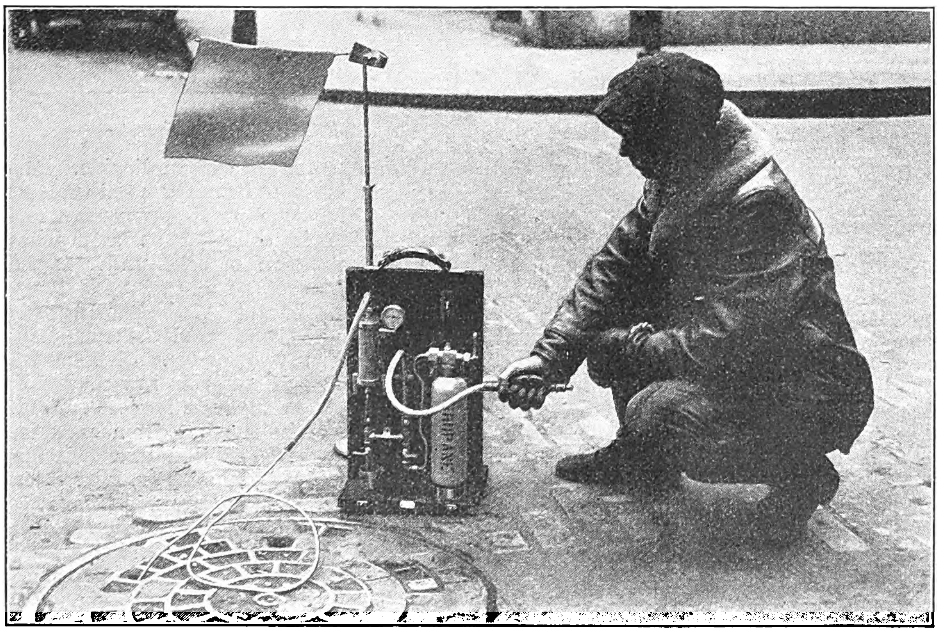
Aluminum in Colors

WHILE aluminum, together with its alloys, has been adopted for a wide variety of uses, (see SCIENTIFIC AMERICAN, June, 1930), its many possibilities have only begun to be realized. With the production of aluminum in colors by a recently developed process, some of the advantages of the metal have been enhanced and some of its disadvantages overcome so that interesting new fields for its application have been opened up.

Colored aluminum, called Alumilite, was developed by the Metals Protection Corporation. The process is an electrolytic method of applying protective and decorative coloring to aluminum and its alloys, the colors available being silvery white, jet black, and various shades of red, blue, yellow, brown, green, and purple.

The developing company makes the following claims for the new product:

The coating is an integral part of the aluminum itself, will not crack or peel, and sheets so treated may be stamped and formed into such shapes as camera bodies, hub caps, trim, et cetera, without marring the finish. Alumilite offers unusual resistance to atmospheric and salt-water corrosion; and although not recommended for use in protecting aluminum against acids and alkalis, it is effective against certain



The gas detector which measures the accumulation of deadly gases in sewers

chemicals. Alumilite will not withstand cutting by a sharp instrument but offers considerable resistance to it. A blunt instrument will force the coating into the softer metal beneath without rupturing. Alumilite-treated metal can be heated above the melting point of aluminum, 1214.6 degrees Fahrenheit, and the metal within will melt while the coating remains intact. The treated aluminum surface will absorb certain lacquers as well as oil and is, therefore, a good base for such materials; ordinary aluminum is not.

Some of the suggested uses of Alumilite are: cameras, scientific instruments, novelties, electrical appliances, switch plates, fittings, automotive trim, airplane propellers, marine equipment, optical goods, toys, aluminum shingles, and many others. Black, for example, has been suggested for the bottoms of cooking utensils, since black absorbs heat more readily than any other color. Water in an aluminum kettle blackened by the Alumilite process will boil in much less time than in a plain aluminum kettle.

Alumilite has been adopted by many large firms for use on their products; by the Navy Department for use on airplanes, submarines, et cetera; and by Army aircraft engineers for use on Army airplanes.

Overweight Children

THE fat baby has always been a pride to its parents, but the fat child of eight to 20 years of age is a problem for its parents. Many cases of fatness or obesity are due to disturbances of the glands of internal secretion, or to the fact that the body does not dispose properly of the material that is taken into it. In many instances, children are fat because the parents and grandparents were fat. This is known as constitutional obesity and is the type that is absolutely resistant to all treatment. In those cases of obesity due to glandular disturbances, the basal metabolic rate or the rate at which the body carries on its chemical process is lower than it should be. However, in many cases of constitutional obesity the basal metabolic rate seems to be normal.

Drs. Anne Topper and Hannah Mulier have made a study of the basal metabolic rates of 35 boys and 35 girls whose ages ranged from six to 14 years, but whose weight exceeded normal by from 13 to 75 percent. In many cases there was a definite indication that the children had been overfed. Naturally only a few confessed to laziness. In some cases the obesity followed recovery from acute infectious diseases or following removal of tonsils or the appendix. In the large majority of these cases, however, it was found that the metabolic rate was normal, in a great many cases being toward a high normal rate. The authors believe that the tendency toward a high normal rate is probably due to overfeeding and to the fact that the body is forced to speed up its activities in order to take care of the excess food.

It should be recognized that these examinations were made in many instances just before the time of adolescence when the child begins to change toward the adult type. At this time the glands in the body undergo various changes and these changes may be associated with the rather high increase in the speed of metabolism.

Obviously, the practical lesson to be derived from this discussion is the necessity of determining how much food is necessary to keep the child at normal weight and thereafter to avoid overfeeding.—*M. F.*

Light Alloys

THE lightest element solid at ordinary temperatures is the metal lithium. It is only a little more than half as heavy as water. While technically a metal, it is too soft to be of any use in the ordinary applications of metals and too active chemically, for it tarnishes rapidly in the air and is completely changed by contact with water, which it decomposes.

In recent years, however, says R. M. Santmyers, of the United States Bureau of Mines, considerable research has been made to determine the possibilities of alloying lithium with other light metals such as beryllium and aluminum. A patent has been issued to Frank A. Fahrenwald for an alloy of extreme lightness, fair permanence, and considerable hardness, in which the component parts were lithium and beryllium. The beryllium protects the lithium from oxidation by moisture or heating and from further action if oxidation has begun, by producing upon the surface of the alloy a closely adherent, finely textured insoluble oxide that prevents further oxidation. The lithium content may be as high as 25 percent. This alloy apparently does not corrode faster than iron, and its specific gravity is only about 1.5.

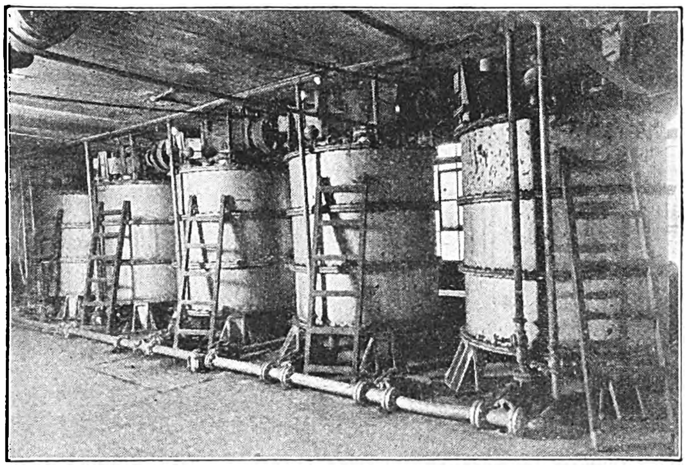
By increasing the proportion of lithium to about 65 percent, an alloy as light as water can be produced, and although such an alloy corrodes fairly rapidly in the presence of water it can be protected sufficiently for many purposes by plating or covering. If the percentage of lithium is increased slightly above 65 percent, small quantities of aluminium or zinc may be added to increase the hardness and strength, but the alloy will retain a specific gravity little or no greater than that of water.—*A. E. B.*

Making the Sparkle for Soft Drinks

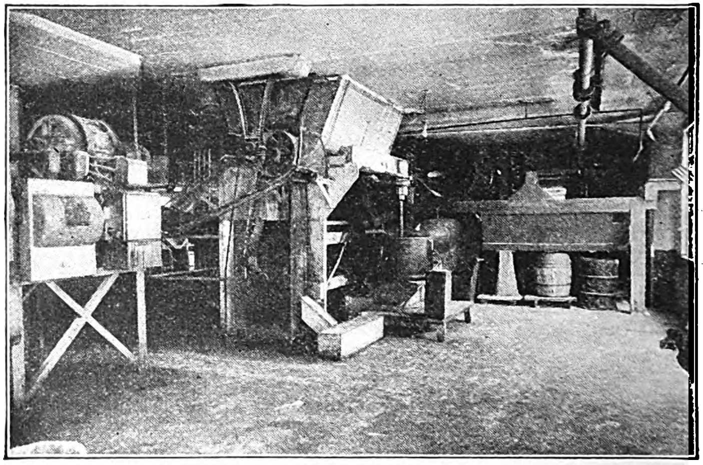
IN these hot summer days, the soft-drink dispensaries once more come into their own, and it is an appropriate time to consider the chemistry that creates the sparkle or "fizz" in the bottled beverages that quench the great American thirst. The sparkle is due to dissolved carbon dioxide gas—the gas that gives soda water its effervescence. While carbon dioxide is one of the most abundant gases in nature, being generated wherever coal or wood is burned, its manufacture for beverage purposes presents certain problems to the chemical engineer which are described by W. P. Heath in a recent issue of *Industrial and Engineering Chemistry.*

"Before prohibition," says Mr. Heath, "carbon dioxide was collected and compressed as a by-product of the fermentation of beer. The most recent method is to pipe it from wells. In California, prospectors drilling for oil ran into large pockets of carbon dioxide under pressure. Under government lease these pockets are now yielding their store of carbon dioxide. Most of the gas thus collected is used in the manufacture of solidified carbon dioxide. Perhaps the most universally used process today is the coke process, whereby carbon dioxide is collected as a product of the combustion of coke under forced draft."

In Atlanta, because of the proximity of raw materials, the Crystal Carbonic Laboratory uses the wet process, with dolomite, sulfuric acid, and water as raw materials. The stone called dolomite is most suitable on account of its freedom from excessive amounts of oxide of iron and alumina, carbonaceous matter, sulfides, and silica. The stone is pulverized and then treated with sulfuric acid. Carbon dioxide is given off rapidly, and the gas is piped to a 2500-cubic-foot rubber gas bag in the basement, where it is ready for compression. The gas is drawn from the gas bag into a three-stage compressor where the pressure is



Lead lined carbon dioxide generators



Driers and screens for Epsom salts

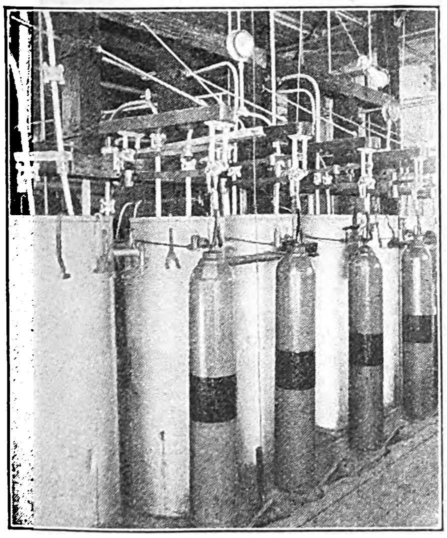
stepped up to 75 pounds in the first stage, 250 pounds in the second stage, and 1000 pounds or more in the third stage. The third stage of this machine is of the solid-plunger type, outside packed, and the gas emerges at over 1000 pounds pressure into brass cooling coils, where the temperature is reduced to below 88 degrees, Fahrenheit, the critical point of carbonic acid. The gas is then forced into 50-pound steel drums. Gases under pressure are classed as hazardous and the filling is carefully regulated so that all excessive pressure may be avoided.

At ordinary temperature the drums are about two thirds full of liquid and one third full of saturated gas. The average purity is 99.5 percent and there are traces of air. Such impurities as may give an odor or taste are not permitted in carbonic acid to be used in the beverage industry.

One of the most interesting features of this process is the fact that it produces Epsom salts as a by-product. The dolomite contains 45 percent of magnesium carbonate, and after the sulfuric acid has acted on this substance, releasing the carbon dioxide gas, there remains a solution of magnesium sulfate—Epsom salts. Although the Crystal Carbonic Laboratory is primarily in the business of manufacturing carbon dioxide for use in the beverage industry, the quantity of magnesium sulfate obtained as a by-product makes this company one of the largest Epsom salt manufacturing concerns in the United States.—*A. E. B.*

Bread

THE battle of cultists against white bread continues. The millers oppose the attacks by pointing out that the American people seem to prefer white bread to whole wheat bread. Furthermore, they are annoyed because there has been a general decrease in the consumption of cereals, since these represent a cheap source of energy and the American people have become accustomed to expensive diets. The bread of today is not the bread of the past generation. Today it is made by the addition of milk, nuts, raisins and other substances which add greatly to its nutritious value.



Compressed carbon dioxide being loaded into cylinders for shipment

Whole wheat is preferred by some because of its bran content and its greater proportions of vitamins, due to the fact that the whole wheat germ is present. On the other hand, whole wheat bread does not keep well and the bran is irritating to persons having inflammations of the gastro-intestinal tract.

Under the auspices of the Medical Research Council in Great Britain, Drs. R. A. McCance and R. D. Lawrence made a special study of this problem. Their views are succinctly stated:

"In advocating whole-meal bread for general use, whether in times of need or in times of plenty, it should be remembered that not only men but also women and children are concerned, and that all the experiments on which the arguments are based have been carried out on animals or adult males. Children are very intolerant of high cellulose diets, and, for some, brown bread is far too irritating, even if given with the idea of relieving constipation. Appetite is such an important factor in all digestive considerations that no one who dislikes a food of unproved value should be forced to eat it if it can be avoided. In time of peace, of course, the grown-up population, if they have the choice, will never eat whole-meal bread unless they like it, no matter how specious the advertisement, but they may force their children to eat it in the belief that they are doing them good. One should, therefore, be cautious in advising whole-meal bread generally, and wait until careful unbiased experiments have been done on a sufficient number of men, women, and children. Thus only can accurate conclusions be drawn."

Courtesy *American Forests and Forest Life*

It must be remembered that man does not live by bread alone. In a suitable diet, bread constitutes only a single part and is supplemented by meat, vegetables, fruits, and many other cereal products. In the light of present dietary habits, there seems to be no reason to believe that white bread is in any sense of the word a harmful constituent of an average diet.—*M. F.*

Navigation in the Air

AERIAL navigation is not a matter largely of astronomical observations. It is, particularly for cross-country work, a matter of dead reckoning, with compass, drift and speed indicators, and a few simple calculations as its basis. It is not a difficult art, but an immensely important one. The subject is splendidly covered in "The Navigation of Aircraft," by Lieutenant Logan C. Ramsey, U. S. N., himself a naval aviator and an acknowledged authority on aerial navigation.—*A. K.*

A Novel Landing Float

IN *Aviation* is described a novel form of semi-circular "button" float which has been placed in use on the Air Ferries [See page 379, May 1930 SCIENTIFIC AMERICAN. *Editor.*] between San Francisco-Oakland and San Francisco-Vallejo; more than 85 landings are made on it daily.

The float is rigid, with a smooth rounded top which slopes gradually into the water. A sand surface is provided to keep the planes from skidding. The float is supported by a pontoon and fitted with an overhanging platform. Along the rim are four solid ballast pockets to regulate the depth still more accurately. At the water line 18 buoyancy tanks are installed to correct any tendency of the float to be too lively. The surface of the float is a variable curve for the purpose of breaking rough water and to give maximum freeboard. The weight of the float is 100 tons and it extends 4½ feet under water. It is built of creosoted Douglas fir and is moored by a cable from a king post to keelsons leading to the rim and then to anchorage. It cost 10,000 dollars to build.

When the amphibian alights on the water, its wheels are dropped and it climbs out of the water on to the button under its own power. It can approach from any direction without the help of landing crews, and can also make a get-away unaided.

Experiments have shown that a complete circular float, slowly rotated, will divert the wave, kill a hollow and make the approach of the plane easy even in a high sea. This makes the use of the float promising even at sea.

It was developed by B. L. Haviside and Joseph J. Tynan, Jr., both of San Francisco, and is arousing much interest.—*A. K.*

Max Valier: Rocket Martyr

THE month of May saw the sad crash of Max Valier in a venturesome plane flight propelled by liquid rocket. The whole fuel charge detonated at once.

The internal combustion engine, the cannon, and the rocket are all heat engines operating on the same fundamental calorific principle. A 16-inch shell, for example, has the energy of an express train; a rocket may possess the energy of an ocean liner.

In the 90's a German and a Russian (Ziolkowski) were developing on paper the concept of space ships, rocket-propelled;

and in 1913 Robert Esnault-Pelterie, the distinguished creator of the French aeronautic engine, delivered a mathematical paper on "Astronautics" before the St. Petersburg Academy. The science, or art, has been more fittingly renamed by a German "Kosmonautics."

Parallel, then, with the laboratory work of our own Dr. Goddard, a close group of Germans and Austrians, and a corresponding group of Russians of the Hydrodynamic Institut, have been working systematically toward the solution of the problem. In the German group were prominently: Dr. Oberth (Hirsch-REP prize 1928-9); Ingr. Hohman (Honorable Mention); Max Valier, Ingr.; Fritz Opel, manufacturer; A. Scherschewski; Sander, pyrotechnist; Willy Gail and Frau Harden, writers; Rhoen-Rossiten Gesellschaft; pilot Stammer, and a number of others. Their headquarters are at Breslau. The UFA has collaborated, and even made a "moon" film. The equivalent American society is the American Interplanetary Society, at the American Museum of Natural History.

Mr. McEachron with a sectionalized Thyrite lightning arrester

Valier was the principal proponent of working toward the space craft or vehicle from the known forms of surface or air craft. For example, he proposed first to drive a boat with rockets (which Opel tried); then an automobile (reported speed 230 miles per hour); then a rail car (reported speed 300 miles per hour); then an ice sledge (still faster); and recently a light plane (60 miles an hour by Stammer, July 1928, the first man so to fly). Valier at the time of his death was substituting oil fuel for gunpowder in the expulsive jet, preparatory to hopping the channel at a speed hoped to be about 100 miles per hour.

A National Advisory Committee report has demonstrated that jet propulsion is not efficient at aircraft velocities—indeed at less than the speed of sound, for flame jets. But beginning with projectile velocities, and up to a mile or so a second, the jet principle approaches an efficiency of 70 and 80 percent, or better than any other heat engine. It is this happy circumstance, more than any other factor, that gives one confidence in the ultimate solution of Kosmonautics.

The name Valier should be placed beside those of Icarus and Lillienthal.

Two Freak Metals Find New Uses

TWO rare metals, caesium and rubidium, formerly known as chemical curiosities, have found their first important commercial use as a result of the development of radio and photo-electric cells. Both these queer metals, members of the alkali group, are soft enough to be cut with a knife and have to be kept in a vacuum, else they ignite spontaneously, due to their extreme chemical activity. This very property is now being utilized in the manufacture of radio tubes. The caesium is introduced into the tubes in the form of chloride, mixed with magnesium or calcium, and compressed into small tablets or "pills." At one stage in the manufacture of the tube the pill is flashed, eliminating the last trace of air and thus securing the desired vacuum. The caesium chloride supplies positive ions at the surface of the filament.

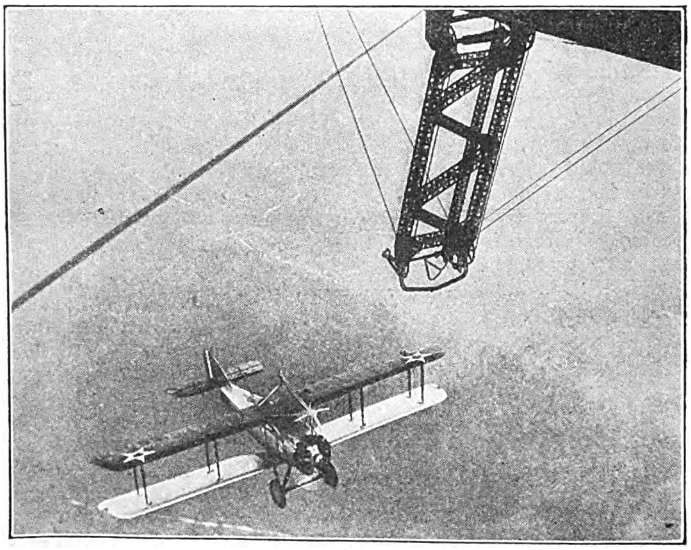
Both caesium and rubidium are employed to a limited extent in the manufacture of photo-electric cells. Rubidium, however, appears to be more suitable for this than caesium, because an extremely thin layer can be applied on the inner side of the glass. In the manufacture of these cells the metal, either caesium or rubidium, is introduced in excess but later is removed entirely except for the molecular layer that has formed on the silver or other base-metal electrode. The photo-emission of the molecular layer is greater than that of the massive metal.—*A. E. B.*

Thyrite—Both an Insulator and a Conductor

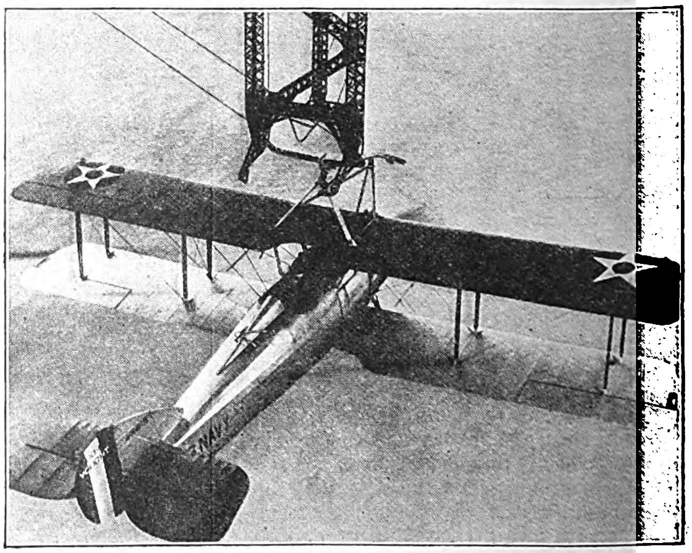
AN entirely new type of material, one that is both a good insulator and a good conductor of electricity, was announced by K. B. McEachron of the General Electric Company recently in New York City. This material, which has been called Thyrite, meaning gate or valve, has the remarkable property of changing its resistance to the flow of electricity as the voltage or pressure is changed. This change in resistance is such that each time the applied voltage is doubled, the resistance decreases so that the current flow is increased more than 12 times. This means that if the voltage is increased 16 times the current flow is increased more than 25,000 times.

The usual conductor with which electrical engineers are familiar does not change in resistance except when the temperature of the conductor changes. To illustrate: the tungsten filament in the Mazda lamp increases its resistance considerably as the filament heats up; the carbon lamp shows, on the contrary, a decrease in resistance as the filament increases in temperature. With either of these materials the resistance change is slow since it depends on the time required to heat the filament. Unlike any materials now in commercial use, the resistance change of Thyrite does not depend on the temperature, but on a change in the applied voltage. Thyrite will change its resistance as quickly as the applied voltage changes; in fact, tests have shown that the resistance can be decreased to a millionth of its original value in a time as short as a millionth of a second.

Thyrite is a manufactured product which required more than five years of intensive research to develop to the state where it can be produced commercially. Mr. McEachron exhibited some disks six inches in diameter and three-fourths of an inch thick, made for use in lightning arresters for the protection of power stations against the damaging effects of lightning. Such disks have a resistance of about 50,000



The dural framework which extends from the lower part of the airship frame, and a plane maneuvering for "hooking" position. Tests of the device were successful



The slight impact that ensues after hook and bar meet is evidently sufficient to adjust hook so that it is sesecurely attached. Note construction of plane hook

ohms when 100 volts are applied to the parallel faces; the resistance decreases to less than one half an ohm when the voltage is increased to 10,000 volts. These disks of Thyrite will carry lightning discharges as heavy as 30,000 amperes without any sign of distress.

The characteristics of Thyrite are permanent. Some of the first material made is still on life test, with no change in its characteristics, even though it has been carrying current continuously night and day over a period of several years.

Thyrite resembles black slate in color. It has mechanical properties similar to those of dry-process porcelain. In manufacturing it, the material is moulded to the shape required, and the contact surfaces coated with metal by the Schoop metal-spraying process.

It is possible to use the material successfully on any alternating or direct current circuit; it is necessary only to supply a proper amount of the material so that it will not become overheated.

In connection with lightning arresters, Mr. McEachron explained that the use of Thyrite allows a considerable reduction in the space occupied by the arrester, and that it is possible to calculate its performance accurately. This feature will be of great assistance to engineers using such protective equipment. Furthermore, it was pointed out, it is possible for anyone to determine the characteristics of Thyrite over a considerable current range, without the use of expensive equipment.

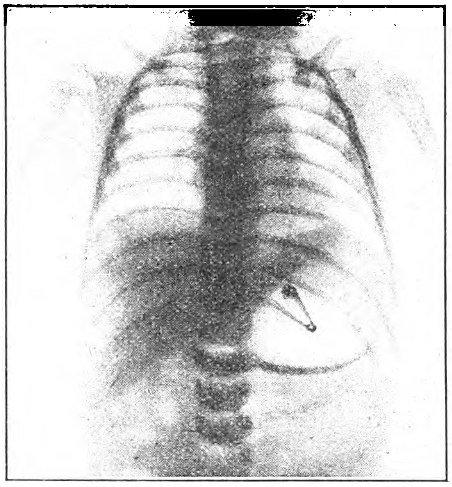
Aeronautical Equipment

THE Curtiss-Wright aeronautical equipment catalog of some 250 pages is a comprehensive compilation. Nothing gives a better idea of the number of things that go to make up aviation: airport equipment, books and maps, cable and wires, clothing, engines and engine accessories, fuels and lubricants, instruments, landing gear and parts, propellers, and so forth. It is a catalog which should be in the hands of every pilot and plane owner.—*A. K.*

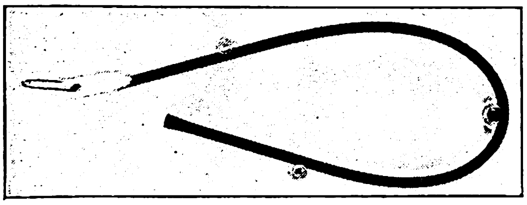
Launching Planes from Airships

ONE of the two accompanying photographs shows a Vought UO-1 Navy Observation plane approaching the *Los Angeles* prior to "hooking-on." The airplane is provided with a frame superstructure into which the weight of the airplane is transmitted without undue local stresses being set up. At the top of the superstructure is a hook which has apparently some flexibility and is controlled by a sort of large spring. From the lower part of the airship frame there extends a dural framework, suitably braced with wire and carrying a bar at its lower end.

When the airplane is about to be hooked on to the airship, the speeds of the two types of aircraft are synchronized and the pilot feels his way cautiously until he can get the hook on to the bar. When the plane is to be released the bar is pulled away. Demonstrations of the hooking-on and releasing of the plane have been made several times on the *Los Angeles* and have been entirely successful. The hooking-on process enhances greatly the military value of the dirigible. The airplane, having a seped of twice that of the airship, is valuable as a scout for transmission of information to the fleet, and also provides the airship with protection against enemy heavier-than-air craft.—*A. K.*



An open safety pin in a patient's stomach as revealed by the X ray



The rubber tube with which a safety pin was removed from the position in a patient's stomach as shown in the illustration above at right. It was not necessary to open the wall of the stomach although the abdomen was cut open

A Pin in the Stomach

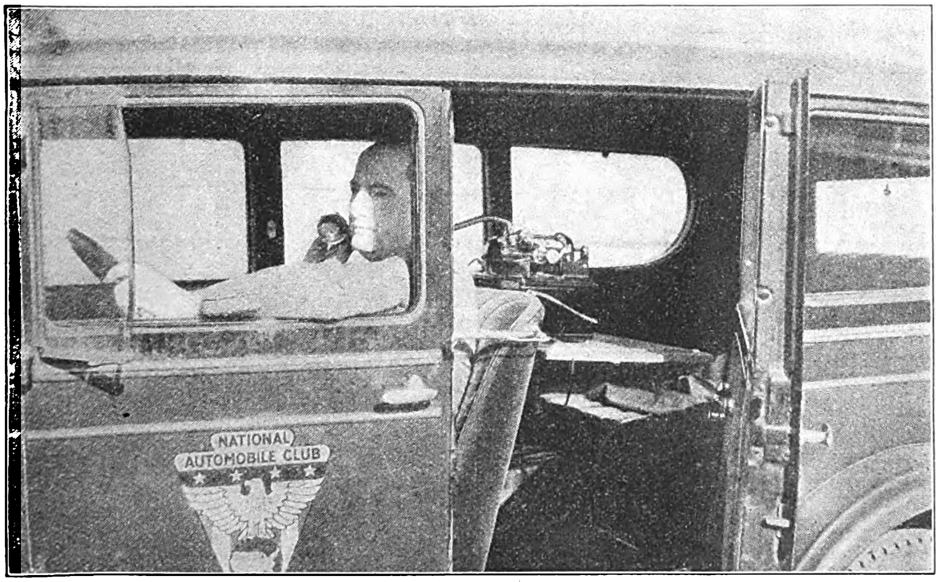
WHEN an open safety pin is swallowed it constitutes a serious menace because of the danger that it will penetrate the wall of the stomach and set up peritonitis. So serious is this possibility that not infrequently the patient is operated on immediately and the stomach opened in order that the pin may be removed.

In a case treated recently by Dr. W. B. Huff a technique was devised which enabled the condition to be handled without opening the wall of the stomach. Ingeniously the doctor introduced into the esophagus a rubber tube with a piece of gauze at the end. The abdomen was opened, the pin felt with the fingers, and then, without opening the stomach, the pin was fastened to the gauze at the end of the rubber tube and closed. The rubber tube was then slowly withdrawn, bringing the safety pin with it. In the instance described the child recovered without further disturbance. The method seems to be of value particularly because it permits proper handling of the condition without opening the stomach wall.—*M. F.*

Ediphone Used for Road "Logging"

LATEST road information for the members of the National Automobile Club, San Francisco, is being gathered in a unique, modern, and efficient manner through the utilization of the Ediphone. Traveling in an automobile equipped with an Ediphone operated by a six-volt battery, a very satisfactory trial trip proved the possibility of this method of road "logging," as the collecting of data on road conditions is called.

Instead of the necessity for bringing the car to a stop or, at least, greatly reducing the speed, for the purpose of making notes, this new system enables the driver to record conditions while traveling at the usual rate of speed. Covering ground as rapidly as safety and the condition of the road will permit, the driver may collect such details as mileages, cross roads, grades, road conditions, and a general description of the country traversed. This information is recorded on the cylinder for later transcription into a typewritten report for use in the drafting of maps and the distribution of touring information to club members.



When road "logging" with the Ediphone, the driver does not have to stop his car every time he wishes to make notes; he dictates his notes as he drives

Strength of Prehistoric Monsters Dwarfed by Huge Testing Machine

THE supposed strength of the prehistoric dinosaur is dwarfed beside that of a huge testing machine installed recently at the University of Illinois.

This machine crushes steel and concrete

with as much ease as a human mashes a piece of dirt beneath his foot. It stretches iron rods as if they were taffy candy. In fact, it can exert as much as 3,000,000 pounds in either tension or compression, either to pull things apart or to squeeze them together.

Building beams 35½ feet long can be tested. The screw that is used to concentrate the great pressure is more than 57 feet long and one foot in diameter. The machine stands nearly 50 feet above floor level and extends 14 feet below. It weighs 140 tons.—*Science Service.*

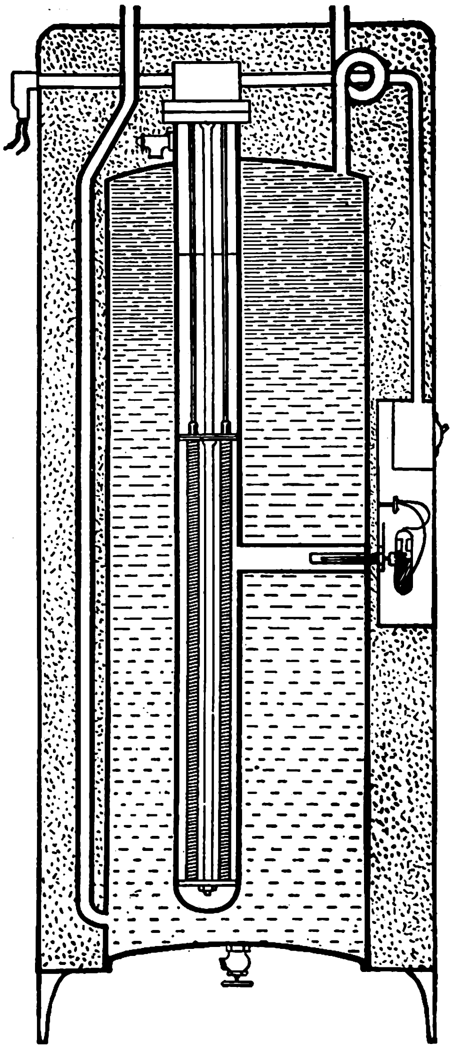
Electrical Water Heater

An automatic, electrically operated water heater for which high efficiency and low cost of operation are claimed, has recently been placed on the market under the trade name Electromatic. It is adaptable for use in homes, apartment houses, doctors' offices, barber shops, beauty parlors, soda fountains, and so forth. Once it is regulated for the temperature desired, it maintains that temperature without any further attention.

The "heart" of this system is the heating element which is immersed in oil in a vacuum tube which extends down through the center of the tank. From this, a lateral tube leads off to the thermostat control which is operated by a mercury tube. Directly above the mercury tube is the switch which turns on and cuts off the electrical supply. The cold-water supply enters the tank through an inlet near its base while the hot-water outlet is at the top. The tank is well insulated against heat losses, the material used for this purpose being a high grade mineral wool packed six inches deep at the top and three inches thick around the sides.

The advantage of the vacuum oil tube is that it becomes, in effect, the heating element and thus gives a heating surface many times greater than that of the average heating device. It can heat the water in less time at a lower unit area temperature. The heat of other devices is more concentrated and thus produces scale.

The Electromatic can be connected with any furnace or kitchen range hot-water circuit. Since it operates automatically, it will maintain the water at the desired temperature after the furnace or range heat has dropped too low to do the job.



Cross-section of new electrical water heater; controller at right

Ants in Indian Surgery

The use of "surgical ants" with powerful jaws to stitch the wounds of human beings, and other primitive medical practices developed by the Indians living far in the interior of Peru, are described in a report received recently at Field Museum of Natural History from the Marshal Field Botanical Expedition to the Amazon.

Llewelyn Williams, leader of the Peruvian division of the expedition, had just returned to Iquitos after a collecting trip along the Amazon and some of its tributaries which took him as far as the Brazilian border. Parts of the regions explored are believed never to have been entered by white men before.

"The natives of the equatorial forest show great originality and dexterity in the treatment of wounds and illness," writes Mr. Williams. "Trees, shrubs, and plants with medicinal properties are widely employed, and a surgical handicraft in which certain insects are used has been developed.

"In the case of a gaping wound, a certain ant which has very powerful jaws is sought, and the ant is made to bite the severed edges of the cut skin and thus bring them into juxtaposition. In the operation the ant-surgeon loses its own life for after it has drawn the skin closed with its jaws, its body is snipped off, and the lifeless head remains with its death grip on the skin until the wound is healed. Sometimes these Indians are found with half a dozen of these ants' heads holding a large wound closed during the long healing process.

"After inter-tribal battles, in which fighting is done with axes and machetes or bush-knives, many of the warriors return home with deep, ghastly, and apparently fatal wounds. The women, however, are usually successful in treating these wounds. After bathing them, they apply ginger as a local anaesthetic. Then a plaster is made from the pulp of a weed known as 'Santa Maria,' and the wound is bandaged with a dried banana leaf. In a week or so most of the wounds heal. Sometimes the crushed body of a certain ant is applied as a salve. The injured men are placed on a diet eliminating salt and fats, and made to drink large quantities of an infusion prepared from the bark of a tree.

"Long thorns are sometimes used as surgeon's needles. The skin at one side of an open wound is pierced with the thorn, and it is then thrust across to and through the opposite skin edge, the protruding end of the thorn being fastened with string and left there until the two edges have fused.

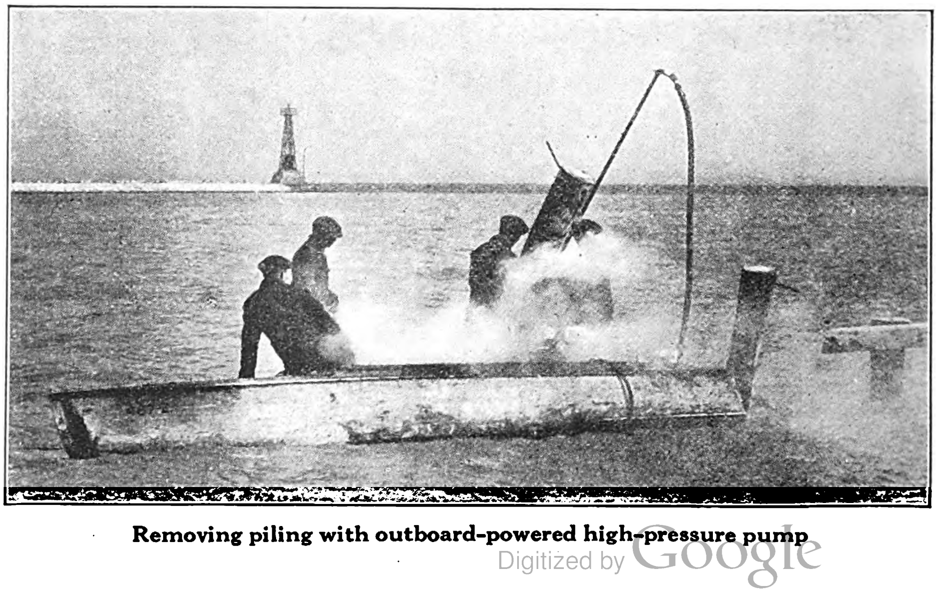
"In the wet lowlands there is a female jigger or burrowing flea which buries itself in one's flesh. There its body swells and becomes globular, being distended with a huge quantity of tiny eggs. The natives remove this by working carefully around the insect's body with a needle. Skill is necessary to avoid breaking the egg sac, for if a single egg is left in the wound the operation is valueless.

"There is also a worm which burrows into the legs of its victims, forming a swelling like a boil which breaks, and then the worm protrudes its head. Any attempt to drag it out suddenly, fails, as it tears. The natives draw a few inches out carefully day by day, rolling the exposed end around a small piece of wood. Much delicate manipulation is required, as this entozoon ranges from six to ten feet in length."

Outboard Motor Becomes a Work Horse

An outboard motor designed for pleasure outings became a work horse recently and helped to repair the ravages committed by Lake Michigan during the March storms. The pounding of the waves reduced the wooden breakwater in front of the Johnson Motor Company at Waukegan, Illinois, to kindling. When the storm subsided, the naked piling was left standing, unsightly and useless before the factory doors.

The factory manufactures outboard mo-



Removing piling with outboard-powered high-pressure pump tors capable of producing from a fraction of a horsepower to more than 32 horsepower. The engineers commandeered a power head capable of producing about 10 horsepower and used this boat engine to remove the piling. Attached to a centrifugal pump, the motor threw a stream of water at high pressure for more than 50 feet.

A raft, the power head mounted in a boat, a length of hose, and iron pipe completed the equipment used by the crew of men to remove about 20 of the piles. The pipe was thrust into the bottom of the lake alongside the piling, and the thrust of the water at high pressure loosened the huge poles. They were then pulled out by the men on the raft and dragged to shore.

New Type of Rubber Blocks X Rays

RADIO fans who happen to be located near a hospital or any other place where an X-ray machine is operated, are painfully aware of the ease with which X rays penetrate ordinary walls. In order to insulate an X-ray apparatus, it has been necessary to line the walls of the room with heavy sheet lead. Now, however, rubber chemists have discovered that certain lead compounds can be incorporated with rubber to make an ideal shield for the vagrant X rays. The new material is known as Ray Rubber and has been successfully tried out in a hospital in New York City.

Ray Rubber contains a homogeneous lead compound which has passed all tests made by X-ray machine manufacturers. Dangerous X rays cannot penetrate Ray Rubber. It provides a good-looking surface easily kept clean, making the X-ray room attractive rather than dull and drab since the material is available in a variety of standard colors.

Ray Rubber replaces the old Holland barium brick, heavy and expensive because it had to be imported; barium mixed with plaster which cracked, permitting the rays to pass through; and lead, which requires expensive burners to perfect its joints. Ray Rubber has a peculiarly fashioned reverse curve edge which permits a small lap joint through which no X rays can pass.

It is easily applied with an approved type of cement to walls and floors, doing away with troublesome fastenings of various sorts. For the floors it may be applied either to concrete or wood. Edges of the flooring and joints are made impervious to ray penetration by application of Rayproof cement.

Ray Rubber is made in blocks 18 by 24 inches and 0.5 inch thick, which has an equivalent screening power against X rays of 0.125 inch of lead.—*A. E. B.*

Blind Spots and Collisions

IT is an interesting fact that three important aeronautical publications, *Aviation* in the United States, *The Aeroplane* in England, and *L'Aéronautique* in France should discuss at about the same time the question of blind spots on the airplane and their effect in increasing the possibility of collisions.

In the early days of flying, when traffic was very slight, pushers with nacelles forward of the wings were quite common. An example of such design is the Farman F.40, which was quite famous during the World War. In this plane, both pilot and observer were seated so as to be practically clear of all obstructions to vision. The disadvantage of this type was the placing of the heavy engine behind the crew, and so it was gradually discarded. Yet from vision considerations, this type was well nigh perfect—or at any rate far superior to the airplane of today.

Monsieur Henri Bouché, Editor of *L'Aéronautique*, illustrates the collision dangers of the modern airplane in some graphic diagrams, which we reproduce in these columns. In one diagram is shown the "parasol" monoplane; that is, a monoplane with the wing placed at some height above the fuselage. The range of vision is indicated by the lines. When two parasol monoplanes meet they may readily strike head-on.

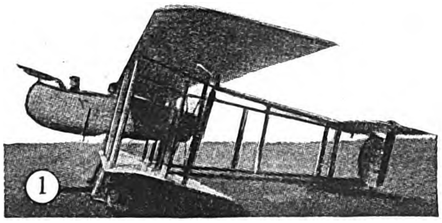
In another diagram, the upper machine, with enclosed cabin, may be struck by the parasol monoplane approaching it from below.

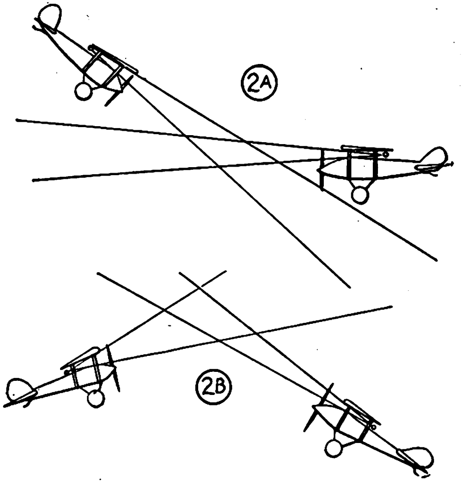
It is not difficult to imagine similar difficulties when machines are landing or taking off on a busy field.

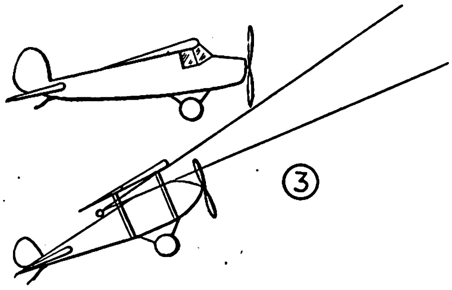
Two engineer-pilots, also writing in *L'Aéronautique*, suggest a number of remedies, some novel, some borrowed from the practice of other designers.

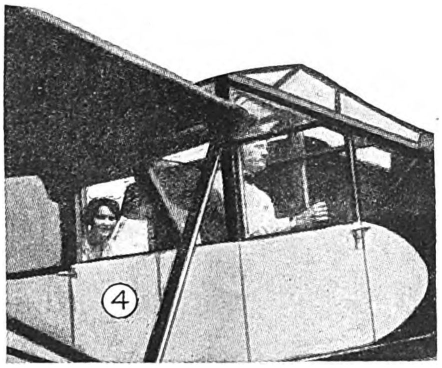
Suppose that the designer, for a variety of reasons, has decided to build a high-wing cabin monoplane. Then the pilot should be placed well forward, ahead of the wing, with the wing somewhere about the level of his eyes. The entire cabin should be provided with non-shatterable glass—ahead, above, at the sides, and below far toward the rear. The Berliner-Joyce cabin

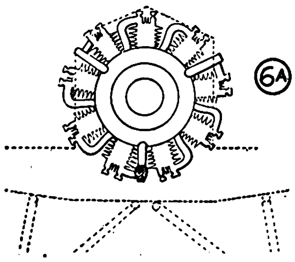
In the famous Farman war-time plane, *1*, the pusher nacelle made possible almost perfect vision. Parasol monoplanes, *2*, may collide head-on because of restricted area of sight. A parasol plane coming from below may get into difficulties as in *3*. The pilot's position in the Berliner-Joyce monoplane, *4*, affords an almost unobstructed view. The open cockpit, low-wing Aeromarine-Klemm monoplane is at *5*. A comparison of the obstructing qualities of engines is given in: *6A*, a radial; *6B*, a conventional in-line; and *6C*, an inverted in-line. A conning tower, *7*, has been suggested for flying boats

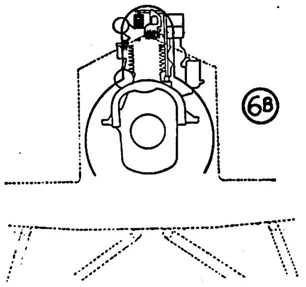


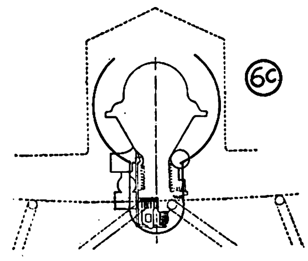


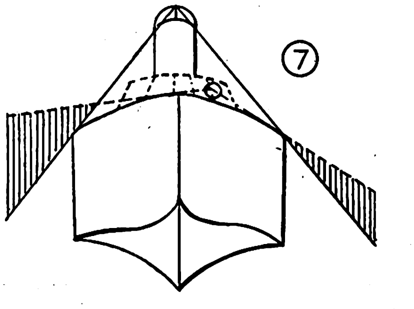


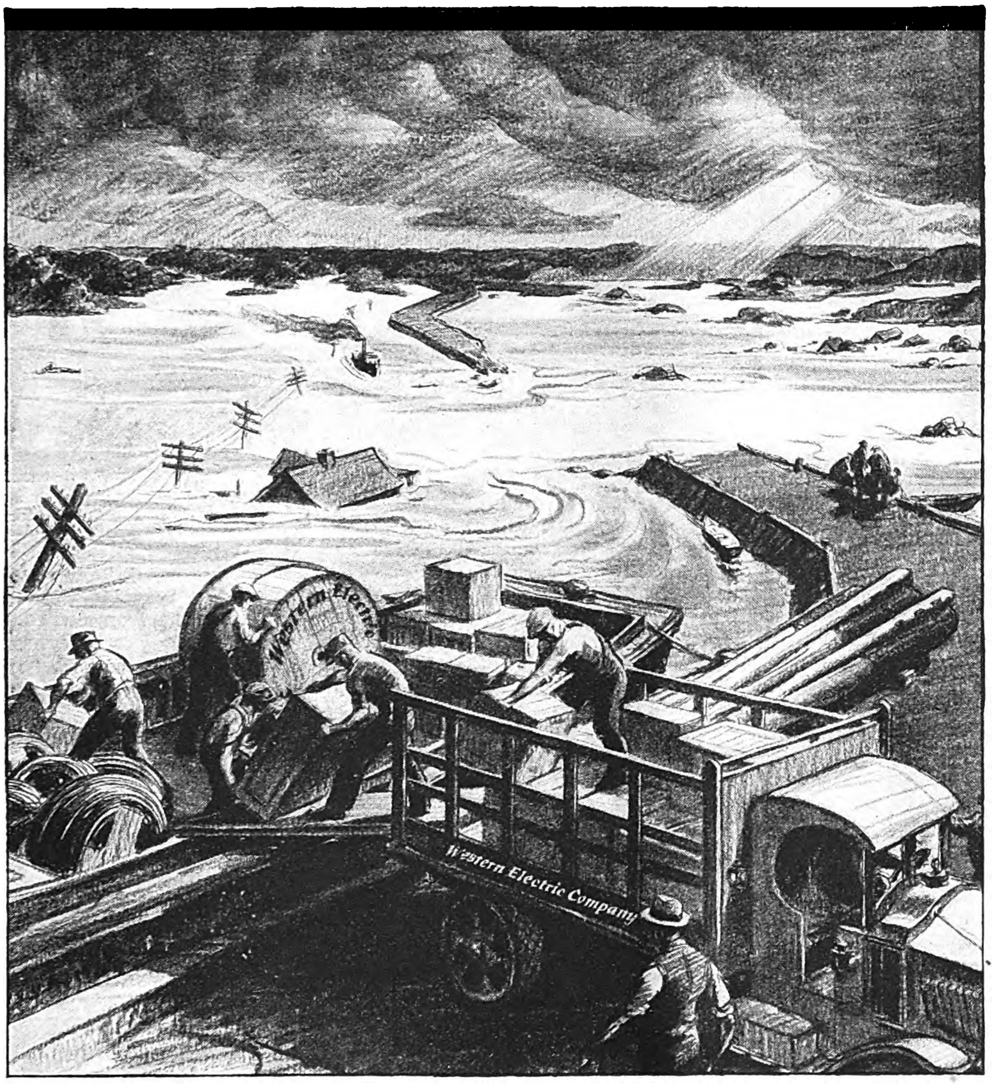












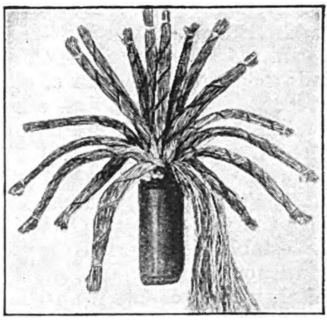
In fair weather or foul . . .

Western Electric backs up your telephone service

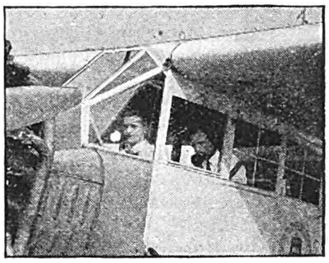
In foul weather, just as in fair, Western Electric backs up the Bell System with all the apparatus and supplies needed to restore, maintain or expand your telephone service.

This Company manufactures telephone equipment of every sort, with a skill acquired through 50 years' experience. At 32 warehouses it holds great reserves of telephone material available for shipment day or night. It delivers and installs the apparatus when and where needed.

The large scale manufacture of standardized equipment, too, is an economy. So is the concentrated purchasing—a responsibility that Western Electric undertakes for the telephone companies of the Bell System. All in all, here is a work of mass production, purchasing and distribution which for size and complexity has no parallel in industry.



1818 conversations at one time can be carried on through this new type cable. It contains 3636 insulated wires within a diameter of 2⅝ ins.



The flying telephone laboratory in which Western Electric airplane telephone equipment has been developed by the Bell Laboratories. Provision for communication between ground and plane marks a great forward step in flying.

One of the 18 materials in your telephone is rubber from the plantations of Sumatra. Western Electric goes to market in every corner of the world.

Western Electric

THE MAKERS OF
BELL TELEPHONES

tion did not show any change. However, in the third generation dwarfism, degenerations, and bent leaves and blossoms, appeared. Thus it is obvious that factors affecting the human cell may actually have their influence not only to the third generation but primarily in the third generation.

Before a German society for the advancement of science, Prof. Ernst Rüdin announced the fact that several of the children of people with hereditary chorea developed chorea at an early age. Among the children of people with manic-depressive insanity, 33 percent of the children are affected; among the children of epileptics, 10 percent are affected; and among the children of parents with hysteria, 13 percent are affected. The mental health of the child is clearly the reflection of the mental health of its parents. Notwithstanding the fact that this inheritance is clearly established, persons continue to marry without any attempt at investigation of their antecedents from the mental point of view and without any realization that the offspring are bound to reveal the effects of the mentally weak heredity.—*M.F.*

A Plane Price War

THE Stinson Aircraft Corporation, recently acquired by the Cord automobile interests, threw a bombshell into aviation circles, at the time of the St. Louis show, by announcing some startling price cuts. Our photograph shows the Stinson four-place cabin plane, powered with a 210 horsepower Lycoming radial air-cooled engine. The plane is of neat though conventional design, and has excellent performance and flying characteristics.

The airplane builders are now rivaling the automobile builders in the completeness and luxury of equipment. The Stinson has an electric self-starter, adjustable metal propeller, wheel and emergency parking brakes, cabin heaters, hydraulic and spring shock absorbers, broadcloth upholstery, shatter-proof glass, rubber-insulated motor mount, gasoline gages, dual wheel control, adjustable pilot seats, balloon tail wheel, navigation lights, and smoking sets.

Last year planes of this type were selling at about 9000 dollars. Now the Stinson company announces a price of 5775 dollars. In some aviation circles the opinion is held that the Stinson Company will lose money rapidly. Others hold that increased sales and better production will justify the reduction in price and that eventually a plane of high finish and performance will sell to the private owner at prices no higher than those of a really first-class automobile.—*A.K.*

A four-place Stinson Junior cabin plane that sells now for only 5775 dollars, a price far lower, for this particular type of plane, than ever before quoted

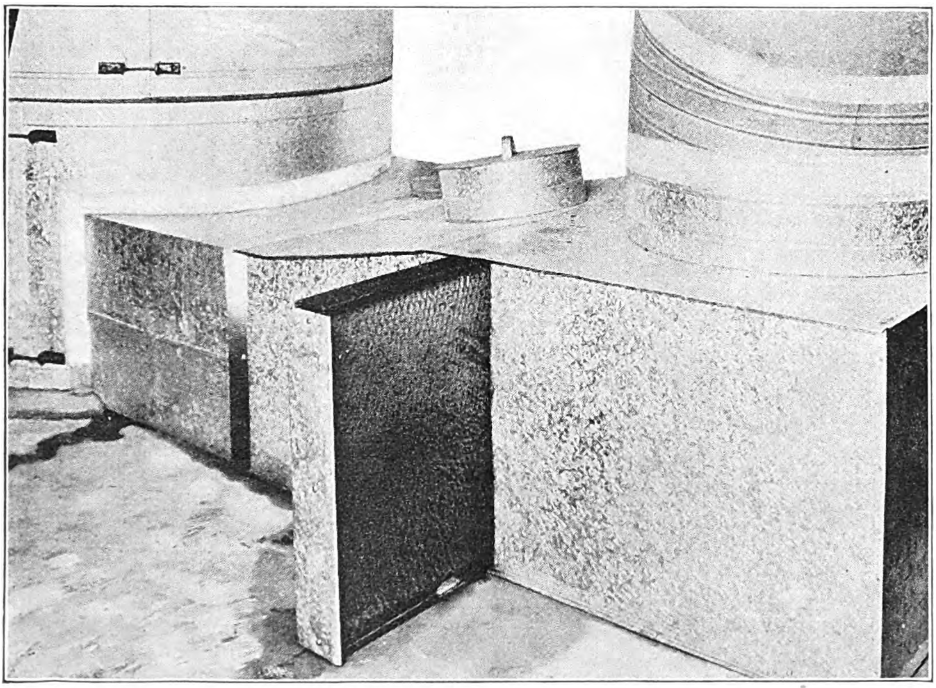
Fever and Radio Waves

FEVER is the reaction of the body to disease. Heat developed in the body helps to control germ activity. In the attack on general paralysis by the malaria injection method, one of the results of the injection is to produce fever. In the treatment of other conditions like general paralysis the production of fever may be an important factor. Fever in the human being follows the injection of any foreign protein substance. When such injections are made, their actions are sometimes severe.

Attempts have been made by the workers in the Research Laboratories of the General Electric Company to develop some system of raising the temperature of the body without injecting anything into the body. Drs. C. M. Carpenter and A. B. Page have been developing a method of raising the temperature by the use of short wavelengths. In this method the energy is concentrated between two condenser plates made of aluminum covered with hard rubber to prevent arcing should the patient or any attendant come in contact with the plates. The person whose temperature is to be raised is suspended on cotton tapes stretched across a wooden frame and surrounded with Celotex so that there is a fairly tight air chamber around the body. The plates are placed at each side of the Celotex box and the waves oscillate through the body from one side to the other.

It has been possible to raise the temperature of a man five degrees in one hour with this apparatus. Indeed, it would be possible to raise the temperature much higher than 104 to 105 degrees, but this has not been done because of the possible danger.

When the temperature of the body is raised rapidly by such a device, the person begins to have a fast pulse and to breathe more rapidly. Usually the blood pressure falls. In some instances high temperatures were maintained for one hour without apparent distress or fatigue to the patient. It is believed that the development of the heat in the body is due to the resistance made by the body to the conduction of the current. The evidence thus far available from studies in some 25 human beings and of many laboratory animals indicates that the heat within the body makes it less favorable for the multiplication of germs and that the increased rate of the various chemical processes in the body aids the resistance to disease and infectious agents. —*M.F.*



Filtered, forced warm air for heating and ventilation is now possible with this combination of filter, shown here partly withdrawn from its housing, and electrically driven fan. The fan draws cold air through the filter for cleaning, and delivers it to an ordinary hot-air furnace for heating

Welding Copper Made Easy

UNTIL recent years it was considered that the satisfactory welding of copper was impossible. The high thermal conductivity of the metal gave rise to grave practical difficulties, and even if these were overcome it was found that the copper became brittle by the action of the gases in the acetylene flame. As the result of recent research work, however, a process for welding copper has now been evolved which renders the operation simple and safe, provided the correct materials are used.

A demonstration of this welding was carried out recently at Swansea, England. At this demonstration copper pipes were welded together without difficulty and the joint subjected to severe flattening and bending tests, the results of which proved conclusively that the weld would withstand conditions of service as satisfactorily as the pipe itself. Sheets of copper were also joined together by the welding process, and it was shown that these would withstand a considerable amount of work and stretching; in fact, as much as the solid copper itself could be expected to withstand. The welding of varnish-pot seams was also demonstrated, a process which eliminated a great deal of troublesome riveting. It was observed that the welding operator worked quickly and as easily as if he were merely brazing the pieces together, and after the weld had been made and trimmed it was difficult to see where the joint occurred, while it had a tensile strength equal to that of rolled copper.

The demonstration proved that the difficulties previously associated with the welding of copper had been overcome, and it is certain that there is a wide field in industry for the application of the process. Riveting will be largely eliminated, and vessels which previously had to be forged out of solid copper—a very expensive procedure—can now be built up by welding sections together. All this has been achieved by means of slight modifications in the technique of welding ferrous metals, by the use of copper alloy filler rod and flux of the appropriate type.

The copper that has been developed for welding purposes is not attacked by the gases of the acetylene flame, and it is essential to use this copper if the weld is to be perfectly satisfactory. The copper is a modification of the tough pitch variety, supplied at the same price, but not inferior to it in any way; in fact, it might be expected to give better service generally. The filler rod, again, is of specially modified copper, which is very fluid when molten, and so runs well into the joint, leaving no air locks or gaps. It is essential to use this filler rod in order to obtain a homogeneous weld. The flux is used in order to hinder the formation of scale on the red hot copper as the scale prevents good metallic contact, and hence a solid joint, from being obtained.

Using these materials, it was demonstrated that with an hour's practice a welder could acquire the technique of copper welding and produce sound joints as easily as he could with ferrous materials. —*A. E. B.*

Regulating Air Transport Services

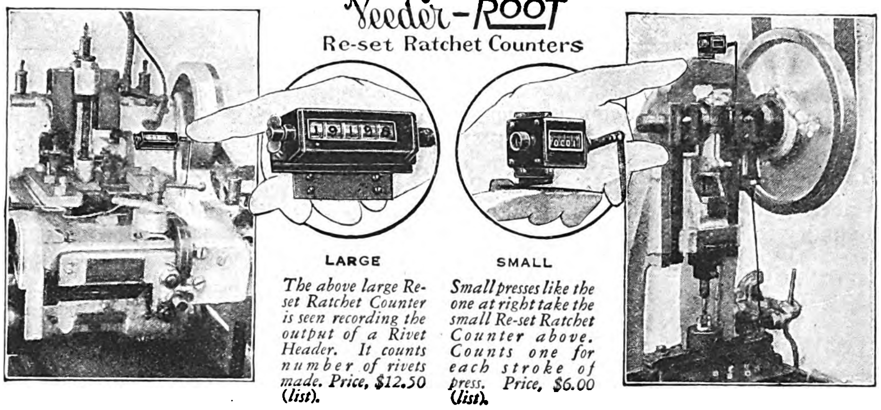
IN the continued depression of the aviation industry, there is one bright spot—the continued and rapid growth of the transport service; mail, passenger, and (to some extent) express.

We believe that the new regulations of the Department of Commerce regarding transport services will help rather than hinder this growth. These regulations provide that before scheduled operation of passenger air transport is established, a Certificate of Authority must be obtained from the Secretary of Commerce. To secure and retain such a certificate the service must provide satisfactory aircraft and equipment, an adequate number of qualified airmen, a high degree of maintenance efficiency, good airways and navigation facilities, and a first-class ground organization.

Nothing is so well calculated to inspire the traveling public with confidence as regulations of this character, well and diligently administered.—*A. K.*

Machines Pay Counter-Bills Promptly

Veeder-Root
Re-set Ratchet Counters



LARGE

The above large Re-set Ratchet Counter is seen recording the output of a Rivet Header. It counts number of rivets made. Price, $12.50 (list).

SMALL

Small presses like the one at right take the small Re-set Ratchet Counter above. Counts one for each stroke of press. Price, $6.00 (list).

Where rate of production has any relation to rate of profit, use *Counters* with no thought of *cost.* They'll give an accounting for every unit of output; every ounce of material; every hour of labor-cost.

What you *save* on all these items quickly "writes off" the Counters. Your machines pay the bill automatically—in YIELD. Costs you only a moment's thought to realize how they'll economize on production-costs.

Your request brings Catalogue of the Counters needed.

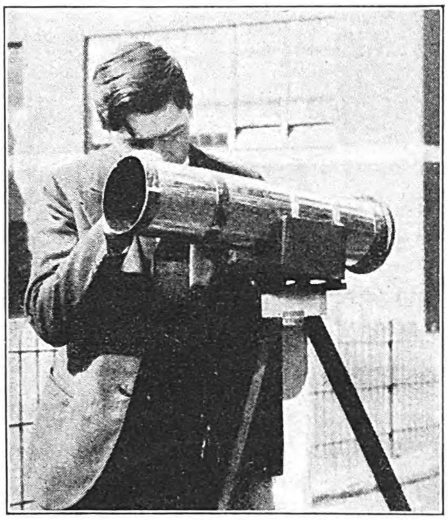
The Amateur Astronomer

Conducted by ALBERT G. INGALLS

WORD comes out of the wilds of Vermont that the fifth annual "get-together" of amateur telescope makers will be held on August 15, 16, 17 at the usual place, "Stellafane," near Springfield. Let this notice serve as sufficient excuse for all and sundry to come. John Pierce and the other members of the "Telescope Makers of Springfield" expect later to send out individual postcard announcements to those in the east, but do not let failure to receive one keep you away; it might be merely a mistake. "The big day," Pierce writes, "is Saturday, the 16th, with Porter, Redfield, Marshall and other illustrious people strutting their stuff." We do not know what profound secrets these entertainers have up their sleeve. Mr. Redfield's specialties are cornbread and poetry.

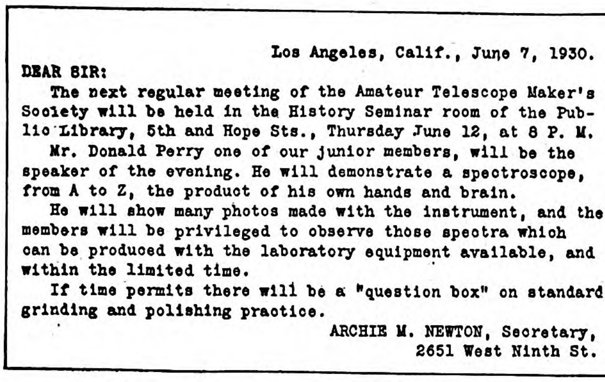


Bob Burns. He saved 80 "bob"

Last year so many attended this informal confab of amateur telescope makers and astronomers that it was a question whether to rent a circus tent next time. People came from all over the east, and some from greater distances, to commune with other enthusiastic telescope fans. There is a small hotel in Springfield, also very limited "quarters" (for men) at "Stellafane." A good many come in their cars, bringing their families and tents. There is all sorts of room to camp, and a good spring of water is nearby. Leave your dress suits in mothballs, as this is not a "high hat" affair but just a friendly, comfortable gathering of "folks." If you have made a telescope or invented any kind of optical dingbat of which you are unashamed, bring it along and give the other fans a chance to knock it. If you wish to make any special arrangements write to the Secretary of the "Telescope Makers of Springfield," Oscar S. Marshall, 135 Wall Street, Springfield, Vermont.

WHEN the hot months come people usually let up their efforts in telescope making; they had rather be out of doors than working in the cellar workshop. About September the orders for the instruction book "Amateur Telescope Making" always begin to come in thick and fast, and then we know the game is on again. However, to judge from the postcard announcement which is reproduced on this page, telescope making activities never wane, even in hot weather, in lively Los Angeles. Fragments of information reach us from time to time about the various activities of the Amateur Telescope Maker's Society of Los Angeles, the latest being that they have gone in heavily for refractor making. The seed that was dropped in that city four years ago is growing—in fact, already has grown—into a thriving tree. We wish the amateurs of "L. A." would send in accounts of their doings, with photographs of the jobs done, for publication.

Some of the telescopes made by amateurs have been pretty elaborate affairs and some are not so elaborate. However, we publish them all because we do not wish merely to feature the finer ones. A worker who builds a small instrument may lack facilities for making a large one, he may not happen to have had special training in machine work, he may not be rolling in wealth, but he derives as much fun from making it as the fellow who puts together a big one. One thing, however, is that we have found that the work is not suited to boys. Very few have made good at it, and those, we suspect, were unusually bright lads with an aptitude for mechanical work and for thinking.



Los Angeles, Calif., June 7, 1930.

DEAR SIR:

The next regular meeting of the Amateur Telescope Maker's Society will be held in the History Seminar room of the Public Library, 5th and Hope Sts., Thursday June 12, at 8 P. M.

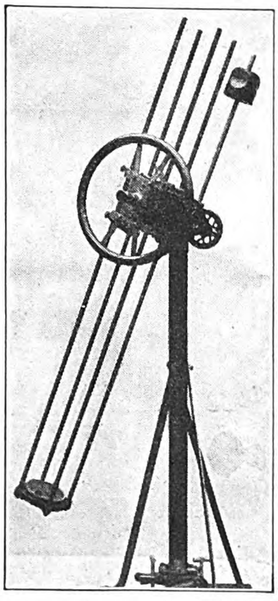
Mr. Donald Perry one of our junior members, will be the speaker of the evening. He will demonstrate a spectroscope, from A to Z, the product of his own hands and brain.

He will show many photos made with the instrument, and the members will be privileged to observe those spectra which can be produced with the laboratory equipment available, and within the limited time.

If time permits there will be a "question box" on standard grinding and polishing practice.

ARCHIE M. NEWTON, Secretary,
2651 West Ninth St.

Thriving amateur activities in "L. A."

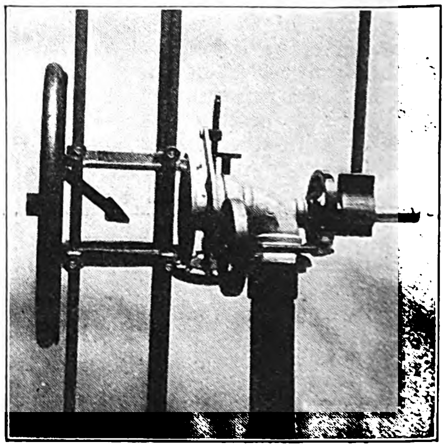


Above and at right, "Friday" Angier's unique design

JUST how inexpensively a telescope can be made never has been settled, but Bob Burns, of 326 Courtland N. E., Atlanta, Georgia, has shaved a big chunk off the average cost of a six-inch reflector. The materials for a six-inch telescope which will magnify from 50 to 200 diameters usually cost about 25 dollars. The initial outlay is ten dollars for a prepared package containing the glass disks, abrasives, and pitch. With these the mirror is made and then after some time the eyepiece and diagonal prism, each at six dollars, are obtained. The average amateur worker can be trusted to pick up the remaining parts, chiefly secondhand, for little or no more than the remaining three dollars. Often we are asked whether there is a way to make a telescope still more cheaply than this. There is. If one can pick up a microscope eyepiece this will save six dollars. Other savings are possible in some cases, depending on the worker's resourcefulness.

A four-inch, instead of a six-inch mirror, provided the main solution of the cost problem, in the case of Mr. Burns, who made a telescope at a total cost of $5.35. We asked Mr. Burns to tell the amateurs how he did it. Here is what he reports.

The four-inch glass disks were cut from two pieces of one quarter inch broken windshield glass which I procured for the asking at an auto junk dealer. Cost	$ .00
Cutting and grinding the edges of these disks, at an automobile glass service station, was	.25
The American Optical Company furnished me three grades of emery (No. 60, 120, 302) and the rouge for	.65
Silver nitrate, one quarter ounce, cost	.25



I used household ammonia and formaldehyde to reduce the silver nitrate, when silvering the mirror. Cost to me	.00
A wood turning shop made the wooden mirror cell for	.50
The 24-inch tube is made of polished sheet zinc, and cost	.90
For my diagonal I used a piece of one quarter inch plate glass of oblong shape, 1¼ by ¾ inches, corners rounded, the supports being soldered to the inside of the tube. The cost of this was	.00
The eyepiece was taken from a "pencil" microscope which cost	1.00
Brass tubes for eyepiece (plumber's shop)	.15
Lumber for tripod, cut to size	1.25
Bolts for tripod	.20
Lacquer and brush for painting tripod and inside of tube	.20
The total expenditure came to	$5.35

I polished my mirror by gluing the crown of an old felt hat to my tool and polishing on this pad. It finished out in about 1½ hours. I made no attempt to change the curve from a sphere to a parabola.

With the three quarter inch, double-convex eye lens the telescope gives about 50 to 60 diameters magnification. The innumerable craters on the moon are very interesting

PHIL E. CHURCH, 104 East LaRue, Streator, Illinois, sends in a few pictures of an unusual telescope. He says: "Three of us did the work, but 'Friday' Angier conceived and built the mounting. The steering wheel is for rapid control in directing the telescope but there are slow-motion screws and these are turned by means of sewing machine flywheels. The three of us, 'Friday,' Herbert Prafcke, and I, are greatly satisfied with this arrangement and we invite comment from other amateurs." Are there any who want to break a lance with these three musketeers?

THE following hint is from the April number of the *Journal of the British Astronomical Association* and was contributed by Walter E. T. Hartley, 11 Manor Road, Edgbaston, Brimingham, England. Birmingham is one of the great industrial centers of Great Britain and much bitumonious coal, with its inevitable content of sulfur which quickly tarnishes silver, is used. He says, "I keep two layers of cotton wool in the cover, and while observing put the cover in front of the fire—this ensures a dry film, but I have now between the wool and the mirror two thicknesses of blotting paper which have been soaked in a strong solution of lead acetate and then dried. As a result my last silvering was done in 1923, and the mirror is only now beginning to show signs of tarnish." Try it, someone, and see how it works, for soft coal sulfur in America is the same as soft coal sulfur in England.

HERE is an interesting hint. Harold A. Lower, 1032 Pennsylvania Avenue, San Diego, California, who is always trying out something new in amateur optics, writes: "I discovered a new use for a microscope the other day. The mechanical stage makes an excellent arrangement for controlling the knife-edge when making the Foucault test. Just attach the razor blade to the mechanical stage by means of a small D-clamp, and it works as if made to order."

Current Bulletin Briefs

Short Reviews of Bulletins and Papers on Scientific and Allied Subjects, and Where to Get Them

Longleaf Pine Primer (Farmer's Bulletin No. 1486, U. S. Department of Agriculture) by W. R. Mattoon, describes the growing of longleaf pine as a crop, pine timber being so scarce. The pamphlet is fully illustrated. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Porcupine Control in the Western States (Leaflet No. 60, U. S. Department of Agriculture) by Ira N. Gabrielson and E. E. Horn deals with a pest, for they girdle trees and injure forests. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

Properties of Soils which Influence Soil Erosion (Technical Bulletin No. 178, U. S. Department of Agriculture) by H. E. Middleton gives valuable light on an old problem. *Superintendent of Documents Washington, D. C.—5 cents (coin).*

The Cofee Industry in Brazil (Trade Promotion Service No. 92, U. S. Department of Commerce). *Superintendent of Documents.—20 cents (coin or money order).*

Bismuth (Circular of the Bureau of Standards, No. 382, U. S. Department of Commerce) gives very full information on the metal and its alloys. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Geology and Oil Resources Along the Southern Border of San Joaquin Valley. (Bulletin 812 D, Geological Survey, Department of the Interior) by H. W. Hoots. *Superintendent of Documents, Washington, D. C.—50 cents (money order).*

Breeding Tobacco for Resistance to Thielavia Root Rot (Technical Bulletin No. 175, U. S. Department of Agriculture), by James Johnson, is a study of a common and important disease of tobacco. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

New Brunswick, Canada, by L. O. Thomas, describes the industries, agricultures, natural resources, and development of New Brunswick. *Address the Director, National Development Bureau, Department of the Interior, Ottawa, Canada.—Gratis.*

German Chemical Developments in 1929 (Trade Information Bulletin No. 690, U. S. Department of Commerce) reports the important events in the industry during 1929. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

The North West Territories 1930 is the title of an attractively illustrated handbook of 137 pages. A concise compendium of general facts relating to Northern Canada, it is accompanied by a beautiful map. *Address the Director, North West Territories and Yukon Branch, Department of the Interior, Ottawa, Canada.—Gratis.*

Tides and Currents in Chesapeake Bay and Tributaries (Special Publication No. 162, Coast and Geodetic Survey, Department of Commerce) by F. J. Haight, H. E. Finnegan, and G. L. Anderson, contains many folded maps. *Superintendent of Documents, Washington, D. C.—65 cents (money order).*

The Marketing of Nickel (Trade Information Bulletin No. 685, U. S. Department of Commerce) by J. W. Furness tells what nickel is, where it is produced, for what it is used, and where it is marketed. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Tin in 1928 (Excerpt pages 321-346 of the Mineral Resources of the United States, Bureau of Mines, U. S. Department of Commerce) by Charles White Merrill. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

Preliminary Reports of the Aerial Mineral Exploration of Northern Canada gives an interesting account of investigation of large areas with the aid of airplanes. *Address the Director, North West Territories and Yukon Branch, Department of the Interior, Ottawa, Canada.—Gratis.*

Water-Power Resources of the Umpqua River and its Tributaries, Oregon (Water Supply Paper 636-F, Geological Survey, Department of the Interior) by Benjamin E. Jones and Harold T. Stearns. *Superintendent of Documents, Washington, D. C.—40 cents (money order).*

Geology and Coal Resources of the Meeker Quadrangle, Moffat, and Rio Blanco Counties, Colorado (Geological Survey Bulletin 812-C, Department of the Interior) by E. T. Hancock and J. B. Eby. *Superintendent of Documents, Washington, D. C.—30 cents (money order).*

Ultra-Violet Reflecting Power of Aluminum and Several Other Metals (Bureau of Standards Reprints, No. R.P. 141) by W. W. Coblentz and R. Stair. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

How to Build Home Radiovision Equipment explains the technique of radiovision reception and what is required by way of equipment, and then goes on to describe the construction of a practical radiovisor made from a kit of parts now on the market. *Jenkins Television Corporation, 370 Claremont Ave., Jersey City, N. J.—Gratis.*

An Electrical Method for the Determination of the Dew-Point of Flue Gases (Circular No. 20. Engineering Experiment Station, University of Illinois) by *Henry Fraser Johnstone, University of Illinois, Urbana, Ill.—15 cents.*

Standards Year Book 1930 (Miscellaneous Publications No. M 106) is a clothbound book of 301 pages. *Superintendent of Documents, Washington, D. C.—75 cents (money order).*

Nation Building and Beyond (The Richard Cobden Lecture given at the Royal Society of Arts, London, May 7, 1930) by Nicholas Murray Butler is a very famous lecture which made a great sensation both here and abroad. *Carnegie Endowment for International Peace, 405 W. 117th St., New York City, N. Y.—Gratis.*

The Kyoto Conference of the Institute of Pacific Relations (No. 260 of International Conciliation, May, 1930) by Chester H. Rowell. *Carnegie Endowment for International Peace, 44 Portland St., Worcester, Mass.—5 cents.*

Weights and Measures References (Miscellaneous Publications No. M 103) including an index to the reports of the National Conference on Weights and Measures, from the first to the twenty-first inclusive. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

The Commercial Standards Service and its Value to Business (Commercial Standard CSo-30, Bureau of Standards, U. S. Department of Commerce) gives the whole idea in a nutshell and is an exceedingly valuable little pamphlet. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Trailside Conversations. Parts One and Two (New School Series Number Four) by Wm. H. Carr. Describes the nature trails and trailside museum at Bear Mountain, New York. It is beautifully illustrated. *American Museum of Natural History, 77th Street and Central Park West, New York City.—20 cents.*

Our Point of View

Navies and World Problems

(Continued from page 93)

tration and the delegation had frankly said it was the best treaty obtainable under the circumstances. President Hoover was in no way responsible for our present inferior position in cruisers and submarines, nor for the unwillingness of Japan to reduce her tonnage *already built* to the 5 to 3 ratio.

The country is under obligation to Senators Hale, Johnson, and Robinson of Indiana, for the severe scrutiny they have given the draft of the treaty. They uncovered an ambiguity in the wording about cruiser replacement that might have caused serious misunderstanding; this was cleared up by an exchange of notes between the contracting parties. More important still, the answers to their persistent questions have more fully informed the public about the effects of the treaty.

The group of admirals led by Rear Admiral Hilary P. Jones, who analyzed the treaty, who showed the extreme concessions made to Japan, and who bore strong testimony to the value of 8-inch gun cruisers, deserve well of their countrymen. Called by the Senate committees, they were obliged to bear true witness to their beliefs; and though we support the treaty, we have no doubt of their sincerity or sound judgment. We believe with them, that 8-inch gun cruisers would better serve our purpose; but can't believe that 6-inch gun cruisers will not serve us well in any war that we might be drawn into. Important political factors have to be considered as well as naval, and with those in mind, we reluctantly conclude that our best hope for a navy within the next five years is to ratify the treaty and commence to build ships, instead of indulging in more conferences.

INSTEAD of frightening tax payers by talking about an 800,000,000-dollar program that will be spread over 8 to 10 years, the Administration should explain that the appropriation for this program will be about 90,000,000 dollars a year or about 75 cents per capita annually, a paltry sum for the protection it affords our country and its sea-borne trade.

A disquieting fact disclosed by the Senate testimony is the scant heed paid by the delegation to their naval advisers—apparently even Admiral Pratt was consulted only after the decisions were made by the delegation. There is a current opinion in the United States that in the past too little attention has been paid by the State Department to Army or Navy advice. The results of this rather disdainful attitude of the State Department is expressed loosely by the phrase heard in so many places "We never lost a war, and never won a conference." The country believed that Mr. Hoover, himself an expert engineer, would insist that the naval experts he attached to the delegation be consulted; Mr. Stimson almost airily relegated them to the rear. Democratic government is essentially a government by amateurs. Americans would not have it otherwise, but they believe Admiral Jones is more apt to be right on a naval problem than Secretary Stimson, and we think we would have had a better treaty if Stimson, Dawes, and Reed had not been a little over-eager to play it alone.

Fortunately, the life of this treaty is less than six years; then the whole question of ratios will be subject to reconsideration. If our people really want a navy and are willing to pay the small premium required for their naval insurance, they can build up to the treaty limits by 1936, and enter the next conference in a position to insist that our naval necessities be recognized. If we do not want a navy badly enough to pay for it, we should cease demanding that more prudent powers stop their building programs simply because we are too niggardly to build a navy that we all know we need, and need badly.

We should realize that, now having outbuilt us, Japan is unwilling to make the concessions that we made in 1922, when our ship-building program was about to give us sea supremacy. If our people appreciate the significance of this fact, and lose some of their naive belief in the altruism of other States, eventually they will be well compensated for the temporary disadvantage of the treaty.

ITALY and France are no nearer agreement than they were in London and it is quite possible that England may have to invoke the "safety clause" which allows an increase in her cruiser strength in the event that Italy and France enlarge their naval programs. We would be permitted the same increase granted England. Much more alarming than an increase in the Latin navies is the apparently irreconciliable rivalries of these two Mediterranean powers. Observers, who are usually well informed, speak in measured terms of the possibility of war between these two neighbors. Such a conflict would be bound to spread to other European States, and no one could predict its limits.

This is an uneasy period for Premier MacDonald. The unrest in India continues unabated and if this passive resistance extends as urged by Gandhi's successors, to a refusal by the great mass of Indians to pay taxes, the task of the Viceroy, Lord Irwin, will be difficult indeed. To add to MacDonald's troubles with Egypt and India, the small but strategically important island of Malta took occasion to flare up, and it is reported that considerable discontent with British rule exists within its limited confines. Unquestionably both India and Egypt have benefited by English rule; it is certain that neither could maintain law and order at home or resist foreign States unless supported by Great Britain; and yet, led by sincere but uninformed reformers, they continue their agitation for independence without any let-up.

It is one of life's fine ironies that the Labor Party which, in opposition, is fond of declaiming against imperialism, is face-to-face with one of the great problems of empire. Gladstone, England's great Liberal leader, often accused of being a "little Englander", found himself in a similar quandary on more than one occasion; and Sir Henry Campbell-Bannerman, another great Liberal, faced and solved the problem of the Union of South Africa after the Boer War. And it is not unlikely that a Labor Premier will find a solution to Great Britain's imperial problems. Needless to say, the action of the Labor cabinet in dealing with India will be no less firm than the Conservative.

For small motors to meet your requirements—to make your product a salable one—Signal Fractional Horsepower Motors offer you the correct principles of design, made by a manufacturer who has been making small motors for forty years, and a design to make your product perform the way you intend it should perform. Either induction or series wound motors. Signal can help you. What are your motor problems? Information free.

Magic

Learn at Home, By Mail!

Scientists, doctors, all professional men and business executives find Magic a great asset. Dr. Harlan Tarbell, Famous Magic Wizard, teaches you the Principles of Magic and a marvelous array of educating and fascinating magic tricks. You learn easily and quickly at home by mail. Write today for *free* literature.

Tarbell System, Inc. 1926 Sunnyside Ave., Studio C-184 Chicago, Ill.

Books Selected by the Editors

Aviation Engines—*By Ray F. Kuns, Editor, Automobile Digest*

QUITE the best presentation of the very latest types of aeronautical motors that we have seen. Each engine is taken up in detail with general construction and description of the parts, including special, individual, characteristic points comprehensively outlined. Care and upkeep are covered and various "trouble" notes are added, so that the whole is a most practical manual. $2.15 postpaid.

Radio and Its Future—*Edited by Martin Codel*

A COMPREHENSIVE survey of the various phases of radio communication—commercial, broadcast, amateur, industrial—each phase being covered by an acknowledged authority in his special subject. Past and present are dealt with in a comprehensive manner, giving the reader a broad background which will aid materially when following the progress of the art. Future possibilities of radio are handled with the sane foresight of the practical scientist; particularly is this true of the concluding chapter by Lee de Forest. $4.25 postpaid—*A. P. P.*

OUR previous message to readers of these pages has been accepted so spontaneously by many book seekers, that we wish again to state, for any who did not notice the previous offer, that if you want to know what literature is available on any subject you are studying or any hobby you are pursuing, write to L. S. Treadwell, the editor who is responsible for this department and every attention will be given your request. Should there be nothing available we will be frank to tell you or advise as to the possibility of advertising for second-hand copies. Let us try to help you solve your problems.

The Radio Amateur's Handbook
By A. Frederick Collins

THIS, the sixth edition of this highly popular elementary book on applied radio, has been entirely revised, rewritten, and reset. New illustrations have been added and those of the old ones that are used have been redrawn, bringing the book up-to-the-minute in every respect. This volume is directed especially to those who desire a working knowledge of the theory and practice of radio, and who have a leaning toward home construction. Various types of receiving and transmitting (C. W. and phone) sets are described, several in such complete detail that the reader can start work with the text as the only necessary guide. Appendices of Useful Information, Glossary, Radio Don'ts, Insurance Requirements, and Radio Laws, as well as a comprehensive index make the book a valuable one to every radio fan. $2.15 postpaid.

New Building Estimator's Handbook
By William Arthur

WHETHER it be a residence or a railroad shop, a store or a school, or almost any conceivable kind of building that is to be constructed, this handbook will give information as to quantities of all materials needed and will quote comparative prices on everything from the foundation to the roof. The 15th edition of this invaluable work, long accepted as an authority by architects, builders, contractors, engineers, plant superintendents, and draftsmen, has been fully revised and enlarged. 1056 pages, 600 tables, 480 illustrations—$6.25 postpaid—*F. D. McH.*

Die-Casting Practice—*By Marc Stern, A. C. Spark Plug Co.*

A WELCOME authoritative treatise, based on the author's long and vital connection with the die-casting industry. It represents concisely detailed and practical data on the application of die castings, the principles of design, the limitations and possibilities of the many alloys in use, and the finishes suitable to such alloys. 270 pages, 128 illustrations. $2.65 postpaid.

Matter and Radiation—*By John Buckingham, Asst. Director of Scientific Research, The Admiralty*

A PECULIAR book, exhibiting a well-known English trait—it wanders casually over a large field touching with interest on this and that but without covering anything very amply. Yet the present reviewer found it so interesting that every word was read. Of the five chapters (90 pages) three are on electric waves, atomic physics, and radiation, the other two (40 pages) being on infra-red rays and their use in the detection of invisible objects, in secret signaling, fog penetration, self-steering torpedoes, navigation and so on—most fascinating things, every one—but since the author treats them with so much interest and lucidness, it is a pity that only a half portion of each could be served up. A full-sized book giving details on the same application of the infra-red if written by this author, should make reading which would defer the bed hour, for he has an evident flair for making simple things seem as simple as they really are. $3.20 postpaid—*A. G. I.*

The Aluminum Industry—*By Junius D. Edwards, Asst. Dir. Research, Francis C. Frary, Dir. Research, and Zay Jeffries, Metallurgist, Aluminum Company of America.*

VOLUME I covers the history of the discovery of aluminum and the development of the industry, the ores of aluminum and their mining and refining for the production of pure alumina, and closes with a discussion of the production of metallic aluminum. Volume II gives the reader a broad view of the various processes by which aluminum is fabricated and discusses also its properties and uses. Two volumes (not sold separately), $12.50 postpaid.

The New Evolution—Zoogenesis—*By Austin H. Clark, U. S. National Museum*

IT has been said by some that Dr. Clark's new theory of organic evolution will take rank with Darwin's original theory as set forth in 1859 in "The Origin of Species." Darwin's great book created an immediate furor and the first edition was snapped up in next to no time, and first editions are today rare and highly valuable. What effect Dr. Clark's theory will have on biologic thought no one now knows but it seems certain to provoke a great deal of argument and controversy among men of science. The present volume sets forth the theory in detail and in language comprehensible to the reader of average schooling. Since it is likely to be the center of a major controversy, persons having interest in scientific events are advised to post up on it in advance and be in a position to comprehend the arguments. $3.20 postpaid—*A. G. I.*

Exploring for Plants—*By David Fairchild*

AN intimate narrative of a scientist's adventures in little known lands, based on notes of the Allison V. Armour expeditions. Dr. Fairchild is a botanist of note with a remarkable record for doing things, the results of these expeditions being the introduction into this country of many useful new plants and trees. Ranking as a scientific book, its charm for the average reader lies in the ease of style and the joyous appreciation of life looked at from every angle. The story is so smooth one assimilates the botany with no effort whatsoever. Good science, good reading, good writing. We highly recommend it. Abundantly illustrated. $5.20 postpaid.

THE MATERIALS OF LIFE—*By T. R. Parsons, M.A., B.Sc.*

A "DEBUNKED" presentation of biochemistry, for the chemistry of the human body is certainly a pin on which loose statements have been hung from time immemorial. "An apple a day" does not keep the doctor away. One orange contains more vitamins than a basket of apples. Light treatments and backless bathing are popular but many of us will be surprised to learn that the effect of ultra-violet rays is similar to that of cod-liver oil. The book gives sensible as well as accurate accounts of such things as gland secretions; vitamins; the cycle of nature; food energy; the living fire; wear and tear; blood and iron; starch, sugar, and fat; digestion and indigestion, et cetera. The author eschews horrifying formulas in which those who deal with such matters professionally are wont to encyst their ideas and writes in a language which all can understand. $3.20 postpaid—*A. A. H.*

PRIMITIVE METHODS OF WORKING STONE—*By Alonzo W. Pond, Logan Museum*

THIS most fascinating book is based on the flint-flaking and artifact-making experiments and activities of Mr. Halvor L. Skavlem, mentioned on page 88 of the present number. It describes Mr. Skavlem's actual technique; therefore it is, as the author intended, a practical instruction book: "Any student who will take the trouble to read the foregoing," he says, "will be able to apply the principles as has Mr. Skavlem and like him will, with a little practice, be able to make arrowheads and other chipped instruments." The book, though paper bound, contains 143 large pages, is handsomely produced and there are 64 fine half-tone plates. It is suggested that would-be purchasers obtain it direct from The Logan Museum, Beloit College, Beloit, Wisconsin. $1.15 postpaid—*A. G. I.*

MY LIFE—*By Leon Trotsky*

MEMOIRS of the exile Trotsky ought to be interesting when we consider the enormous power once wielded by himself and Lenin. The whirligig of fate, however, has been exceedingly swift in the case of Trotsky who was sent into exile by the present Soviet government in January, 1928, and he writes his book from Constantinople. Trotsky makes note of his arrival in New York as follows: "*Sunday January 18 (1917):* We are nearing New York. At three o'clock in the morning. Everybody wakes up. We have stopped. It is dark. Cold. Wind. Rain. On land, a wet mountain of buildings. The New World!" He stayed in New York about two months and contrary to many stories his only occupation or profession was that of a revolutionary socialist. He rented an apartment for 18 dollars a month and the colored janitor ran off with three months' rent. It is by such sidelights that we enjoy a book of this kind. In attempting to return to Russia via Norway he was taken off the steamer at Halifax with his family, and placed in a detention camp, but was finally released and allowed to continue his journey to Petrograd—a journey fraught with so much history. The theme of his rise to power and his eclipse is a very long story which you will have to read for yourself. His life was weird and fantastic. $5.20 postpaid—*A. A. H.*

SLEEP—*By Laird and Muller, Colgate Psychological Laboratory*

THE many thousands who have taken keen interest in Professor Donald A. Laird's articles, published in the SCIENTIFIC AMERICAN during the past year or two, will find in this new book the substance of about 18 more equally interesting articles, all of which center around that rather familiar activity we all indulge in more or less—sleeping. After you have read this treatise you will be a sleep scientist. How can we get to sleep more quickly? How much sleep do we need? How does noise affect sleep? Do dreams affect the benefits of sleep? What types of covering, mattresses, and springs will best promote sound sleep? These are a few of the aspects of sleep covered in this semi-scientific work. The authors deny categorically that they were subsidized by any maker of beds, bedding, pyjamas, negligees, or cures for insomnia; they have tried merely to ascertain scientific facts about sleep, no matter whom these helped or hurt. The book makes easy reading, though it is packed full of fact, and is suited to the understanding of mere mortals. $2.65 postpaid—*A. G. I.*

PIONEERS OF FREEDOM—*By Sveinborn Johnson*

HERE we have vivid account of the Icelanders and the Icelandic Free State (874-1262) issued on the eve of the 1000th anniversary of the founding of the Althing or Parliament of Iceland which was celebrated by appropriate exercises on the ancient site where that body regularly convened for approximately 900 years. It is interesting to see how these isolated people founded and maintained governmental institutions while the rest of Europe was largely in the grip of absolute power and centralized monarchies. Iceland maintained a government strikingly free and responsive to the popular will. This far-away island was perfecting popular institutions while most of contemporary Europe was drifting towards despotism. Under the influence of civil and political liberty there flourished a legal system which in excellence rivaled that of Rome; and during the same period a literature blossomed which contained some of the finest creations of the human mind. The government finally collapsed because of elementary defects and a spirit of lawlessness. $3.70 postpaid—*A. A. H.*

VERDUN—*By Marshal Petain*

THIS is a definite record of the most heroic and spectacular last-ditch defense of the great war written by the man himself who conducted that defense to a successful conclusion. The author presents no argument, makes no bid for fame, he tells the facts with an impartiality that is amazing. Judgment on the German commanders is free from bias; the Crown Prince is given credit for a humanity the world has little suspected. But the most significant statement, in view of the comparatively quick demolition of Liege, Namur, and Maubeuge, is that permanent concrete fortifications such as Douaumont when properly manned and equipped can be of indispensable value in maintaining a defense and will resist the fire of the heaviest ordnance. The style of narrative is of such perfection and the generalizations are so clear and comprehensive as to make this work one of the literary gems of war history. $4.20 postpaid.

PRINCIPLES OF SCIENTIFIC PURCHASING—*By Norman T. Harriman, Bureau of Standards*

A LONG experience in railroad purchasing and specializing for the last nine years in the standardization of purchasing and its procedure of the Federal Government under the Bureau of the Budget, has given the author a sweeping comprehension of the fundamental necessities, the basic rules of scientific buying, and the philosophy of Budgetary Control that applies equally well to private business. A complete summary and thorough analysis of the best present day practice. $3.25 postpaid.

Commercial Property News

Facts and Notes of Interest to Inventors, Patentees, and Owners of Trademark Rights

Attorney's Delay Unavoidable

A DELAY of a few months in filing an application for a patent, due to the accumulation of business before the patent attorney entrusted with the filing, does not show a lack of diligence on the part of the applicant in prosecuting his claim to an invention and a patent therefor, the Court of Customs and Patent Appeals has ruled in an appeal from an interference proceeding in the Patent Office, according to *The United States Daily*.

The court held that the Patent Office had properly awarded priority of invention to George W. Heise as against the senior applicants, Martus & Becker, for certain improvements in battery cells.

The invention, the opinion states, "relates to the addition of zeolitic agents—one of which is 'permutit'—to the electrolyte in a caustic alkali electric cell for the purpose of increasing electrolyte efficiency."

Plan to Include Patents in War Settlement Favored

THE House Committee on Ways and Means at a recent hearing agreed to report favorably a bill (H.R. 9142) to extend jurisdiction of the Arbiter under the War Claims Settlement Act of 1928 to "patents licensed to the United States pursuant to an obligation arising out of their sale by the alien property custodian."

The purpose of the bill, according to the Special Assistant to the Secretary of the Treasury, E. C. Alvord, who testified before the Committee, is to extend the Arbiter's jurisdiction to the chemical foundation patents.

The 1928 act provides for compensation to alien owners of patents for use, or licensed to be used, by the United States, the licenses being restricted to those issued by the alien property custodian. That, according to the Government, left out the so-called chemical foundation patents, and at the time the case of the Government against the chemical foundation to set aside the sale of the patents involved, on the allegation of fraud in the sale, was pending in the courts.

Limited Novelty—Limited Claims

THE Board of Appeals has held that one claim only is allowable in a patent application covering an invention relating to the production of a water-resistant, porous, rigid, coherent mass by puffing the mixture of a ground filler and a water solution of sodium silicate, according to *The United States Daily*.

The slight novelty of the invention over the prior art was held to warrant the allowance of but one claim, the others being held not to be patentably distinctive.

The finished product of the invention is said to be suitable for use as a building material. The invention is alleged to be based on the discovery that the maximum resistance to moisture is obtained under certain conditions, they being: Particle size of the ground filler, composition of sodium silicate solution, and ratio of sodium silicate to filler.

British Mail Ban on Cigarettes

GREAT BRITAIN is seizing parcels containing sweetened cigarettes made in America and other countries which are being sent through the parcel post mails in violation of British postal regulations, according to advices received by the Post Office Department and made public in a memorandum sent to postmasters, who are to advise mailers that such parcels will be accepted only at their risk.

The brands of cigarettes affected are all popular in America, and are mailed principally by individuals as gifts to friends abroad and not by the manufacturers who sweeten their products to meet the taste of smokers, it was stated orally.

The full text of the memorandum follows:

In view of the existing prohibition in Great Britain against the importation of sweetened cigarettes, numerous reports of the seizure of parcels containing these articles are received from the postal administration of that country.

As practically all brands of cigarettes manufactured in the United States contain a certain percentage of sweetening properties, postmasters will advise mailers that cigarettes addressed for delivery in Great Britain will be accepted only at their risk.

Reduction to Practice Governs Priority

AFTER an invention has been reduced to practice, the abandonment of the invention will not be inferred merely from failure speedily to file an application for patent or to commercialize the product, the Court of Customs and Patent Appeals has ruled. Abandonment must be affirmatively proved, it was ruled, according to a recent issue of *The United States Daily*.

The opinion of the court states that "the diligence required of one claiming to be an inventor is primarily diligence in reducing to practice after conception, and the law is not so much concerned with speed in filing application for patent, provided, of course, there is no secreting or abandonment of the invention."

The court affirmed the Patent Office in awarding priority of invention for a process of manufacturing formamide to Burritt Samuel Lacy, who did not file an application for patent until three years after the conception of the invention and its reduction to practice.

The subject of the invention, according to the opinion, is a "process for the production of a material called formamide, one of the uses of which is as a raw material in the production of hydro-cyanic acid much used as an insecticide for fumigating citrus trees, ships, rooms, and so forth."

In another case involving the question of reduction to practice, the Court of Customs and Patent Appeals has upheld the Board of Appeals of the Patent Office in ruling that priority of an invention of a process for vulcanizing rubber involving the use of so-called high-power accelerators should be awarded to Sidney M. Cadwell over Marion M. Harrison and Harold A. Morton, whose assignee is the owner of patents No. 1434892 and No. 1434908, for the process. The patentees were the junior parties, the Cadwell application having been filed previous to theirs, although patents have been issued to them.

The opinion describes the steps that have been taken in the art of vulcanizing rubber. Problems arising in the use of high-power accelerators were solved by both parties, it is stated. The sole issue between the parties on appeal was which had first reduced the invention to practice.

The court held that the numerous laboratory tests conducted by the appellee in the usual way for determining proper vulcanizations, which tests were in common use in the rubber laboratories of the country, constituted a sufficient reduction to practice although no factory tests were made nor commercial operations conducted.

Pay for Service Is Not Free

"FREE" spectacles to a customer who would obtain orders for glasses from other persons were offered by the Clear Sight Spectacle Company, Chicago, but the glasses were really not free, according to the findings and an order to cease and desist just issued by the Federal Trade Commission.

"Take the scientific self-tester you now have to your friends," the customers were advised. "Ask them to make a test of their eyes as you have done. They too should have the benefit of our expert service and low price.

"Tell them you are going to order a pair for yourself and that they might as well send their orders with yours.

"Collect one dollar deposit from them and they can pay the balance to the mailman upon delivery. They will receive the same, strong iron-clad guarantee of satisfaction for five years to come.

"You may keep the one dollar deposit you collect as your pay. Take only four orders and you will earn more than enough to pay for your own glasses. Take as many orders as you can. You make one dollar each."

The Federal Trade Commission has ordered the company to cease and desist from representing the spectacles as "free" when the fact is they are not given free but "in consideration of personal services rendered or performed by certain customers in securing for respondent cash orders for two or more pairs of its spectacles from other customers."

Customers were invited to take two orders with a dollar deposit on each, send in the two orders and the two-dollar deposit. The person taking such order was to obtain his own glasses "free."

"Only one free pair of spectacles will be sent into a community," read an advertisement.

In one instance the company described its proposition as a "Special Ten Day Offer."

But the commission has also ordered the respondent to discontinue representing that the spectacles "can be obtained at the prices stated for a limited period of time only, or that said spectacles can be purchased by a limited or restricted number of persons only," as these restrictions were not put into effect.

"Army and Navy Supplies" May Be Misleading

NATHANIEL ABRAHAM, trading as N. Abraham Company and Warehouse, in San Francisco, offered for sale paints, automobile oils, and varnishes as "Army and Navy Surplus Supplies," when in fact this merchandise had never been the property of the United States Government.

In his advertisements Abraham displayed the following notices: "This Merchandise is Now Offered for Sale at Warehouse, 701 Battery Street, Corner Pacific," and "Warehouse, 701 Battery Street, San Francisco; Mail Orders Promptly Attended To."

Abraham was ordered by the Federal Trade Commission to cease and desist from these misleading uses of the words "Army and Navy Surplus Supplies," or the word "Army" or the word "Navy" standing alone or in connection with the word "Warehouse" or with other words.

Parachutes Are Developing

AFTER several years of more or less stagnation, development of parachutes for use of aviators has taken place, according to J. E. Sullivan, of the Bureau of Aeronautics, Department of the Navy.

The industry is a growing one, said Mr. Sullivan, who pointed out that the latest figures compiled by the Aeronautics Branch of the Department of Commerce show that the number of aircraft pilots holding active licenses now totals 10,701. Furthermore, parachutes constitute no minor item in the equipment of an aviator, as they sell commercially for approximately 350 dollars each, although they are bought for military purposes for considerably less.

A cotton substitute for the silk used in parachutes is being subjected to experiments, which has the advantage of being cheaper than silk. While commercial interests are employing cotton to a certain extent, the Bureau of Aeronautics has not arrived at any definite conclusion regarding its use for naval purposes.

There are four major manufacturers of parachutes today while there were only one or two five years ago. A recent improvement made by one manufacturer has been to make the pack perform the functions of the pilot parachute. The pilot parachute on the ordinary parachute is the first to open and drags the large one after it. When the rip cord releases the spring on this new type the bottom of the pack opens and replaces the usual pilot 'chute.

Another manufacturer has improved his product by reducing the size, which, although it makes the rate of descent somewhat faster, opens more quickly. Still another manufacturer, it was pointed out, is working on a triangular-shape parachute, which is claimed to be steerable.

Nearly all the accidents in the past due to the failure of the parachute have been attributable to improper packing or improper operation of the releasing device by the person making the descent, or hasty release of the spring, causing the parachute to open too quickly and catch on the plane.

The present development of parachutes is being worked out to a large extent on increasing their performance characteristics—making them stronger, more durable, with smaller packs and less bulky. The features which the Navy looks for in a parachute are the certainty and rapidity of opening, slow rate of descent which must be about 20 feet per second, and non-oscillating.

"Dry Ice" Package Patent Valid

THE Slate patent, Number 1595426, for a refrigerating apparatus using solid carbon dioxide, so-called "dry ice," principally used for packing for shipment food products not damaged by excessive freezing, has been held valid by the Circuit Court of Appeals for the Second Circuit.

The defendant company, which was alleged to have supplied solid carbon dioxide for use in the plaintiff's packages, was also held by the court to be a contributory infringer of the patent.

The court over-ruled the defense of invalidity of the patent, holding that while the use of carbon dioxide as a refrigerant had been long known in the art, the arrangement adopted by the patentee in his apparatus was not anticipated.

The patentee was stated to have reversed the usual process by placing the refrigerant in the center of the package, surrounding it with ice cream or other substance to be refrigerated, and enclosing all in a packing box or insulating wrapping.

The court held that the method of utilizing by specified physical means the operation of a law of nature is patentable, thus overcoming the objection that a law of nature may not be patentable.

It was also found not to be fatal to the patent that the solid carbon dioxide is to be destroyed by its use as a refrigerant.

The doctrine of implied license to renew perishable and subordinate parts was also held not to be applicable to the perishable solid carbon dioxide, particularly where the exclusive licencee of the owner of the patent sells carbon dioxide with a license to use it in the package described in the patent.

Malt Product Mark Restrained

THE owner of the trademark "Budweiser," for malt syrup and other products, has been held by the District of Maryland to be entitled to an injunction restraining the use of the notation "Budd-Wise" on malt products. The matter was referred to a master for an accounting.

The court ruled that the defendant's allegation in answer to the suit for infringement that the plaintiff was deliberately and intentionally selling its goods for use in violation of the prohibition act and that its goods are not fit for legitimate use should be stricken from the pleadings as irrelevant and impertinent.

It was further held that the fact that the defendants had procured a copyright of their label was immaterial in a controversy as to trademark infringement, the copyright giving the defendants no trademark rights whatsoever.

Advertisements in this section listed under proper classifications, rate 25c per word each insertion; minimum number of words per insertion 24, maximum 60. Payment must accompany each insertion.

Anyone desiring the address of a patentee listed in this section may obtain it by addressing Munn & Co.; those desiring official copies of patents herein listed, may secure them by remitting 15 cents for each one (state patent number to insure receipt of desired copy) to Munn & Co., 24 West 40th Street, New York City.

Pertaining to Aeronautics

AEROPLANE—An amphibian air liner, in which the body simulates a bird, is particularly adapted for flying in sleet and snow, exhaust gases being utilized for heating the body and for preventing the formation of ice on the wings. Patent 1757879. John T. Rydberg.

Pertaining to Apparel

REAR YOKE FOR DRESSES—A reinforcement which extends from the rear opening at the neck to the sleeve openings and downwardly to the lower part of the sleeve opening for protecting the dress against perspiration without detracting from the pleasing appearance. Patent 1758852. Louis C. Rosenblatt.

Chemical Processes

PROCESS FOR RECOVERING BORAX FROM BRINE—Containing borate in solution together with sodium carbonate, which consists in treating the brine with carbonic acid gas to precipitate from the solution, and crystallizing out the borax by cooling. Patent 1756122. Henry D. Hellmers.

PROCESS FOR INCREASNG THE LUSTER OF GOODS MADE OF ANIMAL HAIR AND WOOL—Particularly felt and velour in hat bodies by bringing into contact therewith an aqueous solution containing chlorine and hydrogen ions, and an aqueous solution of peroxide of hydrogen, and causing the two to react with each other in contact with the goods. Patent 1760738. Erich Bohm.

Designs

DESIGN FOR A DRESS—Patents 81098 and 81099. Dorothy Long.

DESIGN FOR A TEXTILE FABRIC OR SIMILAR ARTICLE OF MANUFACTURE—The inventor has been granted two patents, 81252 and 81255. Joseph H. Mack.

Design for an Ensemble Suit—Patent 81139. Dorothy Long.

Design for a Suspension Bracket—Patent 81168. Robert D. W. Vroom.

Design for a Candy Doll—Patent 81245. Mildred C. Knapp.

Design for an Ensemble Suit—Patent 81251. Dorothy Long.

Design for a Textile Fabric or Similar Article of Manufacture—The inventor has been granted two patents, 81235 and 81236. Herman Haug.

Design for a Textile Fabric or Similar Article of Manufacture—Patent 81238. Christian Hoffmann.

Design for a Suit—Patent 81100. Dorothy Long.

Electrical Devices

Electric Furnace—Such as those usually employed in dental laboratories, which will be capable of generating the necessary amount of heat with much lower resistance than usual, constructed in a simple manner prolonging the life for an indefinite period. Patent 1757895. Andrew J. Asch.

Radio Tube—Which may be used in several different ways, such as a detector, an amplifier, a static eliminator, etc., provision being made whereby the characteristics of the tube may be changed to effect the desired results. Patent 1757345. Howard M. Strobel.

Thermostat—Forming part of an electrical circuit, in which a thin strip of resilient material is bent and maintaned under a predetermined stress, so that when expanded by heat it will suddenly buckle, thus instantly breaking the circuit. Patent 1758787. Arnold Escher.

Electric Water Heater—Adapted to be readily associated with or removed from a sink or similar kitchen or household fixture, whereby the water passing through coils brings it in contact with various portions of the heating element. Patent 1759774. Angelo Andriulli.

Fluid-Operated Circuit Controller—Which is capable of controlling a circuit including a signal for indicating to the operator of a motor vehicle whether or not the lubricating system of the vehicle's motor is properly functioning and sufficient lubricant circulating. Patent 1759537. Walter C. and Arthur R. Buckbee.

Of Interest to Farmers

Stalk Cutter—A farm implement which includes a frame having equal portions extending on opposite sides of a draw bar and carrying knife-equipped rotors for cutting stalks and chopping them up, over at least four rows. Patent 1757873. John F. O'Kelley.

Of General Interest

Marcelling Iron—Comprising a plurality of forks disposed one above the other and means for moving certain of the forks laterally with respect to the others, the other forks remaining stationary, may be worked in the same manner as hair clippers. Patent 1756104. Nellie Stone.

Condiment Holder—A partitioned container, wherein salt and pepper may be served from a single holder, the construction is simple, while at the same time functioning to prevent the mixture of the condiments, and keep them moisture proof. Patent 1757525. Frank A. Hart.

Easel—Comprising two strips of material forming a U-shaped frame having an L-shaped bracket capable of holding and displaying thin objects such as paintings or photographs, or thicker objects such as books. Patent 1755518. Edward M. Roberts.

Closure Cap—For milk bottles, or any form of container where disk-shaped cardboard caps are used for closures, whereby the cap may be gripped by the hand and easily removed entirely eliminating the use of an instrument. Patent 1755522. Samuel J. Smyth.

Optical Device—Primarily intended for amusement purposes, optical illusions being produced when viewed by a person, or if employed in connection with an ordinary or motion-picture camera, such optical illusions will be reproduced on the film. Patent 1758801. Bertram Moses.

Means for Acoustical Correction and Sound Deadening—For absorbing sound by causing reverberation or resonance of sound in a manner which eliminates interfering echoes, or which confines sound refection to a determinate non-interfering limit or area embodied by walled structures. Patent 1758808. Fred J. Sersen and Kenyon B. Conger.

Plant Support—For growing plants which includes a post adapted to be driven into the ground alongside of the plant and a girdle adjustable, vertically on the post and circumferentially, in order to compensate for growth of the plant. Patent 1758839. Theodore Kelsey.

Adjustable Mirror for Barbers' Chairs and the Like—Whereby the mirror may be moved to various positions so that the occupant of the chair may view the results of a hair cut, wave, or the like, the mirror being adjustable for customers of different heights. Patent 1758021. Peter D. Barakauskas.

Aspirating Head for Flowing Liquids—An aspirating head for submergence in a well or reservoir of liquid to produce a jet of suction-producing gaseous fluid under pressure causing movement of the liquid in a flow line. Patent 1758812. George McW. Williamson and Glasgow W. Haywood.

Tellurian—An orrery, specifically a tellurian having sun and earth sphere mounted for bodily movement of the earth relative to the sun in a path denoting the ecliptic circle. Patent 1758759. David Phillips.

Combination Brush, Comb, and Mirror—In which the various parts are entirely enclosed when not in use, thus keeping them clean and sanitary, the casing being divided into brush-receiving and comb-receiving compartments, one of the partitions forming a mirror. Patent 1757999. Christoph Hagen.

Price Tag or Sign Holder—An attachment for supporting tags from the edges of shelves, which affords a means for associating the tags either in an upright or depending position, an advantage where two varieties of stock are arranged on one shelf. Patent 1759781. Louis Fontannaz.

Loud-Speaker Envelope—Comprising an envelope body including conical walls secured together at the major portions of their edges, leaving an opening constituting a sound outlet, functioning to produce more individual notes and less harmonics. Patent 1759785. Roy H. Guldman.

Cooking Pot of the Self-Closing Type for the Cooking of Food—Having a cover adapted to be placed in position and removed, by sliding and rotating horizontally, thereby preventing its contact with the food and providing more food-containing space within the vessel. Patent 1759732. Moise A. Charlot.

Seat Back-Rest—A collapsible back-rest for association with board seats, such as are employed in row-boats and bleachers on baseball and athletic fields, thus producing a comfortable and rigid seat structure which may be effectively secured. Patent 1759694. Peter Greenwood.

Device for Removing Eggs from Fish Hatcheries—More particularly for the separation and removal of dead eggs from the live eggs in the hatchery troughs, thus preventing the development of fungus liable to destroy the health of the live eggs during the period of incubation. Patent 1759729. Joseph Berger.

Nested Chair—Which may be formed as a chair or a table and readily nested for shipment or storage, the structure being formed either of wood, metal, or a combination, and the parts so constructed as to telescope. Patent 1758826. Louis Dellert.

Massage Device—Which comprises a plurality of vacuum cups, one being disposed within the other, the inside one being of less height than the outside one, thus producing a greater suction and a more effective massage to the skin. Patent 1758962. Carl Miller.

Adjustable Furniture—Especially adapted for printing establishments, having two opposed edges swingable at various angles with respect to each other, so that a cut may be locked in the chase on a bias, thus obviating the use of specially cut wood. Patent 1758980. Wayne F. Rossiter.

Safety Barrier for Roadways—For placement along dangerous curves or embankments on a highway, which in the event of being hit by a motor vehicle will eliminate or reduce the shock to a minimum, both to the barrier and the vehicle. Patent 1759794. William McDade.

Oarlock—Formed integral of metal, with an oar-receiving eye supported for swinging movement by a pin and socket in upright position above the gunwale of a boat, and having means for preventing displacement of the oar during rowing. Patent 1757378. John E. Mathewson.

Combination Ladder, Step and Support—Which may be positioned wherever desired, along the length of the ladder at an angular position of a building or roof, and will also function to support a bucket. Patent 1760803. John Wirth.

Hose Coupling—Consisting of male and female members with simple means for positively locking them to form a fluid-tight joint, and whereby a worn male member may be replaced by a new one and the desired connection assured. Patent 1761352. Henry H. Logan.

Memory Pad—Having means for covering a portion of the subject worked upon, thus causing the student to recall by memory the portion covered, the entire sheet may be covered for constant repetition until the problems are memorized. Patent 1760408. Rebecca E. Hooper.

Stopper for Gas and Water Mains—An inflatable stopper which will be effective in forming a complete closure for the main, the proper emplacement not being prevented by buckling or deformation after its insertion, means are provided for ready insertion and removal. Patent 1760750. Patrick Goodman.

Display Device—Showing in miniature the reproduction of a pattern of dress material proportionately reduced to enable a purchaser to determine how the garment will look when made up, through a reduced picture of the garment and the material selected. Patent 1760792. Bernard F. Stenz.

Mounting Anchor—Particularly adapted for mounting the corner clips in decorating pocket books, bill files, wallets, or the like, serving to positively secure the clips in attached relation, without marring the appearance of the cover. Patent 1760728. Murray A. Wachs.

Comb—Characterized by being conveniently manipulated to form a compact case excluding dust and dirt, may be carried in a pocket, pocketbook, or form part of a traveling kit, the teeth are formed to be substantially self-cleaning. Patent 1760778. Henry J. Ries.

Article Support—A simple means for holding paper or other bags in open position, for dropping into the same waste material or refuse from household kitchens, the bag may be readily detached from the support and placed in a garbage can. Patent 1760752. George D. Happer.

Hardware and Tools

Hoe—Having a plurality of interchangeable blades for performing various garden operations, and a durable and interchangeable shank is provided between the blade and handle for withstanding a maximum strain; handles of various length may be used. Patent 1757882. Ernest F. and Alfred Sill.

Casing Cutter—Which is provided with automatic means for gripping the interior wall of the casing at any desired depth, the cutting means being actuated by the weight of the drill stem, and jars for severing the casing. Patent 1756128. Albert M. Monroe.

Suspension Hook—Which may be formed from a single piece of metal, will be durable and will readily support a framed picture or the like at various angles, without liability of slipping, or disengagement of the suspension cord. Patent 1757875. Thomas S. Rainey.

Locking Device—Especially adapted for windows, automatically locking the sash together when in closed position and providing means for rigidly holding the window against lateral vibration, may be readily used on doors, cabinet doors or the like. Patent 1758337. John C. Sheller.

Knob-Attaching Device—For securely holding the knobs of covers for pots, kettles and the like, may be readily screwed into place, and is automatically locked against accidental removal, may be used in connection with old covers. Patent 1759771. Otto B. Willi.

Adjustable Cutting Instrument—In which a blade is provided with two cutting edges adjustable to expose more or less of the edge as required, whereby the manual manipulation of the cutter or scraper will be greatly facilitated. Patent 1755535. Otto M. Bratrud.

Wrench—Having a jaw head which may be manually rotated to assume various angular positions, so that it may be used from different starting positions in operating a nut or bolt which is particularly difficult of access. Patent 1755486. Ross E. O'Dell.

Lock—A simple locking means wherein the bolt is projected by gravity, eliminating the use of springs, which cannot be "picked" or manipulated by a skeleton key, from the outside of the door. Patent 1758872. Robert Wheeler.

Heating and Lighting

Furnace—Having a coal hopper in open communication with the casing, and a mechanical stoker operated from the floor above adapted to force a charge of fuel onto the grate, the fuel, including the volatile products being completely consumed. Patent 1757878. Carl H. Root.

Attachment for Gas Water Heaters—A form of cowl, readily applied to the conventional type of heater, serving to direct the hot gases into intimate contact with the hot water discharge pipe, before such gases are dissipated into the air. Patent 1758788. Alexander H. Frank.

Domestic Incinerator—Which rapidly desicrates refuse and maintains a sufficiently high temperature to drive off volatile moisture without recondensation in the incinerator or in the stack, completely consuming fats, carbohydrates and other garbage without appreciable odor. Patent 1758487. Harry L. Warren.

Machines and Mechanical Devices

Centrifugal Pump—In which roller bearings and lubricating oil may be used, all possibility of the oil coming in contact with the liquid passing through the pump being eliminated by the use of wear-compensating rings, instead of packing. Patent 1757670. Herman L. Keun.

Mechanical Pencil—Wherein a thin flat lead may be employed and fed as desired, at all times producing a line of uniform width, particularly adapted for draftsmen requiring a certain kind of point for their work. Patent 1757884. Edgar C. Tuggle.

Pump—Wherein a sort of floating dam may be mounted in a comparatively swift stream, to form a double acting force pump driven by a waterwheel, for delivering a maximum quantity of water to any desired point at minimum cost. Patent 1757885. Grant Weaver.

Oil Pump—Adapted for continuous high-speed operation in connection with oil or other wells of great depth, being operable with a minimum of care, and containing few parts which are liable to get out of order. Patent 1755516. Edward P. Reynolds.

Method of and Apparatus for Reactivating Charcoal—For the revivification of charcoal laden with organic matter as in sugar refining, by passing the charcoal through a kiln and subjecting it to a continuous recirculation of pre-heated hot gases which support the combustion of organic matter. Patent 1758202. Edgar W. Rice.

Ship-Propelling Means—A form of hydraulic ship propulsion, an assemblage of mechanism whereby a jet or stream of water is directed rearwardly and downwardly for propelling a ship forwardly, or in a forward direction for reversing the vessel. Patent 1758847. Amos C. McIntosh.

Oil-Well Pump—In which the expulsion of a combustible gas is employed in such relation to the oil within the well as to subject the latter to a series of lifting impulses, until it is finally ejected from the well. Patent 1758346. Armais Arutunoff.

Fluid-Dispensing Apparatus—Characterized by its ability to control dispensing of different flavoring syrups from different sources of supply, and carbonated water, through a single nozzle, and by the employment of a single valve, particularly adapted for use at soda fountains. Patent 1758552. Philip S. Allen.

Gas and Liquid Contact Apparatus—A tower for the absorption of gases in liquids or their distillation therefrom, means for delivering liquid from one section to another, a plurality of enclosed bubbling trays, and means for controlling the temperature of particular trays. Patent 1759750. Meinhard H. Kotzebue.

Variable-Speed Mechanism—In the form of power-driven or automatic scissors intended especially for barbers' use, may be driven by any suitable means, for instance, an electric motor or other power or by hand. Patent 1760712. Tatsuji Morimoto.

Dry-Cleaning Machine—Characterized by the functional relationship of a movable body, within a casing, upon which apparel to be cleaned is supported and adapted to move in a cleaning liquid, and to circulate the liquid around and through the article. Patent 1760218. Onesime Thibault and Robert Reid.

Indicator for Wrecked Submerged Crafts—Such as submarines, boats, aeroplanes, etc., in which novel means of pressure-actuated release is used for freeing a buoy when the craft sinks to a predetermined depth, or may be manually or automatically released. Patent 1759839. Peter M. Cirimele.

Grader for Vegetables, Fruits and the Like—A rotatable sorter, in which the articles to be graded are fed to one end of the machine and during their passage therethrough are discharged at different points according to the sizes of the articles. Patent 1760742. William G. Bunker.

Curtain Holder—Which may be attached and positioned to hold a window shade away from the window so as to permit a free circulation of air without permitting a view of the interior of the room from outside. Patent 1760701. Godel Kalenoff.

Plumbing and Fittings

Copper - Boiler Outlet — Wherein the threaded portion of the outlet is welded to an extension of the boiler with anchoring means for including solder surrounding the thread, whereby a mechanically strong and air-tight structure is produced. Patent 1758869. Albert H. Trageser and Louis Hassinger.

Pertaining to Recreation

Fish Lure—An artificial bait, for casting, trolling, or still fishing, which when grasped by the fish will automatically release a hook so that the fish will be impaled thereon, a smooth surface preventing entanglement of the bait with weeds. Patent 1758817. Elwin J. Babbitt.

Stirrup—Having flexible portions for obviating the possibility of a rider's foot being held in the stirrup, should the rider be thrown out of the saddle, and which is more comfortable than the usual rigid type of stirrup. Patent 1758930. Archibald D. Cameron.

Toy Pistol—Adapted to hold and "shoot" by release, a plurality of elastic bands held under tension and successively releasable rapidly or at intervals as desired, the toy having the properties of a "repeater" or magazine pistol. Patent 1759084. Fred T. Baum and Clarence G. Norris.

Pertaining to Vehicles

Vehicular Signal—Whereby semi-flexible arms are adapted to advise traffic in front or behind the vehicle, the turning direction by mechanism positioned on the steering column, whereby the indicators may be manually controlled for visual positioning. Patent 1757869. William Lipsky.

Vehicle Spring—In which friction between the leaves is increased on the recoil, thereby damping the spring action so that the recoil is much slower, thus improving the riding quality of the vehicle and increasing the life of the leaves. Patent 1757405. Edwin Bagnall.

Reflex Spring—Wherein the action on the downward thrust is free, thereby providing a device which loses none of the easy riding qualities, one of the spring leaves acting as a fulcrum for dampening the action on the recoil. Patent 1757406. Edwin Bagnall.

Safety Valve for Tires—Whereby the inflation may be produced to any predetermined pressure within the limits of the gauge, and upon reaching the predetermined pressure an audible signal will be given preventing further inflation, thus avoiding danger of over-inflation. Patent 1759796. Albert R. Miles.

Motor-Vehicle Holddown—Constructed from lengths of iron rod bent to provide divergent anchoring barbs at the ends for penetrating the floor of a freight car, for holding automobiles or other vehicles against rolling while in transit. Patent 1759733. William B. Cook.

Road Magnet—Which may be mounted on a suitable vehicle, preferably a motor truck, and drawn over the road for picking up objects liable to puncture tires, the magnetizing motor may be readily removed and used for other purposes. Patent 1759687. Walter M. Carter.

Vending Machine—A form of tricycle, the hollow body of the vehicle being in the shape of an airplane, having storage space for commodities, and a seat from which the operator may manually propel the mechanism and control the steering. Patent 1758432. James T. Crow.

Steering Gear—Whereby steering wheels may be set in true alinement even though the steering axle bolt be sheered or otherwise defective, thus increasing the life of the tires and at the same time permitting free and easy steering. Patent 1760749. John F. P. Gillespie.

MAKE YOUR INVENTIONS PAY

Millions have been made from ideas properly developed and protected by inventors. One of the first steps is the development of a practical working model.

Send us rough sketch or model of your idea. We will submit complete report backed by 30 years experience in model making. Confidential service. Modern equipment. Bank references furnished. FREE booklet "Making Inventions Pay."

CRESCENT TOOL COMPANY, Dept. H, Cincinnati, Ohio

I SELL PATENTS

If you wish to add New Products to your line, or have a good Patent to sell, write me—

Across the Editor's Desk

As this is written we have before us the advance printer's proofs of the feature articles for this issue. Going through them, page by page, we stopped and reread the article "Railroading Today." No less than when we first read the manuscript, did it bring us face to face with the gripping romance of the mighty networks of steel that have united the far reaches of this country by providing safe and rapid transportation. Old yet always new, the story of railroading in its ever-changing phases holds a unique fascination, probably because it is so intimately interwoven with the very fabric of our every-day existence. We feel sure that you will agree with us that Mr. Milholland is to be congratulated on the story he has written for you this month.

Another article to which we particularly want to call your attention is the one by Dr. T. A. Jaggar on "Volcanology." Dr. Jaggar spends his whole time at the crater of the active volcano Kilauea in the Hawaiian Islands. Thus he is qualified to write with the pen of authority on how the science of volcanology has a direct bearing on the daily lives of each and every one of us, and for that reason his call for amateur seismologists will not go unheeded. Whether you live in the Adirondacks, West Virginia, or on the Pacific Coast, you may, if you answer Dr. Jaggar's call, contribute valuable data to the science of volcanology. Here's hoping that many of our readers will go in for amateur seismology with the same enthusiasm that has been manifested for amateur telescope making.

As long as the evolution of organic life—animals and plants—remains uncertain, there will be two sides to each and every question that arises. Thus, when Dr. Austin Clark expounded *his* theory in our August issue, we felt it only fair to open our pages to any logical refutation of his statements that might be brought forth. And forth it came. Professor Matthew, a paleontologist of high standing, presents *his* side in a masterful article on page 192. Which authority is right? Each reader will have to study the two presentations carefully—and then draw his own conclusions. We remain open-minded.

The Peking man—or woman, to be exact—is fast growing in importance. Professor G. Elliot Smith, who is one of the world's first five authorities on the subject involved, which is called "paleoanthropology," has written an article for you on the Peking man which we feel sure you are going to find of great interest.

These are only some of the high spots that stand out as we scan our proof sheets. Other articles of equal interest and importance cover such subjects as the truth about our much abused patent system; the new type of racing car that is bound to make new history on the speedways; what surgery is doing to rehabilitate cripples; the yachts that have been built to defend the America's Cup; and a dozen or more selected subjects—not to forget the SCIENTIFIC AMERICAN Digest that brings to you the news of all the sciences in brief.

So now we turn to the schedule of the October issue. Of course it is not complete, space having been reserved for important features that are bound to come up at the last minute. But we can tell you something of the articles that are ready for release. Signaling to Mars, that much abused subject so dear to the hearts of the so-called popular magazines, has at last been treated in a logical manner. Even if we could get visual or electrical signals through to the red planet, how could we be sure that there are intelligent creatures there to receive them—humans or animals made up of protoplasm, which is the only criterion of living matter in our experience?

A 69-inch mirror has been cast for a telescope in the Perkins Observatory, as told in an article illustrated by a most unusual series of photographs. And there is a touch of human interest in the background. The funds for the telescope, 330,000 dollars, were provided by the will of the late Professor Perkins of Ohio Wesleyan University. This sum represented the life savings of an 1800-dollar-a-year professor, accummulated through numerous sacrifices on his part and that of his wife, invested judiciously and allowed to flourish at compound interest. Just as the professor devoted his life to science, so did he provide for the continuation of his work after his death.

These articles are by no means all we have to offer for October. The issue will be replete with interest for the astronomer, professional or amateur; several major articles will assure that. There will also be discourses on the cricket's chirp; a gun mount that makes a super-weapon of the 75-millimeter gun; mining of a valuable metal that is recovered from ore by evaporation; the aircraft industry; the sphere in which William Beebe descended deeper into the ocean than man has ever dived before; and other absorbing subjects. All in all, we feel that the October issue will be one of the best we have given you in many months.

Orson D. Munn

The Vanguard of Progress

WRITERS of fiction have woven many romantic stories around the coming and going of the engineers on railroad construction, their loyalty to their jobs, their unceasing efforts to conquer nature and wrest from it a route, in spite of storms, floods, and natural obstacles of all kinds. The engineers who blazed the trails when railroads were new and stretching into the timberlands and the coal fields, were inured to the hard labor of the pioneer. Now, however, the fastnesses of the highest mountains having been penetrated and the paths of commerce clearly marked, the work of the railroad civil engineer, with improved methods and machinery, is less romantic. In former years when railroads were building, these men of the rod, the chain, the level, the stake, and the transit, were found delving into the wilderness, looking for the "saddle" that would get them over the summit. Everyone of the "gang," from the engineer in charge and transitman, down to the lowly stake man and "back rodman," worked hard and long, often under trying conditions—cold and heat—often braving great dangers. Most of the territory has now been covered and the work of the railroad civil engineer is mostly on small projects and maintenance work, except in undeveloped countries of the world.

Railroading Today—

Construction and Maintenance

By **FRANCIS X. MILHOLLAND**

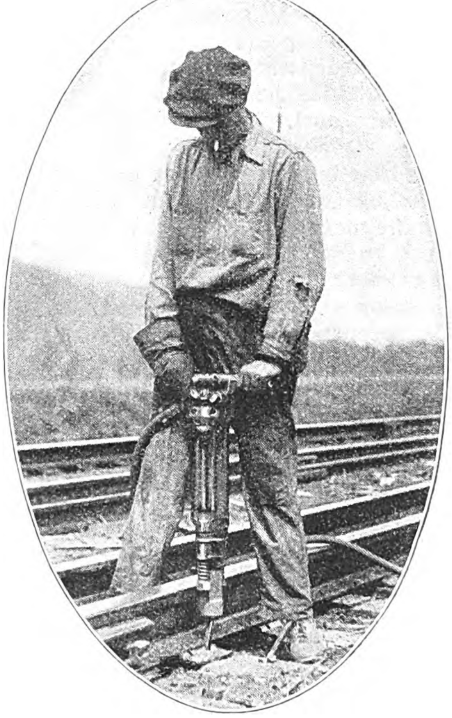
Assistant to the Senior Vice-President, Baltimore and Ohio Railroad Company

WHO has not, at one time or another, gazed down the length of a straight-away stretch of railroad track and found a fascination in watching the steel rails converge to a vanishing point in the distance? But how many of us know the story, equally fascinating, of how those rails were put there and how they are kept so straight and true—the story, in short, of the construction and maintenance of a railroad?

Let us start from the very beginning of this undertaking and consider some of the many problems involved. First, of course, there is the present or probable future need of a railroad as a means of transportation between two definite points. When this has been determined, a corps of field engineers or surveyors start to map out the best and most economical route. From their observations they prepare plans so that the necessary right-of-way can be purchased. They also draw up plans and specifications for the use of the contractor who will do the work of grading.

Now comes the big job of preparing the grade on which the railroad tracks will be built. In this work it is interesting to compare efficient modern methods with the crude means used when the first railroads were built. In former decades, when it was necessary to cut through a hill or along a hillside, the dirt was plowed loose and hauled away with a horse-drawn scraper. When rocks were encountered, the men drilled holes in them with a hand drill and blasted with slow-burning black powder. Then came the steam shovel and the dinky dump cars run on a narrow-gage track, which were big steps forward in promoting speed and economy of operation.

TODAY, automobile dump trucks are used and even the steam shovel is being supplanted by the tractor or crawler shovels run by gasoline or oil engines. Steam-operated hammers drill the rocks for blasting and dynamite takes the place of black powder.



A pneumatic hammer speeds the work of driving spikes into the ties

At the same time that cuts and fills are being made to obtain a uniform grade line, culverts and bridges have to be built, large or small, according to the size of the stream and the maximum amount of rainfall that might be expected during a given time. Particular attention is given to the

The new track is set in the proper position with the aid of a track gage and is being fastened to the ties by trackmen

possibility of eliminating grade crossings.

As the work of preparing the finished subgrade of the road progresses, materials for the construction of the tracks are assembled at the job and then distributed to place. For the track structure of today 22 treated ties are laid for every 39 feet, which is the length of a steel rail. This is followed by the distribution of the steel rails, joint fastenings, bolts, tie plates, spikes, and rail anchors.

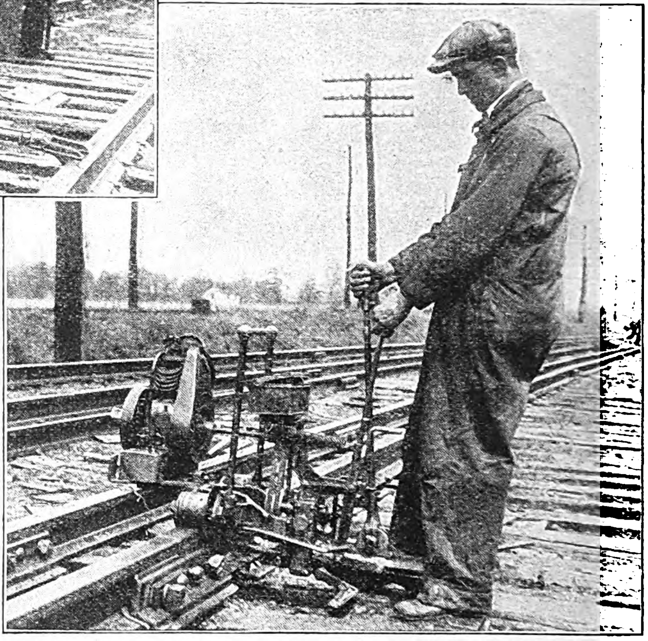
THE distribution of track material is quite an undertaking and the manner of handling depends entirely upon local conditions. Where additional tracks are built parallel with existing tracks, the problem is simple, as the material is unloaded right where it is to be used from cars handled by a work engine.

Where the track is on a new line, however, the problem is more difficult. On large jobs a special track-laying outfit is utilized, consisting of a number of flat cars with special power-driven belt or roller conveyors attached to the sides. As the train proceeds to the end of the new track that has been laid, ties and tie plates are placed on one conveyor and carried ahead of the train, where they drop to the ground. The men immediately put these in their proper positions.

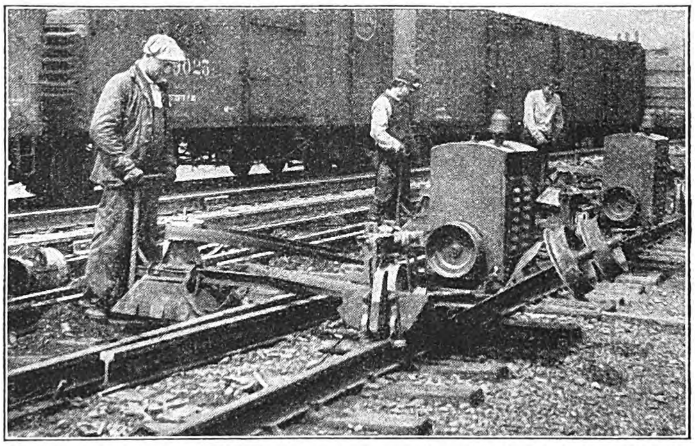
On the other conveyor, rail is carried ahead together with the joint fastenings, bolts, and spikes. A small power crane on the head end of the track-laying machine places the rail into position and the trackmen lay the joint bars and spike enough ties to permit the safe passage of the outfit.

To build one mile of single track railroad, the following material is required: 204 tons of 130 pound (per yard) steel rails; 270 joint fastenings, which with abrasion or rubbing plates weigh 141 pounds each; 5418 tie plates, weighing 16½ pounds each; 48 kegs of track spikes, weighing 200 pounds each; 15 kegs of track bolts, weighing 200 pounds each; 1650 rail anchors, weighing 2½ pounds each, or a total of 4125 pounds; 2979 treated cross ties, size, 7" x 9" x 8½'; 3600 tons of stone ballast. This represents about 89 carloads of material, the cost of which is 22,000 dollars. Labor adds 6000 dollars so our mile costs 28,000 dollars.

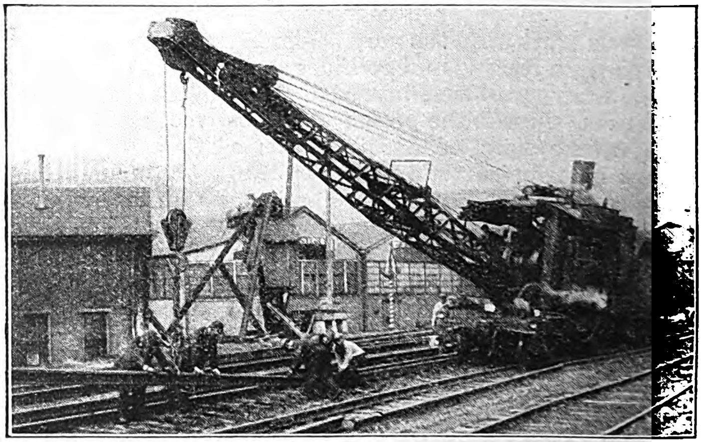
After the distribution of material, the ties are evenly spaced with the ends on one side in a straight line. The tie plates are then placed on the top face of the ties, using a gage, so that when the rail is placed on them, the inner or gage side of the rail heads will be exactly four feet 8½ inches apart. This is the distance that has been adopted as standard on all railroads in this country. As the rails are placed, "shims" or spacers are put between the ends to allow for the expansion and



The bonding drill helps to attach the bindings to ensure connections for the electrical currents

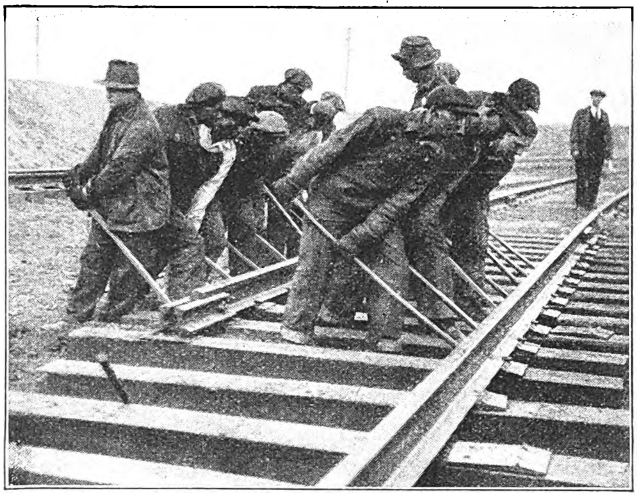


When the old rail is removed the ties are trimmed to a level bearing by power-driven adzing machines



The locomotive crane is seen putting a new rail in position. Rails are now too heavy for hand handling contraction of the steel, the size of the shim depending upon the temperature at that time.

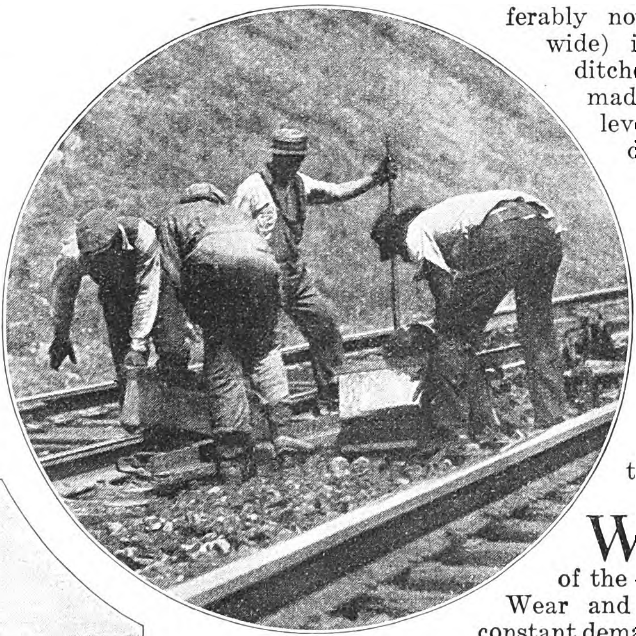
With the rails set and the joint fastenings applied, one line of rail is spiked into place. The second line is next spiked to the ties conforming to the standard gage. Rail anchors are then placed to hold the expansion space between the rail ends uniformly. Next, the track is aligned according to the stakes set by the field engineer, and it is then ready for the ballasting operation.



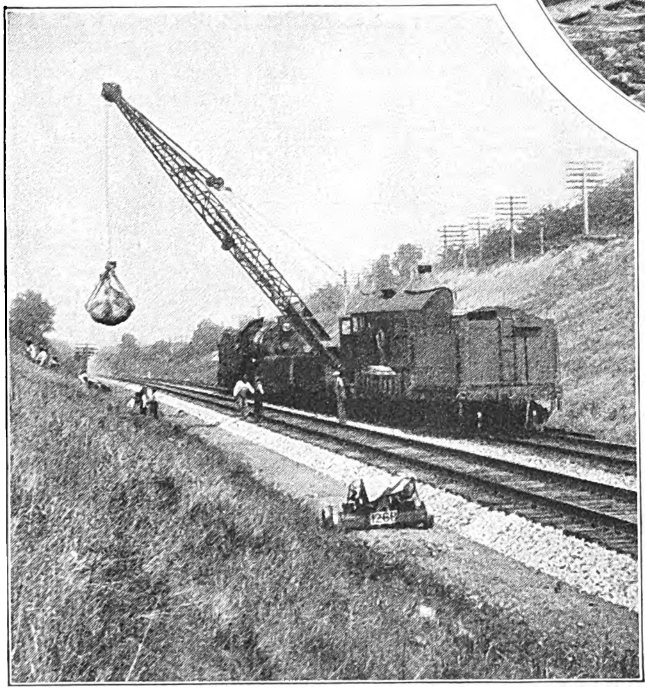
A picturesque operation is the placing in exact position of a new rail on the leveled cross ties

CARLOADS of engine cinders are brought in and dumped on the track. The trackmen raise the rails on these cinders until there is a mat 12 to 18 inches thick, extending over the width of the roadbed. Time is now allowed for settlement of the cinders and then when the roadbed has become stabilized, the cinders are "cribbed out" or cleaned out and used to widen the banks of the roadway, and new ballast, of stone, gravel or crushed hard slag, is distributed. The stone ballast is generally used in heavy-traffic high-speed territories. It is necessary to have from six to twelve inches of ballast between the bottom of the ties and the cinder foundation. This takes between 2200 and 3000 cubic yards of ballast, or from 55 to 75 carloads per mile of single track railroad. Ballast is normally handled in drop-bottom cars and as the work train moves ahead, the ballast, released through the bottom doors, drags out practically even with the top of the rails, giving a surplus on which to raise the track. The ballast is generally unevenly placed in this way, however, and the labor of distributing it where it is wanted and needed is quite an item.

This difficulty has been largely overcome by the automatic ballast spreader, a device designed to control the unloading of ballast from railroad hopper cars. It consists of a trough, the bottom of which is equipped with movable plates, permitting openings of the area required to distribute the quantity of stone needed. At each end of the trough are sheet steel plates also equipped with gates for regulating the flow from the end of the pan onto the ballast shoulder. Suspended from each end of the trough is an auxiliary pan called a shaper, which dresses the ballast shoulder to a section. A lever control lowers the distributor when in operation so that it rests on rollers which move forward on the rails. When not in operation, it is raised and carried suspended from the car. It is a great labor-saver.



A small machine called a "mole" is used to remove ballast between the tracks for cleaning and replacing



Shaping the hillside so as to intercept drainage from the tracks. A locomotive crane is used

After the material is distributed, the ballast is impacted under the ties either by hand (using shovel or tamping pick), or mechanically with pneumatic or electrically driven tools. There are two types of electric tampers, one using the direct hammer blow and the other employing vibration, to settle the ballast under the ties. To give a neat appearance to the job, the "berm" or shoulder of ballast outside the tracks (preferably not less than 12 inches wide) is built up uniformly, ditches are cleaned out and made regular and the ballast leveled off and dressed to a definite standard section.

In addition to the building of the track structure, a very important item is that of drainage. Wet spots encountered in cuts are tiled and cross-drains installed. Ditches are cut to keep water away from the tracks, and every precaution taken to prevent undermining.

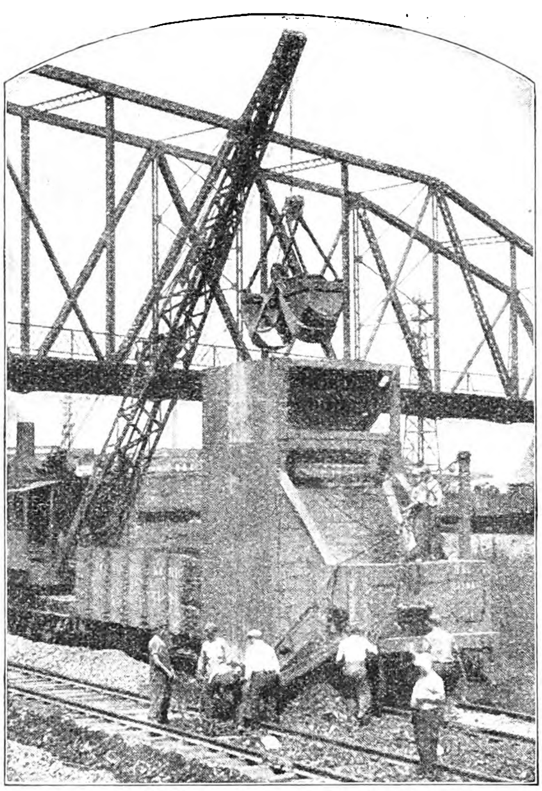
WITH the completion of construction, the work of the engineer is not finished. Wear and tear, increased by the constant demand for greater speed and heavier train loads, needs to be constantly remedied by replacements and repairs, which have to be made without interruption to traffic. This is the maintenance problem.

A slight insight into the magnitude of this important work may be gained from the following statistics covering the seven-year period of 1922–1928, inclusive, for the railroads of the United States:

Roadway and Structures

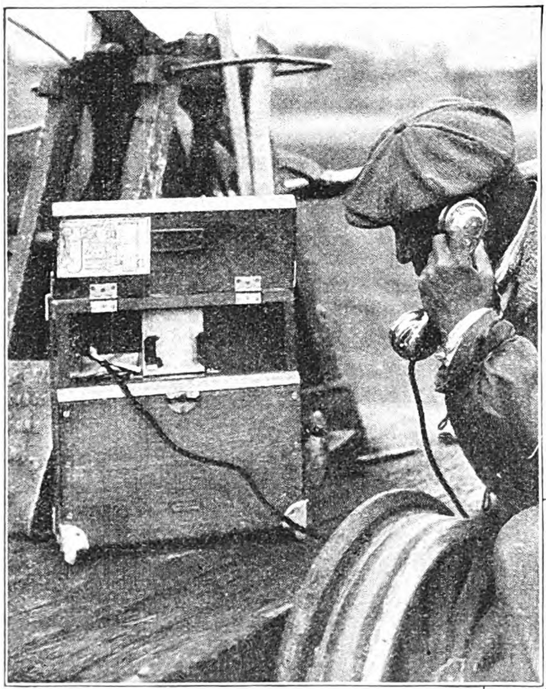
Additional track and track material	$ 843,981,000
Heavier rail	242,848,000
Additional ballast	85,879,000
Shops and engine houses	242,470,000
All other improvements	1,385,603,000
Total	$2,800,781,000

The annual program of maintaining a railroad calls first for the renewal or replacement of rails that have become worn. New rail is generally laid out of face—that is, uninterruptedly, without patchwork—in stretches of from one to five miles on main-line high-speed tracks. Local conditions and the amount of rail to be laid determine the methods to be used.



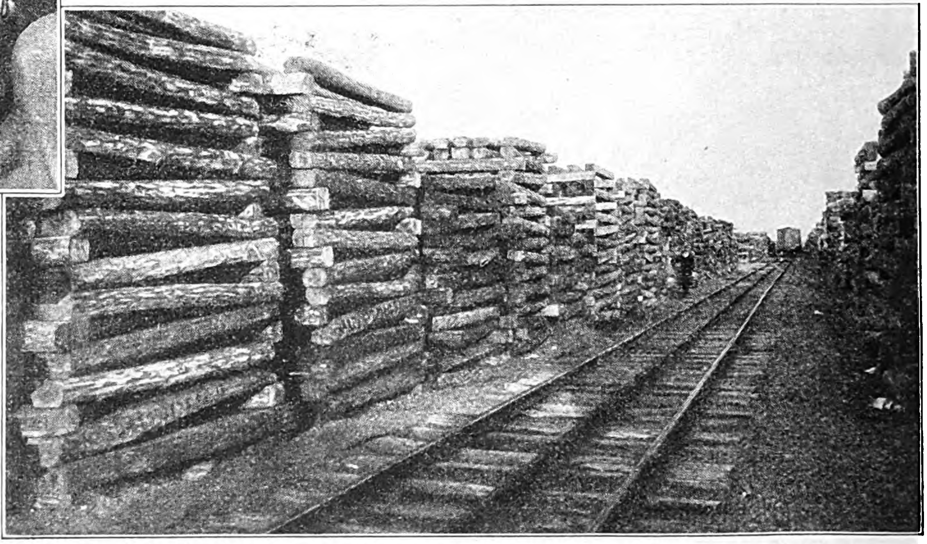
Fouled ballast must be cleaned in a special machine, after which it is replaced

Let us consider, as an example, the events of one day's work where a large amount of 130-pound rail was laid, replacing 100-pound rail. To organize this work thoroughly the supervisory forces determine from experience just how many men will be needed for each operation of work and how best to get the men to the point of work. Foremen are notified just what their men will be expected to do that day and come prepared with their tools. Further arrangements are made with the transportation department whereby the trackmen can have the uninterrupted use of this track for as long as possible.



Crews have telephones which are used to learn of train movements

Sufficient men are gathered so that each man can be assigned to a particular duty and to enable him to utilize the full work period. This eliminates the changing of tools and doubling men back and forth on the work. The operations are carried through in the following sequence: 1. Distributing new materials; 2. Pulling spikes; 3. Throwing old rail in about 12 inches from former position; 4. Removing old tie plates; 5. Plugging old spike holes in ties; 6. Adzing surface of ties to give a sound and level bearing for the new tie plates; 7. Placing new tie plates; 8. Setting new rail into place with a rail-laying machine. (This operation is frequently done with various types of cranes, some designed particularly for this work); 9. Placing joint fastenings and tightening two bolts per joint; 10. Spiking every 4th or 5th tie to proper gage; 11. Full bolting the joints; 12. Full spiking all ties; 13. Placing rail anchors to prevent change in the expansion space between rail ends from shifting the rails; 14. Installing bond wires connecting rails in automatic signal territory; 15. Throwing old rail out of track; 16. Disconnecting the old rail; 17. Assembling and classifying old material removed from track.



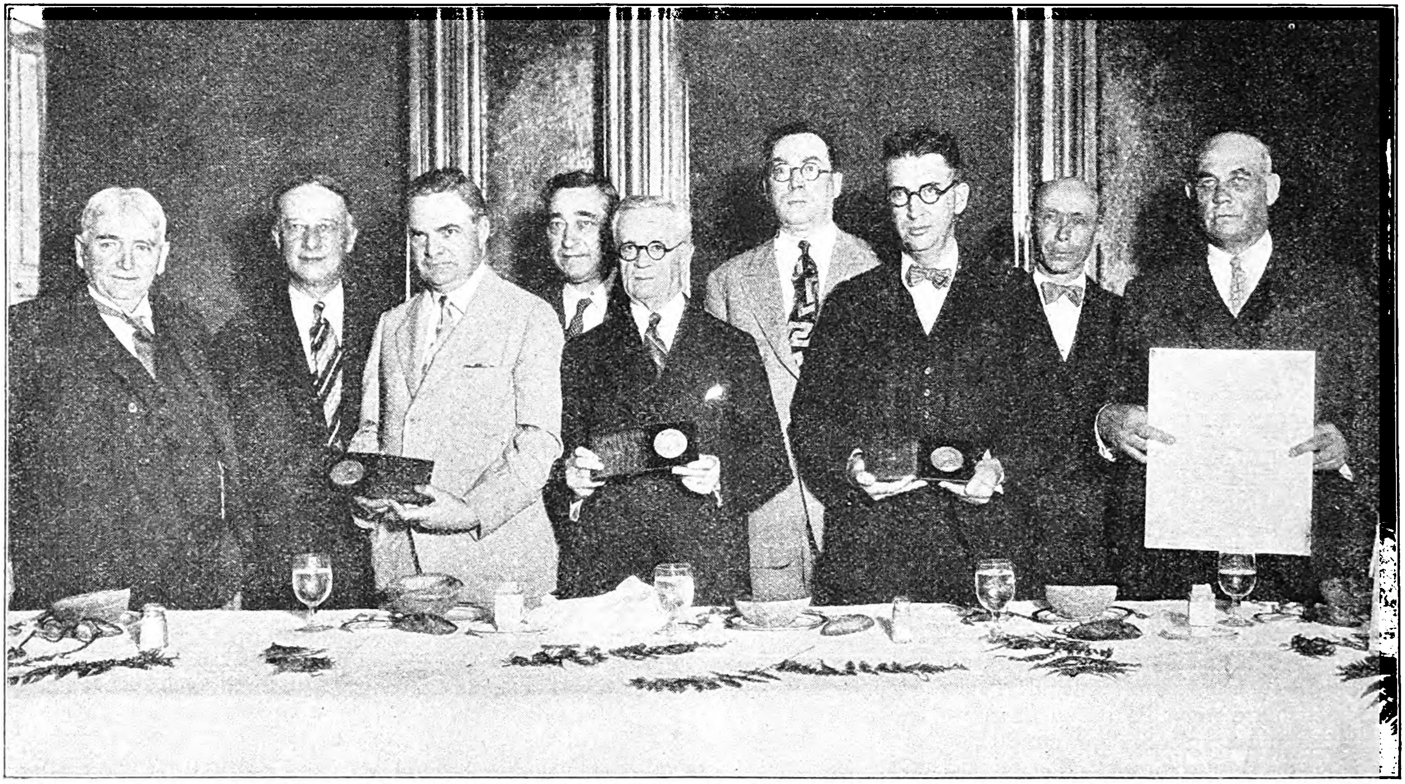
Railroad ties by the thousands are stored in piles ready for use in the laying of new track or replacing old ties. Most of the ties are chemically treated

In this manner it was possible to lay 20,000 feet of rail in one working day with a force of 120 men. With equipment now available, this force could be reduced, since in addition to the machine for setting in rails, there are power-driven adzing machines, power bolt-tighteners, and pneumatic spike-drivers.

Following the laying of the new rails comes the renewal of the cross ties and general rehabilitation of the track. Untreated ties decay rapidly and the average life is but from eight to nine years. With the general use of preservatives injected into the wood to check decay, the life of cross ties has been more than doubled. Ballast becomes fouled and blocks the proper drainage. To restore the drainage and re-establish the uniform grade line or surface of the rail, the ballast is cleaned and the track raised slightly so that fresh ballast may be impacted under the ties.

The rails themselves are subject to heavy wear at the joints because of the hammer blow delivered in the passage of the wheels from one rail to the next, battering out the metal at the joint and also the ballast under the ties. This causes a dip in the rail, referred to as a "low joint," which must be resurfaced and raised periodically. It is this condition that frequently limits the life of rail in main tracks.

More work is required on the maintenance of curves than on straight track, as the centrifugal force of trains passing over the tracks tends to force the weaker points out from the true circular curve, resulting in a bad riding condition. Such curves must frequently be remeasured, calculated,

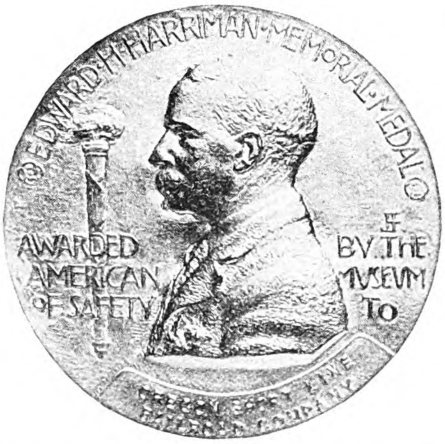


Winners of the safety blue ribbon of the rail. From left to right, front: Mr. Arthur Williams, President of the American Museum of Safety; Ex-Governor Alfred E. Smith, Trustee; Mr. H. J. Plumhof, Oregon Short Line Railroad Co., winner of the Harriman Gold Medal; Mr. J. P. O'Brien, Oregon-Washington Railroad and Navigation Co., winner of the Harriman silver medal; Mr. Earl V. Develer, Nevada Northern Railroad, winner of the Harriman bronze medal; Mr. R. H. Allison, Cleveland, Cincinnati, Chicago & St. Louis Railway Co., Honorable Mention, Group C; Mr. H. E. Trout, Conemaugh & Black Lick Railroad Co., Honorable Mention, Switching and Terminal Roads. Rear (left), Mr. J. F. Patterson, representing the Long Island Railroad, Honorable Mention, Group A; Mr. W. G. Curren, Staten Island Rapid Transit Railway Co., Honorable Mention in Group B

The Harriman Medals for Rail Safety

THE late Edward H. Harriman was a pioneer in railroad safety and the good work he started on his own railroad system is now, by reason of the Harriman Memorial Medals, carried on long after his death, Mrs. Harriman giving annually a gold, a silver, and a bronze medal for the railroad making the best records in their respective classes. The gold medal (group A) is given to the winning railroad in the "over 10,000,000 locomotive mile class"; the silver medal (group B) to the winning railroad in the "1,000,000 to 10,000,000 locomotive mile class"; while the bronze medal (group C) goes to the winning railroad in the "less than 1,000,000 locomotive mile class." The railroad in each group having the second best record receives an honorable mention. A fourth group "D" has been added this year to take care of switching and terminal railroads, by means of a proper certificate.

THE growth of safety on our railroads is most gratifying and the Harriman Memorial Medals furnish a great stimulus to renewed endeavor. The award is based on the records of the Interstate Commerce Commission, interpreted by the aid of carefully worked out formulae. In 1929, 157 Class I railroads carried 148,379,000 passengers a total of over eight billion passenger-miles, without a single passenger fatality. Deducing an analogy from these figures, one passenger, traveling continuously at a speed of 50 miles an hour for 183 years, could travel 32,000 times around the earth without accidental death.



EDWARD·H·HARRIMAN·MEMORIAL·MEDAL
AWARDED BY THE AMERICAN MUSEUM OF SAFETY TO

The medals were awarded at a luncheon on June 24th given by Mr. Arthur Williams, President of the American Museum of Safety, that makes the awards. A very distinguished company of railway men attended. Ex-Governor Alfred E. Smith, a trustee of the Museum, made the presentations. The Committee of Award is as follows: Arthur Williams, Chairman; Samuel O. Dunn, Editor, *Railway Age;* Charles M. Schwab; Hon. Frank McManamy, Chairman Interstate Commerce Commission; Lew R. Palmer, Secretary; F. D. Underwood; and A. A. Hopkins, member of the staff of the SCIENTIFIC AMERICAN and Director of the Museum.

The Harriman Memorial Medals are awarded for safety on railroads

OUR POINT OF VIEW

Machinery and Unemployment

THE blame for unemployment has always been placed, more or less, upon machinery and, in times past, labor has fought its introduction into industries where handwork had been the rule. Even at the present time, there are numbers of pessimists who deprecate the increasing use of machinery and lugubriously point out that it is a Frankenstein monster. Their memory is short; they have been told time and again of the wage earner's gain through machinery, but they seem never to learn. Thus it is necessary to repeat.

Machinery made it possible for one man to do, in 1925, what 3.1 men did in 1914. Thirty years ago, 200 unskilled workers were required to do the work now performed by one steam shovel. In the glass industry, one machine takes the place of 600 skilled glass blowers of a few years ago. In 1920, there was perfected an automatic machine for producing electric light bulbs, that displaced 994 men; and recently this machine has been so improved that it now displaces something like 2000 men. Many other cases are as strikingly significant.

From these figures, it would seem that the pessimists' assumptions are correct. They're not. The number of wage-earners increased 3 percent during the eight years between 1919 and 1927, but—and this is far more important—our production increased 50 percent! With increased industrial prosperity, better wages have been possible and at the same time the worker has been freed from the bondage of labor. Working hours have been cut down: first from a 12-hour day to a 10-hour day, then down to eight hours, and now proposals have been made to make a further cut to six hours. The workingman's week was cut down from six to five and a half days, and it is now proposed to cut it to five.

Better pay and more leisure in which to enjoy the fruits of his work—these are the dividends of the American wage-earner. There is bound to be some temporary unemployment caused by machinery, but this is in an unimportant proportion to the benefits accruing. Nevertheless, certain adjustments are necessary, and it is up to the workingman himself, as well as to industry, to study the question thoroughly so that, as more and more machinery is put into operation, these adjustments may be made with the least loss and an economic balance may be reached.

Sir Arthur Conan Doyle

AFTER an illness of two months, Sir Arthur Conan Doyle died of heart trouble at his home in Sussex, England, on July 7. Famous throughout the world as the creator of that super-detective of fiction, Sherlock Holmes, he was in late years a diligent student and an ardent believer in spiritism. Considering this as a sort of religion, as "infinitely more important than literature, art, politics, or, in fact, anything else in the world," he was annoyed that he was known chiefly for his creation of Sherlock Holmes, and grieved because his friends did not share his unfaltering belief in the spirit world.

Sir Arthur was interested in writing from earliest childhood, having written his first book at the age of six and achieved fame as a story-teller among his early school-mates. His later education was in medicine and he was a practicing physician for several years. His first recognition as an author came when he wrote "Micah Clarke," in 1888, a year after his first volume of Sherlock Holmes; and he won his knighthood with his apologia for the Boer War. The loss of his eldest son in the World War was largely responsible for his devotion to spiritism during his later years.

Sir Arthur was for many years a reader of SCIENTIFIC AMERICAN; and while our opinion relative to psychic, or spiritistic, phenomena, differed from his, we always counted him one of our firmest friends. It may be supposed that the untrammeled imagination which created the greatest detective of fiction "created" much of the spirit world of which he has been called a sort of "Bishop," but that may be countered with the argument that perhaps the practical, analytical mind that worked out Sherlock's crime solutions discovered truths still unknown to many of us. As yet we are not ready to admit either; we are open-minded.

All But the Rattle

EARLY this year it was announced that certain automobile manufacturers would, during 1930, junk old cars up to a value of around 15,000,000 dollars. It was explained that this procedure would have several benefits. First of all the removal of derelicts, still on wheels and a menace to other cars on the road, would prove a blessing to motorists. Manufacturers also said that these rattle-traps undermined their replacement market and their removal would measurably increase sales—a mere matter of 15,000,000 dollars being small compared to the expected sales of 4,000,000 cars at around 3,500,000,000 dollars. Then, too, junking by the manufacturers would decrease the number of old cars that are yearly abandoned along roads to become eye-sores. The plan was heralded as one of the shrewdest moves the automobile industry had ever undertaken.

In the SCIENTIFIC AMERICAN Digest of this issue, our readers are given the first story of how this junking is done. In the Ford plant, the process turns out to be a salvage job in which, with characteristic thoroughness, Henry Ford saves all but the rattle of derelict cars. And although it is said that the salvage per car is 14 dollars, our opinion is that it is more, that the Ford company actually makes money on the proposition.

Other manufacturers no doubt are junking many cars also, but so far we have no details. Those who are not would do well to follow their lead for, aside from all other considerations, the job of salvaging metal in this wasteful country is well worth while and may in time be a vital necessity.

International Affairs

THE INTERNATIONAL BANK

THE beginning of the Bank of England during the reign of William III was modest indeed, and the most far-seeing financial genius of that era could not have predicted its future or imagined the tremendous effect it would have on England's and the world's commerce. And today as we listen to the advocates and opponents of the International Bank established to facilitate the settlement of war reparations, we suspect that even the brilliant financial leaders that conceived and boldly sponsored this world bank, and the more conservative bankers who sincerely oppose this new venture, could not gather together and jointly form a reasonably adequate conception of its future effects on world trade and world relations.

That it will be a success, granting reasonably proper management, is a foregone conclusion; that it will become a ponderous financial fly-wheel, steadying world trade and stabilizing foreign exchange, seems probable even to financial laymen; that it will become such a prize that its control will gradually become another bone of

Volcanology

What Is Being Done to Make the Observation of the Earth's Internal Fluids an Experimental Science

By T. A. JAGGAR
Volcanologist U. S. Geological Survey

IT may seem strange to many people to learn that the recent campaign suggested by the SCIENTIFIC AMERICAN for interesting amateurs in seismology promises to be of great assistance to volcanology. What is volcanology? A tourist, who recently visited Kilauea Volcano in Hawaii while it was sleeping, expressed the popular viewpoint. He saw the observatory and learned of the existence of a volcanologist. "What a cinch," he remarked, "nothing to do but wait for an eruption!"

It had never occurred to him that some of the fundamental processes of volcanology are happening under Iowa at his home town. It had never occurred to him that possibly the recent Mississippi flood with its losses of three hundred millions of dollars is not unrelated to the forces that made the New Madrid earthquake in 1812. The science of the earth is all one thing whereby the continents rise, erosion carves out the valleys, sedimentation fills the mediterranean seas (of which the Gulf of Mexico is one), and the sea bottoms lower. There is a shift of matter under or within the crust of the earth from the heavier regions to the lighter. There is every reason to suppose that this matter is magma, which makes the intrusive rocks at the core of our mountain ranges, or the lavas which pour out at volcanoes.

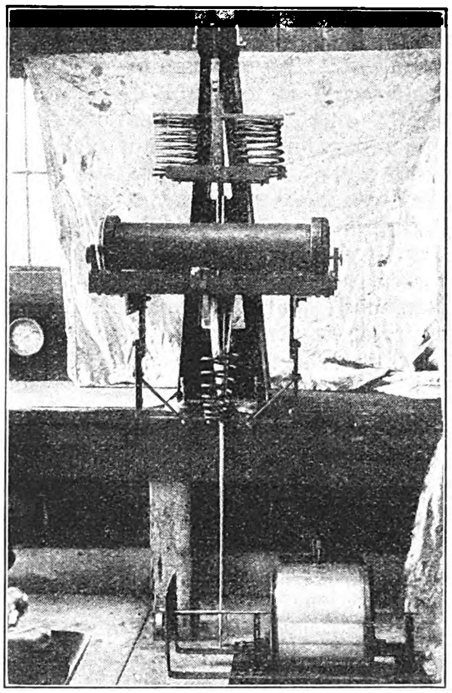
VOLCANOLOGY is concerned with the movement of magma. This movement is going on all the time somewhere, rapidly in some places, slowly in other places. It is probably much more important to mankind in its buried movements underground than in its visible movements at volcanoes. These buried movements and shifts of magma lift the mountain ranges at the sources of the Mississippi, lift shore lines in California and Japan, are somehow concerned with the scorching heat under the steam power plant at Geyserville north of San Francisco, and the high temperatures of our deep oil wells, and play their part in the stresses that make big earthquakes.

Science is gradually learning that what is happening under your home town in Montana or Pennsylvania or Louisiana, at a depth of about 35 miles, is equally important with what is happening in the air 30 miles above you. The aviators and the radio people need all possible knowledge of the air. The geologists need all possible knowledge of the earth and the relations of its gases, pastes, and solids. We explore the air with balloons and radiation. The oil people are beginning to explore the earth with echoes, conductivities, magnetic needles, and torsion balances. Volcanology needs the assistance of amateurs to microscope the tiltings and tremblings of vast continents, because without them the job appears to be too big, even for the government.

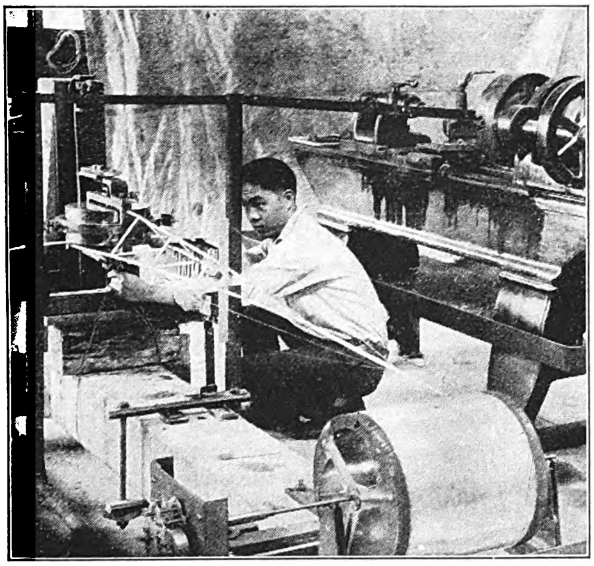
This makes volcanology something very different from what you thought. Nevertheless, the study of volcanoes and volcanic eruptions is a part of the game. For volcanoes have the advantage that they lie over places where the earth crust is thin, where the ground is hot close to the surface, and where the lava may sometimes actually be seen emerging. In a general way all the active volcanoes of the present day lie at places where there was much greater volcanic activity in

Tertiary time. That is, there are more extinct volcanoes at the volcanic districts of the world than there are live ones. Volcanism today is decadent. In the economy of the earth there have been geologic ages representing big cycles when the crust heated up and cracked, and volcanic magma poured out. The Miocene Tertiary was the last of these.

Decadent volcanism, however, in a volcano belt does not necessarily imply decadent magma underground. The magma underneath a chain of volcanoes may be engaged in processes of intrusion at the present age in a fashion much more lively than that which underlies Iowa and Pennsylvania. If we can make our instruments sensitive enough to show the same kind of motion under both Hawaii and Pennsylvania, but quantitatively greater in Hawaii, we are creating a science of volcanology wherein nobody has to wait for "eruptions." The popular conception of an eruption as something violent, steamy, and explosive is based on a very occasional happening at volcanoes, not at all characteristic of that flow of magma which has done most of the building of the great volcanic lands of the world. Volcanoes show us magma flowing out as lava, and a sensitive pendulum set up on a volcano shows us the ground tilting and trembling as a result of the magma spreading underground as an intrusive, or escaping elsewhere as an outflow. This is what makes a volcano so valuable as a natural laboratory. If we may correlate the physics of the ground with visible flow of magma, we may then go elsewhere and interpret underground flow of magma from measurements of the physics of the ground.



An experimental seismograph built in the shop of the Hawaiian Volcano Observatory, on designs by the author, for registration of the vertical motion of local earthquakes. The heavy mass weighs 160 pounds and is supported by spiral springs designed for compensation of temperature effects. The registration apparatus is the long, aluminum arm protruding downward, here not shown in its proper relation to the writing pen on the chronograph drum. In operation, the drum is coated with smoked paper and makes one revolution in 30 minutes. When properly placed, the tip of the boom connects with the short arm of the stylus, the pier is mounted on a concrete table in a quiet cellar, and a time-marking apparatus lifts the pen tip once a minute, while the chronograph drum moves along on its spindle. The action of the earth lifts the pier at a horizontal hinge line around the heavy mass acting as a center of percussion



Shaking table with horizontal pendulum seismograph mounted on it, at the Hawaiian Volcano Observatory. This machine is to make artificial horizontal earthquakes with the aid of a lathe chuck. The connecting rod at the lathe has its motion reduced at the two upright levers which rotate on the floor, two steel rollers under the table containing the seismograph. Any quick period required may be given to the apparatus by means of the lathe gears, and the amplitude is made to imitate local earthquakes. A series of tests compares the actual and theoretical magnification of the seismograph as recorded by the pen writing on smoked paper on the drum. Both drum and pendulum are attached to the shaking table. In this way seismographs made in the shop may be calibrated artificially in order to learn how they will behave under earthquake impulses. The shaking table was designed by the geodesist R. M. Wilson

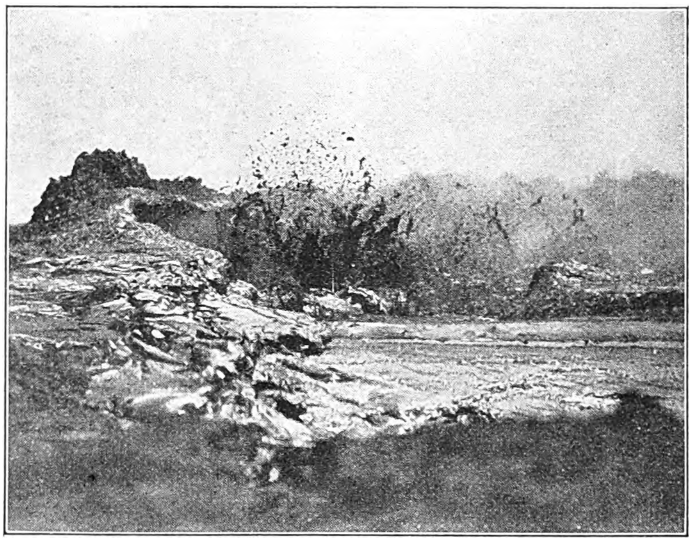
THE original study of volcanoes began with human necessities. Bad eruptions happened at Vesuvius, and the meteorological observatory there turned its scientific work in the direction of keeping a journal of what the volcano was doing. A bad earthquake happened at Naples, and Mallet made some interesting studies of how the buildings were thrown down in relation to a supposed center of bumping underground. The buildings were cracked at right angles to lines extended out in all directions from the center of the shock. If this theory worked, then a building right over the earthquake center, or at the epicenter, ought to be jolted straight up and down, and cracked horizontally. A building far away to the east of a shallow center should be broken vertically along north and south cracks.

If earth movements were as simple as this, the study of earthquake sources would soon become an open book. It was originally thought that steam explosions and collapses underground accounted for earthquakes near volcanoes. Then it was argued that these things are very small, and that volcanic earthquakes are very small. When a very big earthquake happened, like that at Messina, near Mount Etna, it was argued that this could have nothing to do with the volcano, because the volcano did not erupt at the same time. Geological text books have rung the changes on this argument, distinguishing between tectonic and volcanic earthqakes. Tectonic earthquakes are supposed to be crustal movements that have nothing to do with magma, but are occasioned by expansion or contraction or pressure such as are involved in the world forces which build mountain folds and faults in strata. The modern volcanologic viewpoint is that earthquakes occurring at an active volcano may be large or small, shallow or deep, usually occur at faults and not at craters, and represent forces which may be either tectonic or magmatic, according to the way in which those terms are defined. As we have magmatic movements of intrusion and continental balance under the mountains, and as we have crustal movements of pressure, expansion, and contraction under the volcanoes, and as nobody knows what makes an earthquake anyway, the guess of every amateur seismologist is just as good as the next man's.

Between 1891 and 1923 there grew up in Japan a science of field seismology led by Dr. F. Omori. Japan is a land of earthquakes and volcanoes mixed together. Dr. Omori devoted himself at first to devising seismographs and spreading them among the meteorological stations of Japan. He measured thousands of earthquakes. Very exceptional earthquakes were accompanied by big fault cracks, the sides of which moved up or down or sideways. Geologists have the habit of pouncing joyfully on these exceptional ones and concluding that the accumulated stress in the rock at the side of the fault crack was released when the fault gave way and that this yielding to accumulated stress is the usual cause of great earthquakes. Oldham, a distinguished geologist of India, has combated this notion with the argument that the stress is developed very suddenly in the deep region. Omari found out that earthquakes are far from simple, that big ones may occur in the midst of a big volcanic eruption, or near a big volcano not in eruption, or in a district not recently volcanic at all, and that some of these earthquakes have obvious fault movements and that some show no obvious faults at all.

THIS last fact had been observed by Oldham in India, by the Americans at the New Madrid earthquake of 1812, and by Major Dutton at the Charleston earthquake of 1886. Omori came more and more during the last fifteen years of his life to devote himself to the study of volcanoes, for he saw that there is an infinite series of earthquakes, small to great, somehow related to magma. He and his successors have learned in Japan that both volcanic eruptions and strong earthquakes are accompanied by topographic changes of elevation of the land. In using the expression "volcanic eruption," in this sense, the reader should remember that flow of magma is meant. A big gush of explosion with ash and steam is not essential to a volcanic eruption, and a retirement of lava straight downward under a volcano crater might be accompanied by a very important "eruption" or flow of magma. In this case the eruption would be a flow of lava from a rift under the sea which nobody would notice, unless the volcanologists were using their wits. And seven tenths of the geology of the earth is under the sea.

In 1911 an observatory was started at Kilauea Volcano in Hawaii, which the writer has had the honor to operate. This also was influenced by the humane viewpoint, for the terrible disasters at St. Pierre, Vesuvius, Jamaica, Messina, Etna, and Costa Rica had induced donors to create an endowment in the Massachusetts Institute of Technology for geophysical study that might lead to amelioration of conditions in earthquake lands. The observatory was started by the Massachusetts Institute and carried on thereafter by the Hawaiian Volcano Research Association assisted by the government. The Hawaiian Volcano Observatory kept a diary of everything that happened at the Hawaiian volcanoes and measured everything that was measurable within the limit of funds at its command. The volcanoes were mapped, the Kilauea lava pit was mapped again and again as its lava topography changed, leveling circuits were occupied repeatedly, a seismograph station was set up at the crater and afterwards supplemented with other stations about the island, and experiments were inaugurated.



Southeastern corner of the lava lake of Kilauea, March 19, 1921, at 2 P.M. A cauldron sink-hole against the pressure ridge at the edge of the pit had formed, and the lava was rushing toward this place and being sucked down in the convectional circulation. Single jets of lava shot up by the escaping gas were 40 feet high. The torrent on the right is rushing into the cauldron, and a rampart is being built up in the background. This was a crisis of high rising when the fire-pit overflowed and the gas pressure was enormous. Photo by the author

THE experiments proved, by the use of different kinds of thermometers and pyrometers, that the liquid lava grows hotter from below upward, just as it grows more foamy from below upward, as the bubbling gases are released from solution in the melt beneath. This melt is very dense under pressure down deep, and as the gases escape to the bubble form under release of pressure, they react with each other and with air to produce combustion of hydrogen, carbon monoxide, and sulfur gases along with rise of temperature. A lava eruption is thus a heating expansion of slag foam. This was a new idea. When this basaltic foam spreads out in the crater or beyond, in contact with atmospheric temperatures, it freezes, and in the crater pits it is engaged in an incessant struggle with congealing cold.

The topography of the top of the live lava column in Kilauea Crater becomes diversified into crags, floors, and lakes of lava. A series of experiments with steel pipes was initiated whereby it appeared that the liquid lakes are only 40 or 50 feet deep, with wells and tunnels feeding them. These wells and tunnels are not in the solid rock of the mountain, but form a honeycomb in the partially hardened lava that underlies the crags and floors. This hardened lava column is red hot and pasty, with tubes leading up through it to the shallow saucers of foamy lava on its top, while somewhere down deep both the pasty lava and the liquid merge into the very stiff primitive rising lava, under great pressure, and with the gases in complete solution.

THIS primitive stuff nobody has ever seen. When it is released from pressure to froth into the region of man's ken, it changes, heats, gassifies, and oxidizes to a glassy foam mixed with burning gas which may be very unlike the mother magma. The partially congealed refuse of this makes the lake bottoms, crags, and floors, and this paste rises and falls majestically as the main lava column in the pit, with the liquid lakes rising and falling at about the same rate on top of it, but with small differences between the two from day to day. The discovery of the difference between bench lava and liquid lava was another new idea.

With all this rising and falling, measurable with reference to the bench marks on the edge of the crater, it became of interest after 15 years of work to see how the curve of up and down compares with past curves. It was well known from the work of the devoted missionary Coan in the middle of the 19th Century, that Mauna Loa had more than a dozen outpourings of lava in great streams sometimes 60 miles long, and that Kilauea had lava in its pit most of the time. There had been some hint of a cycle about nine years long. The Hawaiian Volcano Observatory uncovered a cycle between 1913 and 1924, eleven years long, with the pit very deep and inactive at both ends of this time. Moreover, the lava rose from 1913 to 1919, sank from 1919 to 1924, and crashed down with a great engulfment of the walls of the pit in the last named year. Along with this culmination of 1919, Mauna Loa showed increasing eruptions in sympathy with the Kilauea cycle. The 11-year period was compared with what is known of the 19th Century, and it was discovered that the high levels agree very well with years of maximum sunspots, and that 12 cycles of 11.1 years each from 1790 to 1924 agree better with the facts than the older conception of a nine-year cycle. It happens, too, that this is just the sunspot average.

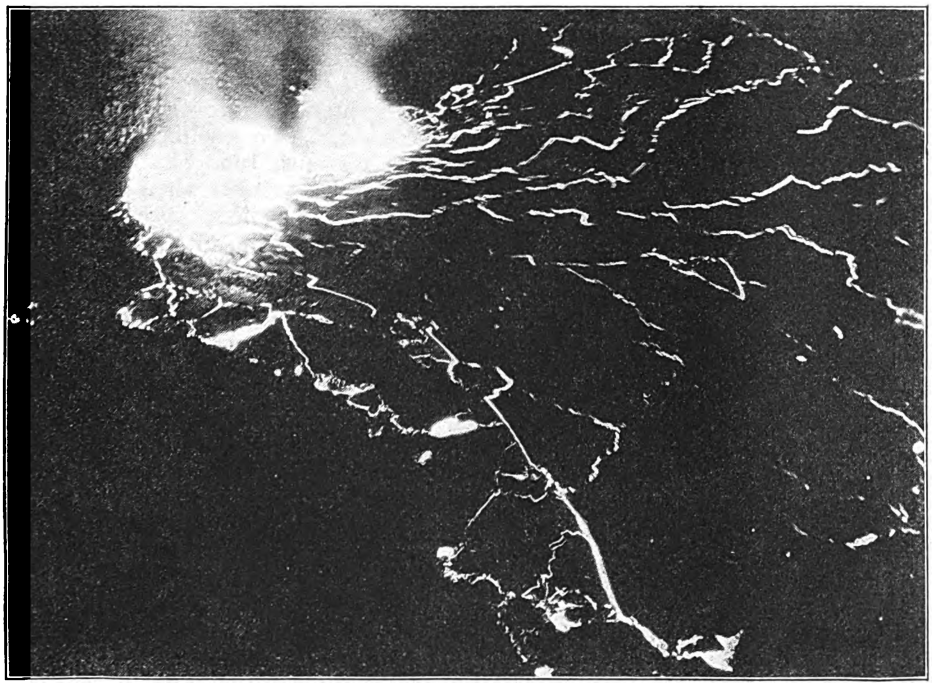
THE facts indicate that Mauna Loa and Kilauea alternate somewhat, and that there is a greater cycle 134 years long during which the lava of the entire Hawaiian system rose to a culmination of outpouring about 1855, declining thereafter until 1924, when there was an explosive eruption at Kilauea, and very probably a submarine lava flow under the deep sea off to the east. The supercycle had followed an explosive eruption at Kilauea in 1790, and this larger in-interval of something like 130 years corresponds to similar periods in Japan and Italy elapsing between great earthquakes or great volcanic eruptions at the same place. It is reasonable that magma should move in waves of accumulated gas pressure and release, and also there may be astronomical controls in these cycles.

The volcano seismographs at Kilauea have indicated thousands of earthquakes, and by comparing the records with those of the secondary stations and with the reports of felt earthquakes at habitations, it has been possible to locate groups of earthquake centers. These have often corresponded fairly well with known volcanic fissures or faults, sometimes when the fissures in question broke into eruption and gave vent to lava flows. The earthquake centers rarely correspond with summit craters. Often the earthquakes, registered by a pendulum and a pen writing on smoked paper, are accompanied by a swinging off of the pendulum to a new position after the earthquake. This means that the ground has tilted during the earthquake. These tilting movements have been compared with changes of level of the country as proved by geodetic levelings. It has been discovered that Kilauea Mountain rose more than two feet while the lava was rising in the seven years following 1913, and sank by a similar amount during the explosive engulfment of 1924. And the pendulums indicated the actual months of maximum tilting, as corresponding with times of maximum lava pressure and lava withdrawal.

All of this means that land underlaid by magma is subject to swelling and shrinking forces, and it will prove increasingly fascinating to harness these forces with simple instruments and volunteer observers until the centers of motion, and the relative motions of different places, have been discovered. To anyone who has worked where these motions are rapid and strong, as on Hawaii, it appears that the geographical facts of distribution of motion, in relation to volcanic centers, are much more needed than precision work at one place. That is where the amateur and volunteer will come in, and consequently the simplification of instruments appears to the writer to be the most important need of seismology.

What is the use of volcanology? On the answer to this depends in part how we ought to attack the science. If we are interested in theories of the earth's internal elasticity, of its heat, of its gases and radioactivity, and care nothing for the effects of volcanic eruptions and earthquakes on mankind and his cities, we should devote ourselves wholly to precision laboratories with only minor attention to geography. But there comes into the argument the Mississippi flood, the devastating tidal waves, the failure of gigantic engineering works at times of great earthquakes, and destruction of cities such as St. Pierre. If a great insurance company were to create a research laboratory of volcanology to solve company problems, what would they demand? They would certainly demand, first, attention to engineering and to geography. In other words, the human need for a science of eruption, of deformation, of sedimentation, and of erosion calls for field laboratories eternally measuring by observatory methods the quantitative aspects of those processes. All the processes are tied together as affecting the pipe lines, dams, railways, farms, cities, roads, bridges, wharves, levees, aqueducts, wires, harbors, and fills on which human beings have spent billions of dollars.

AS it is, the science of volcanology, quite apart from volcanoes, is the forerunner of a new science of the earth, which at this moment in America is being greatly assisted by the new flood-relief measures carried out by the government on a gigantic scale on all the rivers of the United States. Probably few people realize that this study of earth process is the pioneer of a science of geonomy, the workers of which will be geonomers living at observatories and actuated by the same spirit as astronomers. Erosion science has hardly been touched, yet mountain canyons are falling down all the time and their wreckage is being swept to the ocean. It is a marvelous opportunity for new measurements and new instruments. Mountains are heaving up, continents are tilting, flood plains are shifting, waters are muddying and clearing, bays and lakes are filling, the bedrock is shaking and, under all, the magma is welling under the crust of the earth, warming the hot springs, heaving the hills, and accounting for a hundred unmeasured phenomena up and down the Pacific Coast and Alaska, as well as in Arkansas, Virginia, and the Adirondacks. With simplified instruments and hundreds of amateurs, we may expect the natural history of the earth to take a new lease on life.



Night photograph of a live lava lake in the bottom of Halemaumau pit at Kilauea Volcano, July 25, 1929, at 9 P.M. It shows the bright lines on the surface of a crusted pool of lava, and the great luminosity of fountains flaming during an eruption in which a fountaining lava grotto similar to the one on the front cover furnished the molten matter which sweeps over the pool

Why Stars Twinkle

By HENRY NORRIS RUSSELL, Ph. D.

Chairman of the Department of Astronomy and Director of the Observatory at Princeton University
Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

PROBABLY the first thing that many of us learned about the stars was that they twinkle, and the fact is obvious enough to deserve its place in the nursery classic. But does any grown-up, except perhaps an occasional minor poet, notice the phenomenon—and in particular what have the astronomers to say about it?

As a matter of fact the professional observer habitually scans the twinkling lights of heaven as he walks toward his telescope and the more they twinkle the less is he pleased. Whenever the brightest stars, though low down in the sky, twinkle but lazily and those higher up shine steadily, he anticipates a good night's work. But on our clear snappy winter nights, when the wind roars overhead and the brilliant stars are dancing and flickering, he hopes for little or nothing; and after one glance through his telescope he may even shut up shop and go home to bed.

For the twinkling of the stars is the best test that the unaided eye can make of what is technically called the "seeing"—that is, of the state of the air through which we must look. The late Professor Young, translating literally and with his characteristic jocular humor from some French book, used to repeat to his students, "The earth's atmosphere is the astronomer's black beast" and a *bete noire* it surely is.

FORGET for a moment the clouds, fogs, smoke, and rain which so often blot out the heavens altogether and think of the limitations which even clear skies impose. Could we astronomers but live without breathing, and escape for our working time to an airless world, our lot as observers would be a happy one. With nothing above us to scatter the sunlight and veil the heavens with blue sky, we could see the stars as well by day as by night—and photograph them too. The solar corona could be observed at any time merely by hiding the sun's disk by a suitable screen placed in front of our telescope, instead of waiting years for a total eclipse. Best of all, our spectroscopes could get at the far ultraviolet parts of the spectrum of the sun and stars, which is utterly and hopelessly cut off by the absorption of light of this sort in the upper atmosphere and which probably contains more things of astrophysical interest than all the parts that we actually can observe.

But let all this pass again and write it off as hopeless, even to dream of. Even so, the cloudless sky still is too often our worst enemy. The atmosphere is lamentably far from being optically satisfactory to look through. It refracts light, which would not be a serious matter if it were only homogeneous—but this it never is. The air is full of streaks and patches of different temperature and unequal densities, which are carried along by the wind and churned into a still more turbulent complexity wherever the wind is puffy or where winds blow in different directions at different levels. Large scale disturbances of this sort are often directly visible as dust whirls near the ground, or as the long parallel streaks of cloud in the "mackerel sky." They are all too familiar to the airman, too, as the "bumps" which make flying uncomfortable and occasionally even dangerous.

THESE larger irregularities are not always present, fortunately for the astronomer, but the smaller ones are always there and make trouble enough. Looking through them is, on a smaller scale, like looking up through running water or the rippled surface of a pool. Every streak of denser or thinner air, like the crest or trough of a ripple, acts as a lens would do to concentrate or spread out two originally parallel rays of a star's light. If only the starlight was strong enough, said Young many years ago, we should see on a white surface illuminated by it a moving pattern of lighter and darker patches resembling that formed on the sandy bottom of a pond when the sun shines on its rippled surface.

This prediction can be verified by anyone with keen eyesight who takes the trouble to find a dark room with a window free from all disturbance from artificial lights and let the light of Sirius come through the window (stopped down to a couple of feet square) and fall on a white sheet a dozen or more feet away. Until his eyes are fully adapted to the pitchy darkness, which will take 15 minutes or more, he will see very little. But then he will find that the patch of starlight on the screen is distinctly visible, even for considerably fainter stars, while for Sirius it is bright enough to exhibit the shifting lights and darker patches which Young predicted. Now imagine an observer looking through a hole in this screen. As the brighter or fainter patches pass over it he will see the star increase or diminish in brightness. In other words it will *twinkle* and of course it will do so just the same if the screen is not there.

We see now, not only why the stars twinkle, but why their twinkling gives really valuable information to the astronomer regarding the state of the air—much better, indeed, than could be obtained by looking, even with the sharpest eyes, at a screen illuminated only by the feeble light of Sirius. It is clear, too, why stars high in the sky twinkle less than those lower down, for the rays of the first traverse a smaller thickness of air and so pick up less trouble.

Why bright stars seem to twinkle more than faint ones is not so obvious, the explanation being that rapid changes in the fainter object are less conspicuous to the eye than in the brighter one.

NO explanation is needed why the stars twinkle more on a windy night than on a calm one. Indeed, when they twinkle violently on a night when there is a calm or a light breeze at the ground it is very probable that it is blowing half a gale higher up.

It is obvious, too, why terrestrial lights usually twinkle when seen at a distance of some miles, especially when seen through a wind or across ground from which heated air is rising, or from the deck of a moving steamer—as the writer has this moment seen the lights of a Greek seaport, twinkling furiously.

The planets do not twinkle, at least under any ordinary circumstances—which affords one of the simplest rough-and-ready tests by which the novice may distinguish them from the stars. The reason again is simple. The planets, unlike the stars, show disks of considerable angular diameter. The lines along which light enters our eye from different parts of the planet diverge when followed backward. The rays from opposite sides of Jupiter, for example, which enter the same eye were more than a foot apart a mile farther back on their course. If we could isolate the light from any one small portion of the planet it doubtless would twinkle, but the different parts do not keep step in their twinkling and so the whole amount of light received by the eye does not change perceptibly. That this is the true explanation is shown by certain exceptions which prove the rule. Mercury, which shows a small disk, often twinkles, and so may the larger planets when seen near the horizon through turbulent air.

A star, when it twinkles, changes not merely its brightness but its color, especially if it is at a low altitude. How great these changes are is not generally realized because they usually happen too fast for the eye to follow. A simple device reveals them. Look at the star with an ordinary field glass and swing the glass rapidly with a sort of conical motion (a thing easier to do than to describe in a few words) so that the star appears to follow a rough circle within the field of view. If the motion is fast enough the luminous point will appear to be drawn out by the persistence of vision into a curving line of light. A star which is not twinkling gives a uniform line but one which is, shows a surprising variation both in the intensity and color of the light. On a night of bad seeing the luminous line is beaded with patches of brilliant color, almost like the flashes from a diamond. When the glass is held still the successive changes, which may follow one another 20 times a second or more, become partially though not wholly fused into the familiar flickering image.

THIS remarkable and beautiful phenomenon was first explained by the Belgian, Montigny, more than 70 years ago, but it still is not as widely understood as it ought to be, and the writer owes the account which follows to the excellent Italian treatise of Professor Armelline of the University of Rome.

Owing to the refraction of light in the atmosphere the rays of starlight which traverse it are not quite straight, but are curved slightly downward as they go deeper. Blue and violet light are refracted more than red and yellow, so that the corresponding rays are more curved. If, then, we have a streak of air high up which, for example, acts as a convex lens, the red and blue rays, though both concentrated into bright patches of starlight on the earth's surface, will pursue paths of slightly different curvature and will not reach the earth in the same spot. If, then, we could see the patterns cast on the surface by the red and blue light separately, we would find them very similar in design but shifted laterally with respect to one another.

FOR a star in the zenith, indeed, the rays would come down straight and there would be no shift, but in all the cases the red and blue patterns would be out of register by an amount increasing as the star's altitude diminished; and also of course the higher in the air were the regions which produced the pattern. The actual light pattern would be very complex, composed of patterns of all colors, some more out of register than others. But it is evident that, from point to point in it, any given color might happen to be intensified, and any other (not too nearly like the first) might be weakened. The resulting pattern would therefore be irregularly and sometimes strongly colored and as it drifted past an observer's eye the star would appear to change in color as well as in brightness. There can be no doubt that this is the true explanation. It is confirmed by the fact that conspicuous changes of color appear only in stars at a low altitude, for which the curvature of the rays is greatest.

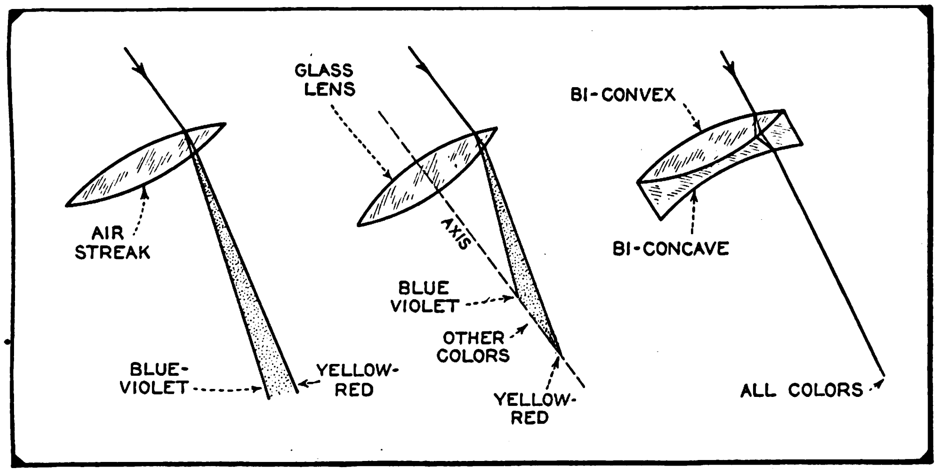
When viewed with a telescope, especially a large one, the appearance of a twinkling star differs greatly from that which it presents to the eye. The changes in brightness and color are far less conspicuous, but the star images at times of modest disturbance appear to shift and dance irregularly about. When the seeing is really bad the image is distorted and refuses to come to any sharp focus, but is continually "boiling" and shifting; and sometimes it "explodes" into a diffused mass of considerable size.

All these effects again are readily intelligible. The rays which strike different parts of the objective of the telescope and are brought by it to one focus have traversed different paths within the atmosphere, so that some of them may be weakened at any given moment and others strengthened. The changes in brightness of the integrated image are therefore pretty well ironed out, and the same is true of the color.

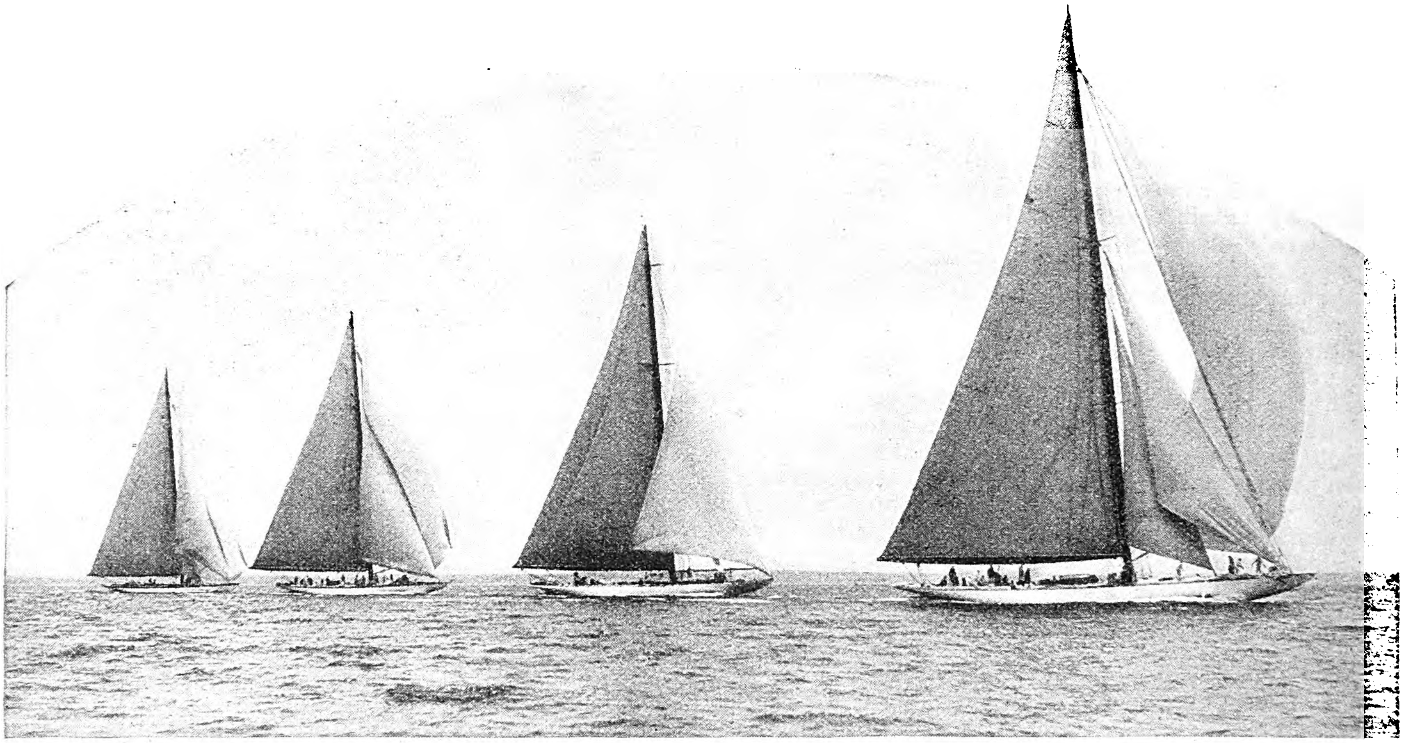
On the other hand the small lateral deflections of the direction of the ray as a whole, which are usually quite imperceptible through the unaided eye, become visible and often conspicuous when magnified. When the disturbance pattern in the air is on a large scale all the rays which enter the objective of the telescope may be deviated in the same general direction, and as this changes from moment to moment the image dances. When the pattern is small the rays entering different parts of the objective are deviated in different ways and the image refuses to come to any good focus but boils, and in particularly bad moments it explodes. This sort of trouble evidently should be most frequent with large telescopes, and so it actually is found to be.

ATMOSPHERIC disturbances of all these kinds are among the worst defects that can afflict an observing station. It is no wonder then that when a great observatory is being planned careful tests of seeing are made at many proposed sights and often enough to get a good average representative of conditions the year around. For work of this importance a telescope of several inches aperture in the hands of an experienced observer is necessary. But in the preliminary reconnaissance which selects the places for further testing the simple observation with the naked eye of the twinkling of the stars should suffice to exclude many hopeless situations and pick those which are more promising.

So the modern astronomer who sees the little stars twinkling—and the brighter ones still more—moves on, fearing that, should he set up his telescope in so ill-favored a spot, he might find it useless for the greater part of the time, and be left "wondering" what the stars "are," rather than finding out.—*In the Gulf of Corinth.*



A streak of denser air high aloft (see left hand sketch, which is of couse diagrammatic) affects the light rays arriving from space in the same way as a simple bi-convex, non-achromatic lens (middle sketch). In the case of the glass lens we can virtually balance out this "chromatic aberration" by adding a second lens (third sketch), but there is no convenient way of capping a dense air streak with a rarefied one, even from an airplane, and this is why the astronomer often must "go home to bed," as Dr. Russell says in the text



The candidates for the defence of the America's Cup. *Right to left:* *Weetamoe* (1); *Enterprise* (4); *Yankee* (2); and *Whirlwind* (3). The defender will be selected in the latter part of August after a series of official trial races

The America's Cup Defenders

By HERBERT L. STONE

Editor, *Yachting*

WHEN the little schooner yacht *America* fared forth across the Atlantic 79 years ago this summer to fling down the gage of defiance to British yachtsmen it is safe to say that not one of the adventurous spirits who backed that valiant effort ever foresaw that the insignificant cup which now bears the name of the vessel that won it would one day stand for the supremacy of speed upon the waters; or that many millions of dollars would be spent in any single attempt to retain it in this country.

For 79 years, during which 13 hard-fought races, or matches, have been sailed for this particular bit of silverware, the cup has never left our shores; and to meet Sir Thomas Lipton's fifth challenge this year we have made, perhaps, the most elaborate preparations for its defence in September that have ever been seen in any yacht race. For we have built no less than four candidates for the defence, the cost of which, together with the expenses of campaigning them throughout the season, will total between three and four million dollars. And this for a cup the intrinsic value of which was originally 100 guineas, or about 500 dollars

The schooner *America*, which was built in New York at the foot of East 12th Street, after a model by George Steers, for a syndicate of New York Yacht Club members headed by Commodore John C. Stevens, was, as far as the records show, the first American yacht to cross the Atlantic for the purpose of racing in a foreign country. It had been suggested that, in connection with a great international exhibition to be held in England in 1851, it would be "eminently fitting" if America send over a yacht to sail in the races to be held in English waters that year. It was also intimated that plenty of matches could be secured in the event of a yacht being sent. So the *America* was built and sailed across in the spring and early summer of that year. She was a schooner of moderate size, being 90 feet long on the water and 101 feet, 9 inches over all, her model following closely that of a smart pilot schooner turned out by George Steers a few years earlier. Her rig was distinctly American, with excessively raking masts, a single big jib, and a loose-footed foresail.

But when the *America* reached British waters she found it exceedingly difficult to arrange for the promised matches. Her crew made the mistake, as she sailed up the Solent towards the Royal Yacht Squadron on her arrival, of tackling the "crack" English cutter *Laverock* in an impromptu brush, during which she beat this boat so handily in a beat to windward that other British yachtsmen seemed loath to sail a race with the stranger. English yachtsmen were most hospitable, but they showed a strong disinclination to arrange a special match with the *America.* Finally, Commodore Stevens, despairing of getting a race, posted a challenge to sail the *America* in a match against any British vessel whatsoever for any sum up to 50,000 dollars. This had no effect in bringing about the desired meeting, but the officers of the Royal Yacht Squadron informed Commodore Stevens that the *America* could race in the regular open regatta of the Squadron on August 22nd, for which all of their yachts were eligible, the race to be sailed without time allowance. The prize was to be a trophy, put up by the Club, valued at one hundred guineas.

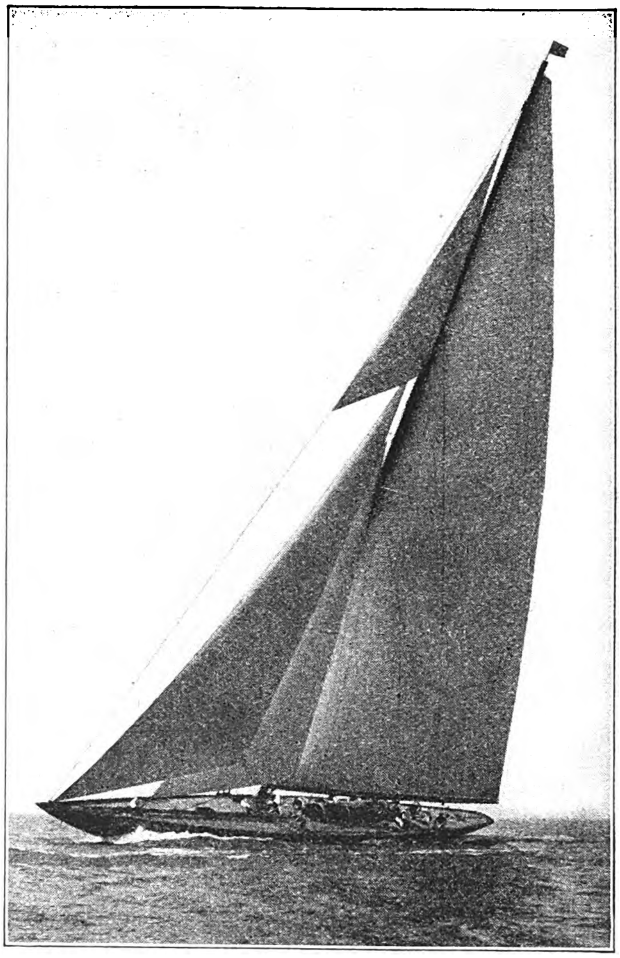
This was hardly what the crew of the *America* wanted, but they decided to start, the course being around the Isle of Wight, a distance of about 53 miles. There were 15 starters in this race, all British except the *America*, and ranging in size from 47 tons to 392 tons, the latter being the big three-masted schooner *Brilliant*. The race was sailed in a variety of light, fluky winds, and with strong tides to contend with, but the *America* won rather handsomely. The original records of that race are not clear as to the time by which *America* finished ahead of the second boat, but the New York Yacht Club records give it as 18 minutes.

The Cup thus represented almost the sole proceeds of that summer adventure, and some six years later, or in 1857, it was turned over to the New York Yacht Club by the syndicate which built the *America*, to be put up for international competition, and has been held by that organization ever since. The race this year marks the 14th attempt to capture it, all the challenges coming from Great Britain, with the exception of two from Canada. Also, this last challenge by Sir Thomas Lipton makes the fifth attempt the Irish baronet has made to "lift the mug," as he expresses it, the first having been in 1899, just 31 years ago. All of his yachts have borne the name of the four-leafed clover so dear to Irish hearts.

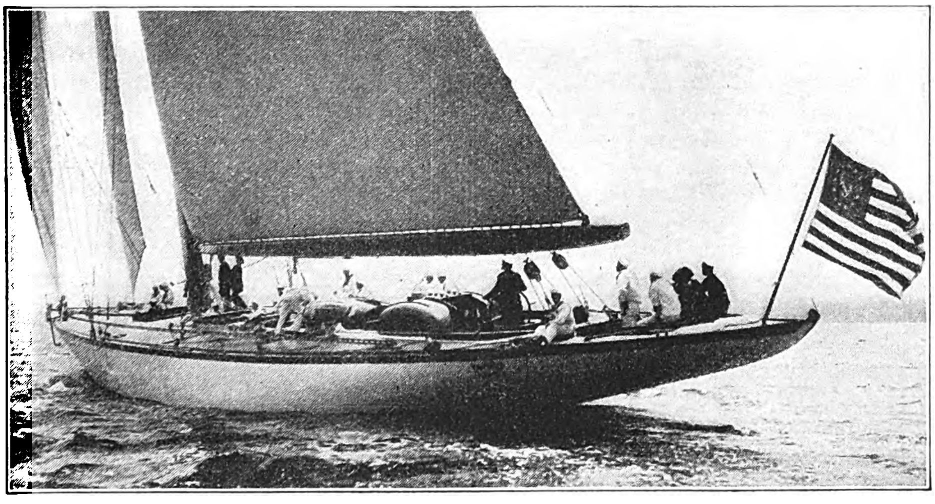
OF late years the cost of building and campaigning a yacht for Cup defence has become so great that it has become a matter for syndicates to handle, rather than individuals, as was the case with most of the Cup yachts up to the time of the *Vigilant*, in 1893. So when this last challenge was received, those interested in seeing a proper defence assured started to form syndicates for the building of candidates to meet the *Shamrock V*. In a short space of time no less than four such syndicates were formed, and work on the design and construction of the four yachts went merrily forward. It is estimated that to build and race a Cup yacht of this size costs between 700,000 and 800,000 dollars.

In the matter of design we found ourselves confronted with a situation which was somewhat unique, inasmuch as none of our active naval architects had ever designed an America's Cup yacht, and few of them had turned out a racing cutter of the size called for. "Nat" Herreshoff, of Bristol, and William Gardner, who created the two candidates for the race of 1920, had both retired and were out of the picture. So the four syndicates turned to three of our younger designers, and to Clinton H. Crane, who is no longer pursuing naval architecture as a profession, but who recently turned out several smaller successful yachts as an avocation.

Towards the race this year the New York Yacht Club displayed a very liberal attitude and suggested to Sir Thomas that instead of his building to a specified water-line length, as in the past, and their meeting him with a boat of the same water-line length, that he build to one of the regular classes of the New York Yacht Club, in which event we would build to the same class and race him boat for boat, without time allowance. Heretofore the yachts have raced with time allowance, so that sometimes the first boat to finish did not turn out to be the winner, which was often unsatisfactory and confusing to the general public.



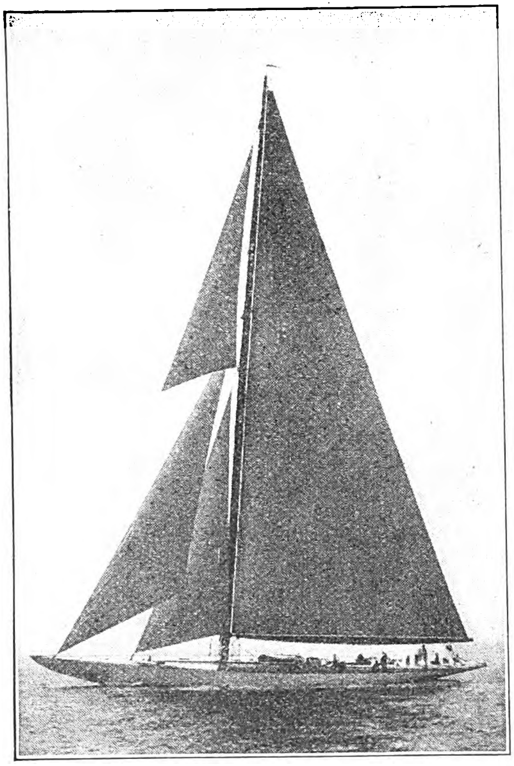
The Shamrock V, **Lipton's Cup challenger**



Deck view of the *Whirlwind*. She is a double ender with canoe stern. This is the first time this form of stern has been used in an America's Cup yacht

SIR THOMAS accepted and elected to build to Class J, or 76-feet rating. Therefore, all of our boats were built to this rating also. This 76-feet rating does not mean that the boats are of this length, but that the resulting measurement derived from a formula taking into consideration length, displacement, and sail area will be 76 feet. As a matter of fact, the various yachts built for this year's race vary in water-line length from about 80 to 86 feet, and in tonnage (displacement) from 128 to 158 tons, all with approximately the same sail area. This allows plenty of scope in design to assure that the boats would not be of exactly the same form and dimensions. The over-all length varies from 120 to 130 feet in our four candidates. With the modern Marconi, or jib-headed rigs that modern yachts carry, all of the boats have extremely long, hollow masts, varying in height from 162 feet to 168 feet. As these are made in one piece, with no fidded topmasts, as in the case of the older yachts, it means that particular attention must be given to proper staying of the masts in order to keep these long slender spars in the boat, and many fears are being expressed as to the possibility of the masts giving way in a hard breeze and jump of sea, such as are likely to be met off Newport in September.

Another forward step this year in these defenders is that the hulls are all built to Lloyd's scantling requirements, which means very substantial construction as compared to the defenders of recent years, in which every sacrifice



***Weetamoe*. Mechanical appliances are used for handling halliards and sheets**

was made to lightness. This practice went so far that it was considered unsafe to race in a wind which to the early Cup boats would have been only a whole-sail breeze, and resulted in one of the races of 1920 being called off in a wind of only some 25 miles-an-hour strength. Also, it means less of a handicap to the challenger, for as our boats are built to the same scantling (or frame) dimensions, they have to be as substantial as the *Shamrock V*, which, to race, must sail across the Atlantic on her own bottom.

ANOTHER feature of modern yachts built for the defence of the Cup that marks a great departure from previous practice is in the mechanical contrivances for handling gear. Below decks, on all the boats built for this race, no accommodations of any kind for the crew are to be found. The entire personnel of each yacht, from 22 to 24 men, is berthed and boarded on a large tender, which follows the yacht to which she is attached to the various ports where she may base. This leaves room below for the stowage of various light sails or "kites" which these boats must carry to make the most out of every vagary of the wind, and for the many winches and drum hoists for handling halliards and sheets. The halliards for all except the lightest sails lead to mechanical hoists below, while the main sheets and some of the headsail sheets also are led to winches below, where a gang of men takes in on them or slacks them off on signal from deck. This is a far cry from the traditional method of all-hands tailing on to sheet and halliard to hoist or trim sail, as in the days of the *America*, and all of those yachts which followed her in the quest for the Cup up to quite recent times

The four yachts built for this year's defence are the *Weetamoe*, *Enterprise*, *Yankee*, and *Whirlwind*. A comparative table showing the principal dimensions of these boats, and of the challenger, *Shamrock V*, is given, and the details of ownership and design follow.

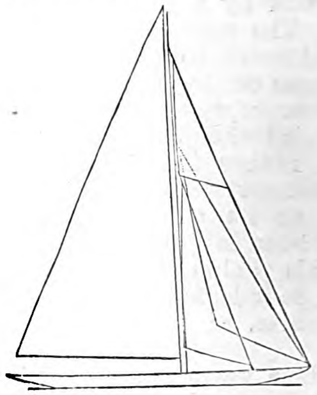
Weetamoe, Racing Number 1. Designed by Clinton H. Crane. Built by the Herreshoff Mfg. Co., Bristol, R. I. She is for a syndicate organized by J. P. Morgan and Junius S. Morgan, Jr., the other members being Henry Walters, Cornelius Vanderbilt, Arthur Curtiss James, Gerard B. Lambert, and George T. Bowdoin. Former Commodore George Nichols is managing owner and skipper and will sail the yacht throughout the season. With him on the quarter deck are John Parkinson, Robert N. Bavier, A. H. Eustis, and Junius S. Morgan

Yankee, Number 2. Designed by Frank C. Paine, a son of General Charles J. Paine, who owned or managed the Cup defenders *Puritan*, *Mayflower* and *Volunteer* in 1885-6-7. Built by George Lawley & Son, Boston, for a Boston syndicate composed of John T. Lawrence, Chandler Hovey, and Frank C. Paine. The first named is syndicate manager, and in the afterguard with him are Raymond Hunt, Frank Paine, Chandler Hovey, and, on occasion, Charles Francis Adams, Secretary of the Navy.

Whirlwind, Number 3. Designed by by L. Francis Herreshoff, son of the famous Nathaniel Herreshoff, the "Wizard of Bristol," who designed all our previous Cup defenders since 1893. Built by George Lawley & Son, Boston, for a syndicate organized by Paul Hammond and Landon K. Thorne, of New York, who will sail her in her races, with Adrian Iselin, II, assisting.

Enterprise, Number 4. Designed by W. Starling Burgess, son of Edward Burgess who turned out the successful defenders *Puritan*, *Mayflower*, and *Volunteer* mentioned above. Built by Herreshoff Mfg. Co., Bristol, R. I. She is owned by a syndicate headed by Harold S. Vanderbilt, and consisting, beside himself, of W. W. Aldrich, Commodore Vincent Astor, George F. Baker, Floyd L. Carlisle, Ogden L. Mills, E. Walter Clark, and George Whitney. Harold Vanderbilt is her skipper, and sailing with him are C. Sherman Hoyt, C. F. Havemeyer, W. W. Aldrich, and the designer, Starling Burgess.

All of these four yachts, excepting the *Whirlwind*, are built with bronze plating over steel frames. The decks are of wood. The *Whirlwind* is of composite construction, with a double planking of wood over steel frames. This latter boat is a double-ender, the ends of the others being of moderate length for a modern yacht and of conventional form. Each of the defenders is fitted with a small centerboard, excepting the *Whirlwind*.



Sail plan of a modern Cup defender

WHILE the four American Cup candidates have been racing since June, the actual defender will not be named until after a series of official trial races to be sailed off Newport, over the Cup course, between August 20th and 30th. After this selection is made, the following two weeks will be spent polishing up the successful candidate to get her in the pink of condition to meet *Shamrock V* in a series consisting of the best four races out of seven, starting September 13th, nine miles southeast of Brenton Reef Lightvessel. And, then, may the best boat win!

	Weetamoe	*Yankee*	*Whirlwind*	*Enterprise*	Challenger *Shamrock V*

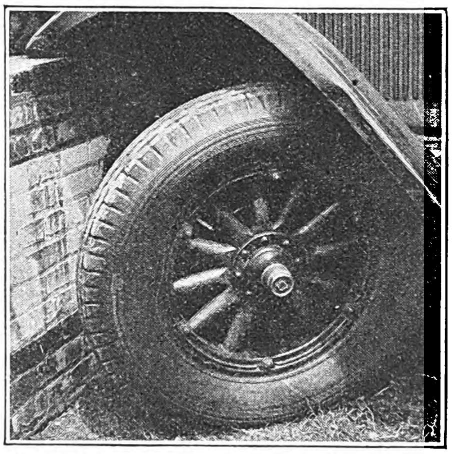
Crash-Testing Tires at High Speed

WHICH of these will best stand the force of tremendous impact: A 10-ton brick and concrete wall, reinforced with steel, and sunk deep in earth, a 3000-pound eight-cylinder automobile, or a few pounds of rubber and compressed air?

The answer to this question was given when Captain Dick Grace drove an eight-cylinder touring car under full power at 37 miles an hour into a solid wall over three feet thick. When the car crashed, the entire wall, 15 feet wide, was moved several inches from its base, the powerful car was wrecked and the front end was demolished, Captain Grace was hurled high in the air by the impact, falling beside the car, but the tires on the car were not damaged in any way despite the fact that they had received the full force of the impact.

Because of the daring exploits of Captain Grace who intentionally cracked up airplane after airplane to furnish thrills in "Wings," "Lilac Time," and other spectacular air movies, the General Tire and Rubber Company asked him to give its new blow-out proof tires the most severe test he could devise. On the company athletic field, engineers built a brick and concrete wall, 15 feet wide, over three feet thick, and six feet in height, half of it buried underground. A heavy steel I-beam was built into it to reinforce it.

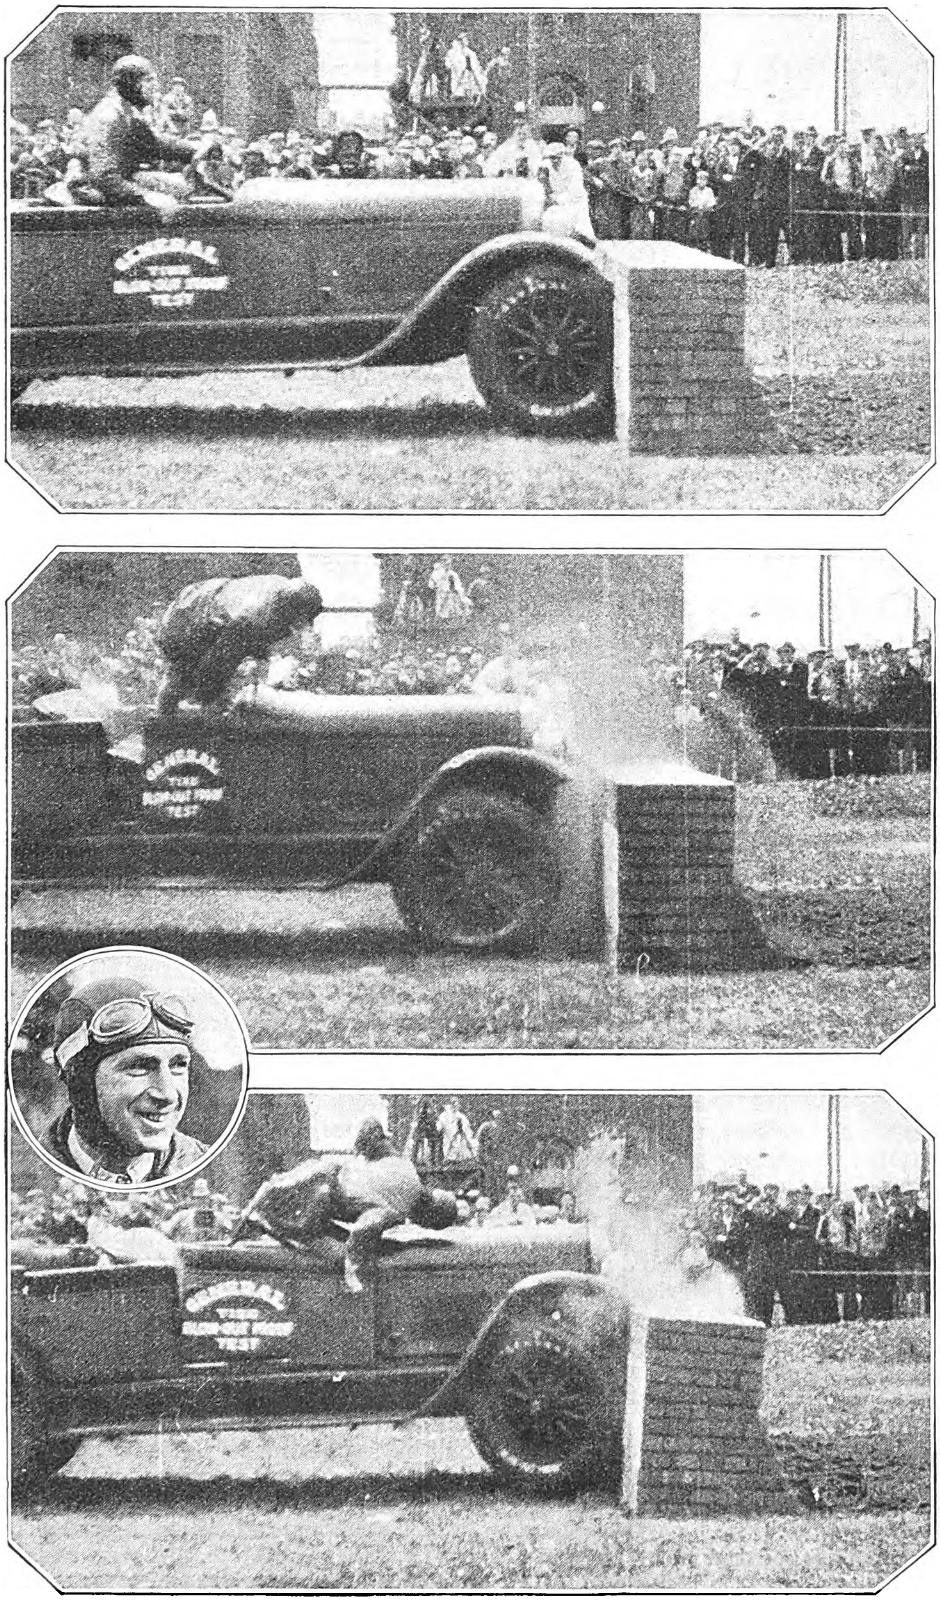
Captain Grace selected a powerful, eight-cylinder touring car with which to make the test. Before it was equipped with the new tires, the front wheels were moved forward so that they cleared the front springs and frame by six inches, making it certain that the tires would get the full impact of the crash. Then Captain Grace circled the field several times, gaining momentum for the final run.



The tires uninjured after the crash although the rim was badly bent

Just before the crash, he raised himself in his seat in a crouching position. With the throttle wide open, the car crashed into the wall, head-on. Slow-motion cameras revealed that the impact flattened the tires back against the rims, which were bent out of shape but the tires were uninjured.

"Such a test shows," said Captain Grace, "that tires will withstand the shock of driving over all kinds of roads at high speeds, even though they are driven unexpectedly into deep holes in the road."



Oomph! The car strikes the wall at 37 miles an hour. The upper left picture shows the flattened tires at the moment of impact; the center picture, the rebound; at bottom, the moved wall and the catapulting driver. In the inset, Captain Dick Grace

Our Patent System

By ORSON D. MUNN

Member New York Bar

THE Use and Abuse of Patent Rights: Just What Rights Our Patent Laws Grant to Patentees: The Government Cannot Give a Patentee the Right to Use the Invention of Any Prior, Existing Patent: Patents for Improvements Are Frequently More Valuable Than Pioneer Patents: Today, as Always, a Patentee Receives the Protection of the Government, in so Far as His Patent Rights Are Concerned, as Well as His Just Reward

THERE has been much unfavorable comment recently concerning our patent system. A western Senator has introduced a bill designed to prevent what is alleged to be the abuse of the rights secured by patents. The Government has instituted a suit against the so-called "Radio Trust," in which it charges that large and powerful corporations, holders of alleged "all-covering" patents, have by means of cross-licenses and agreements practically made it impossible for the independent manufacturer in the radio field to exist. We find others criticising our patent system because of the ineffectiveness of patents and the alleged lack of protection extended by the Government to inventors and patentees in general.

To determine whether or not the proposed legislation and the Government's action on the one hand, and the criticisms of the futility of patent protection on the other hand, are justified, we should first consider just what a patent is. It has been defined as a limited monopoly based on a contract between the patentee and the Government, wherein the Government, as an inducement to the patentee to make his invention known and useful to the people of the United States, promises to the patentee that for a limited period no one shall have the right to make, use, and sell his invention, without his consent. At the end of that period of time the patented invention becomes public property and may be employed by anyone. The rights secured by a patent are exclusive and the Constitutional provision under which inventions are protected provides only for the making of laws to secure "exclusive" rights to inventors. It is extremely doubtful whether Congress could pass any law, under this Constitutional provision, providing for the grant of anything less than an exclusive patent.

THERE are many who do not comprehend just what rights are given to a patentee by his patent. Many believe that a patent from the Government confers upon the patentee the absolute right to make, use, and sell his invention throughout the United States; but this is not the case. What he really gets is the right to exclude all others from making, using, and selling his invention. Obviously, this must be so, because many patents are granted for inventions which infringe prior patents; in other words, for improvements on the inventions of prior patents. Such improvements, everyone will agree, are patentable; but because they are patentable, the patentees get no right to use them if they embody the invention of a prior, existing patent. Our Government cannot take away from one citizen his property and permit its use by another—such monopolies were never granted by our Government—so that when the patentee of an improvement gets a patent from the Government which, in terms, gives him the exclusive right to make, use, and sell his invention, he must remember that he does not get the right, and the Government cannot give him the right, to use the invention of any prior, existing patent.

Patents for so-called improvements are in many instances more valuable than a so-called "pioneer" patent. A case in point is the Bell telephone patent of 1877, which may rightly be designated as a "pioneer" patent. During its life many valuable patents were granted for improvement in the telephone art, and it may be conceded, without detracting from Bell's great achievement, that the practical commercial telephone was developed by these subsequent inventors; but not one of those patented devices could have been used by the owners without the consent of the owners of the Bell patent. Each of them secured to the patentee exactly the same rights that were given to Bell; that is, the right to exclude everyone from using the patented invention without the consent of the owner of the patent.

A patentee having this right of exclusion may do with his patent what he pleases, within the law. He may never put the invention in use during the term of the patent, and yet, he does not lose the right to exclude all others from using it. Having this exclusive right he may sell his patent to whom he chooses, or he may refuse to sell it. He may grant a license to anyone whom he chooses to license or he may refuse to license anyone; also, it follows that he may license those whom he feels like licensing and refuse licenses to others. In all of this no one has the right to complain; not even the Government which granted the patent.

BUT the Government charges that in some instances, as in the so-called "Radio Trust," these patent rights are used in such a way as practically to control the particular art and to eliminate competition, thus monopolizing the business of a particular industry. That this can be done is true, and no doubt patents can be and are used unjustly to intimidate competitors and to drive them out of business. Naturally, the Government cannot and does not complain that the owners of patents have granted licenses and cross-licenses to each other, because that is within their right.

Whether a corporation owns one patent or a hundred, or whether it be licensed under one patent or a hundred is immaterial, because each patent must stand or fall absolutely independently of all other patents, and the monopoly created by a patent is not expanded in the slightest degree by the fact that numerous patents are combined. It is true that a number of patents may afford a more extended protection to a given manufacture than would a single patent; but no one can complain of that. It is another thing, however, to say that an agreement between licensees and owners of patents that they will never license any others than themselves, is within their patent rights. That is the thing to which the Government objects; such agreements are not justified by the patent grant and are clearly in violation of our laws aimed to prevent monopolies and restraints of trade.

Again, patents may be and are used to intimidate independent manufacturers by unjustified charges of infringement and threats of litigation made not only to the manufacturer of the device alleged to infringe, but to the trade, and as the user or retailer is liable for infringement as well as the manufacturer, it follows in many cases that as an alternative to expensive litigation the manufacturer ceases the manufacture of the device alleged to infringe and the retailer not only refuses to buy them for resale, but oftentimes returns to the manufacturer those which he has already bought.

It would be entirely proper for Congress by some appropriate legislation to penalize those who make an improper use of patents in this manner, even to the extent of providing that they shall be deprived of all relief in a suit instituted by them charging infringement, should such a misuse of their patents be pleaded and proved against them. Indeed, without the proposed legislation, courts of equity have frequently denied all relief to the owner of a patent who has maliciously sought to destroy the business of his competitor, by circulating among the trade warning notices of infringement prior to an adjudication of the question of the suit. This, on the ground that the owner of such a patent comes into court with unclean hands and is not entitled to ask a court of equity for any relief.

The criticism, however, that patents do not protect inventors and patentees, and the suggestion that the Government should in some manner enforce the patents which it issues, is without any foundation whatsoever. It has been stated that no patent is of any validity until it has been through the courts, and that when one gets a patent all he gets is the right to a law suit. In just what manner the critics would have the Government proceed is not suggested.

IT is clear to anyone, however, that a valid patent is a protection to the patentee or owner of a patent, and that the Government does in fact protect him in his rights secured by a patent. The courts are always open to him, and it must be known to everyone that the courts constitute a branch of our Government.

The courts, it is true, will only extend their protecting arm to those patents which they find to be good and valid; but this is true of all contracts. No contract is self-executing. When you enter into a contract all you have is a promise in writing, which, if evaded and avoided and disregarded you must go to the courts for enforcement; and like a patent, such contract will only be enforced if the terms thereof are clearly stated and it is not invalid. A patent is no different in this respect from a deed for a piece of real estate; in fact much land in the west is held under patents issued by the Government. You cannot eject a trespasser from your property by simply waving before his eyes your deed and you cannot complain to a policeman to put him off of what you say is your property, because the policeman does not know whether it is your property or not. He may rightly differ with you as to whether or not he is a trespasser, or whether or not your patent is a valid patent. So that in all cases of contracts, patents, deeds, and agreements of any nature, you must seek the assistance of the courts to enforce them.

On the other hand, unadjudicated patents in many cases have proved of great value and been the source of much profit to the owners. In fact, there are instances where an inventor has sold his invention and the right to a patent even before the patent has been applied for or issued, and there are also many instances where an alleged infringer has recognized not only the validity of the patent but the fact that he has actually infringed the patent, and has ceased his infringing acts, or, by treaty with the owner of the patent, secured the right to continue the use of the patented invention. The owners of patents do not always have to go into court to obtain recognition of their patent rights and to receive the benefits to which they may be entitled.

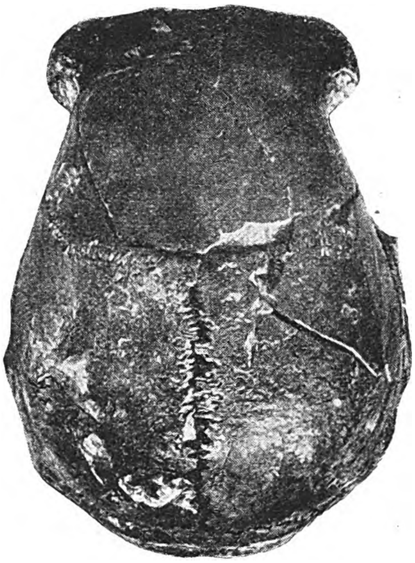
NO inventor, and no patent owner, should permit the present agitation, and the unjust criticisms of our patent system to deter them from creating new inventions and seeking patents therefor, nor should they be disappointed if the thing for which they have obtained a patent should not prove as valuable and useful as they anticipated. The Government is obliged to grant patents for new and useful inventions, but, obviously, there is no place in the arts for many of these patented inventions, either because they are impractical, or because there are things in existence for doing the same work, equally as efficient and economical, or because there is not sufficient capital available for commercial exploitation; under such circumstances no patentee should expect to profit by his invention. On the other hand, many cases can be cited where the inventors of simple things for which they have sought and procured patent protection have been amply rewarded and to an extent they never anticipated. It is true today, as it has been in the past, that the inventor or patentee of anything which materially benefits a given art or industry will not only receive the protection of the Government in so far as his patent rights are concerned, but also that reward, financial and otherwise, which the scope and value of his invention justifies.

More About the Peking Man*

By PROFESSOR G. ELLIOT SMITH, F.R.S.

Professor of Anatomy in the University of London
Author of "The Evolution of Man," and "Human History"

THE revelation of the nature of the brain-case in Early Pleistocene man displayed in the wonderful photographs reproduced in these pages affords ample corroboration of the claim made in *The Illustrated London News*† that the discoveries in China provide "a new basis for the study of human evolution." These photographs were made in Peking immediately after Professor Davidson Black had successfully accomplished his long and exacting task of clearing away the hard matrix of travertine in which the base and left side of the skull were embedded when it was found on December 2, 1929, by Mr. W. C. Pei.



The top of the skull of Peking Man, or *Sinanthropus pekinensis*

Now that the stony matrix has been removed from the surface—the cranial cavity is still occupied by a solid mass of travertine—there is revealed the most complete example of an Early Pleistocene skull so far discovered. It is a very impressive and illuminating specimen, not merely for the intrinsic evidence it provides, but also for the light the new data shed upon the other remains of early man. It is the skull of a young adult or adolescent. Mr. Davidson Black suggests the possibility that it is female.

For the elucidation of its distinctive characters I have made two series of drawings in which the left profiles and the views from behind of the only three Early Pleistocene skulls so far known are shown superimposed upon one another. These drawings reveal the individuality of the new genus from China. While it has the prominent eyebrow-ridges of *Pithecanthropus* (which are lacking in the Piltdown skull), the brain-case is much fuller than the Java skull, especially in the frontal region, which approximates to the condition found in Piltdown man. But the latter is much better developed in the parietal and occipital regions than either of the Far Eastern skulls. The most striking contrast between the cranial forms of *Pithecanthropus* and *Sinanthropus* is revealed in the view from behind, in which the greater height and development of parietal eminences in the Chinese skull definitely differentiates it and justifies its generic distinction.

Sinanthropus Turns Out to be the Most Impressive and Significant Discovery in the Whole History of Human Paleontology

When Sir Arthur Smith-Woodward made his reconstruction of the Piltdown skull from the broken fragments found in 1912, he was vigorously criticised for making a model wider at the base (see the temporal bosses) than in the parietal region. The Peking skull reveals these peculiarities in a more extreme form. As it is an actual skull, and not a reconstruction, it provides welcome corroboration of the reliability of the reconstructed Piltdown skull. The outlines of the profile and posterior aspects of the Piltdown skull in the diagrams are taken from Figures 17 and 19 of my "Evolution of Man" (1927).

In his manuscript notes accompanying the photographs Professor Davidson Black claims that such a form (as is revealed in the posterior view of the Peking skull) is unknown in any other human skull. My drawings demonstrate the same peculiarity in the Piltdown skull. The collective testimony of these three fossils provides an impressive idea of the likenesses (as well as the generic differences) of these Lower Pleistocene men, and suggests the common denominator of the earliest man. The peculiarities already mentioned in the temporal part of the skulls (note, in particular, the temporal bosses in all three) do not exhaust its interest. The form of the mastoid processes (which seem not to have been fully extruded—as they are in other men—from the cranial wall) and the massive ring of rough bone (tympanic) surrounding the ear-hole, differ profoundly from the corresponding parts of all other human skulls. The peculiar modeling of the tympanic bone displays a startling resemblance to the condition found in the gorilla and chimpanzee. The mastoid and tympanic structures have distinctive characters in Piltdown Man, Rhodesian Man, and Neandertal Man, but none of these is so emphatically simian in type as the Peking skull.

WITH the photographs of the skull there has also come Volume VIII of the "Bulletin of the Geological Society of China," containing three important memoirs which throw a clearer light upon the history of the discovery of *Sinanthropus* and the geological and paleontological evidence for the antiquity of the human fossils and the animals associated with them. The Chinese geologist, Mr. W. C. Pei, gives an account of his discovery of what is probably the most important, and certainly the most illuminating, fragment of early man ever found. Father Teilhard de Chardin and Dr. C. C. Young have provided a preliminary report on the fossiliferous deposits at Chou Kou Tien, which not only establishes the fact that all the

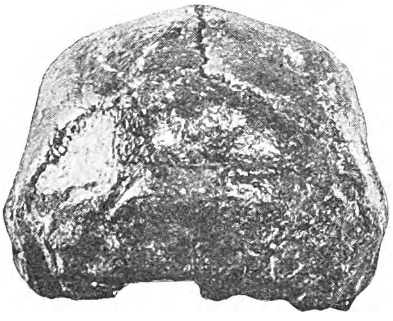
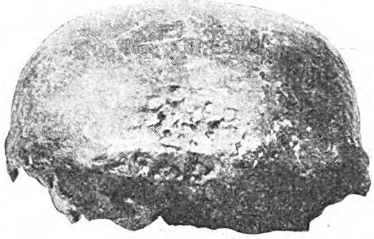
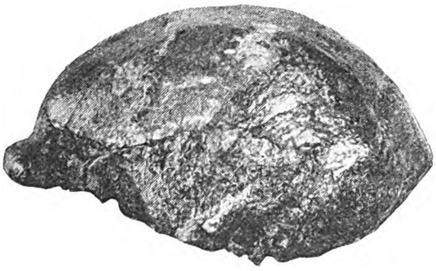
Base of the skull of *Sinanthropus* (the round central object is recent)



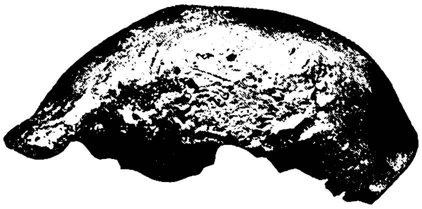
***Sinanthropus*, rear. The parietal eminences mentioned in the text are indicated in the drawing above**



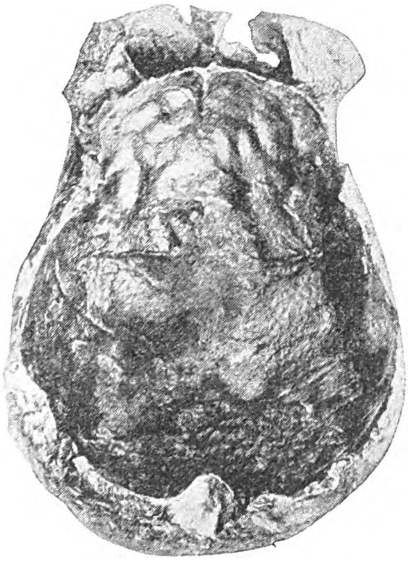
***Pithecanthropus*, rear. For position of "temporal boss" see the drawing**



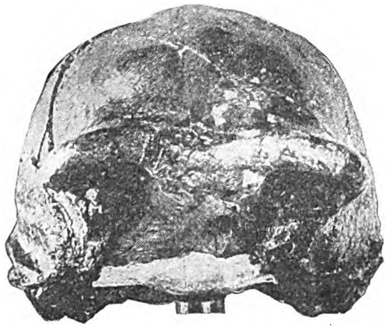
***Sinanthropus*, profile. It has a fuller brain case than *Pithecanthropus* (which is shown at right)**



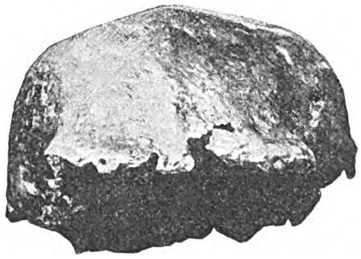
***Pithecanthropus*, profile. *Sinanthropus* (at left) has the same or more prominent eyebrow ridges**



Base of the skull of *Pithecanthropus*—smaller than *Sinanthropus*

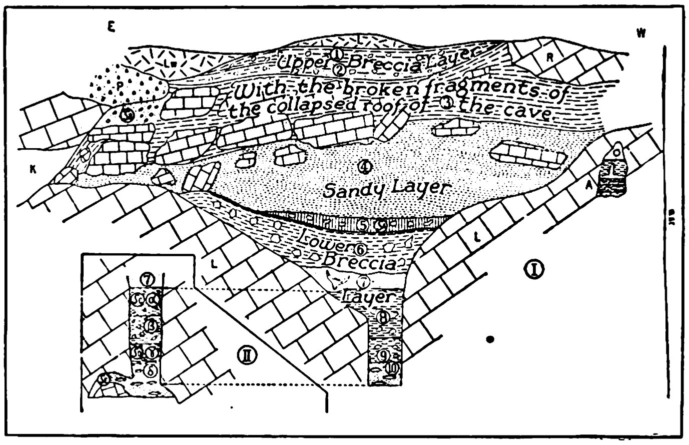


Sinanthropus*, front. Happily the eyebrow ridges are not even partially lost, as in *Pithecanthropus



Pithecanthropus*, front. *Sinanthropus* has the same frontal expansion as has *Pithecanthropus

remains are later than the Pliocene and earlier than the Loess—in other words, they are Lower Pleistocene—but also hints at the possibility that in the lower layers of the formation (the highly fossiliferous beds of Nihowon) they may find "some immediate ancestor of *Sinanthropus*." Professor Davidson Black has described (with many excellent photographs) the process of liberating the skull from its matrix.



Where "the most illuminating fragment of early man ever found" was discovered—at point marked "SE" (extreme lower left-hand corner). The jaw and skull fragments found a year earlier were at "SB," (top, left)

The evidence provided in these three memoirs makes it possible for us in Europe for the first time to visualise the circumstances of this epoch-making discovery. These facts are essential for the understanding of the significance of the new light on our remote ancestry. For several decades European paleontologists have been exploiting the druggists' shops of China for fossils — "dragon's bones" being an important item in the pharmacopœia of the Far East. But it was not until 1919 that a subsidiary bone deposit near Chou Kou Tien was visited by Dr. J. G. Anderson on behalf of the Geological Survey of China. Two years later (1921) he discovered the important main deposit and began excavating it. But its exceptional scientific importance was not realised, even when in 1926, Dr. O. Zdansky found two human teeth among the fossils that had been collected. The Rockefeller Foundation then gave a grant of money to help the Geological Survey of China and the Department of Anatomy of the Peking Union Medical College conjointly to carry on excavation for two years.

IN October 1927, Dr. Birger Bohlin found *in situ* in the Early Pleistocene beds a human tooth, on the evidence of which Professor Davidson Black and Dr. O. Zdansky created the new genus and species *Sinanthropus pekinensis*.

Dr. Zdansky was still sceptical of the justification for the creation of a new genus and species, and the credit of insisting upon the necessity for such action must be attributed to the insight and courage of Dr. Davidson Black, who naturally associated Dr. Zdansky's name with the discovery in view of the circumstances under which the two teeth were rescued in 1922 and described by him in 1926.

A year later (November 1928), Mr. W. C. Pei, working with Drs. Birger Bohlin and C. C. Young, found much additional material, including parts of two lower jaws and numerous skull-fragments of *Sinanthropus*. This induced the Rockefeller Foundation to make an additional grant for the work, and a special department (Cenozoic Research Laboratory) was set up by the Geological Survey of China and put under the honorary directorship of Professor Davidson Black.

The hope implied in the granting of this new appropriation was immediately realised by the most impressive and significant discovery in the whole history of human paleontology. Mr. Pei resumed work in May 1929, and in June and July found a number of human teeth. The summer rains then stopped work for seven weeks, so that it was not until September 26 that excavation could be resumed. Another collection of *Sinanthropus* teeth was then found.

At the end of November, when the weather was becoming bitterly cold, Mr. Pei was so "curious to know what were the lower layers of the deposit" that he prolonged the work for two more days. He found two caves, in one of which, at 4 o'clock on December 2, he found, "partly embedded in loose sand and partly in a hard matrix," the almost complete skull of *Sinanthropus*. He sent special messengers to inform Drs. W. H. Wong and C. C. Young, and telegraphed to Dr. Davidson Black.

THE circumstances under which the remains of *Sinanthropus* were found are totally different from those of *Pithecanthropus* and *Eoanthropus*. The latter were both scattered and deposited in gravels by running water. The Peking Man lived in caves, and left his remains there. According to Father Teilhard de Chardin and Dr. Young, it is probable that not only the rodents, hyenas, bears, and other carnivora roamed the site, but also *Sinanthropus* himself may once have sheltered within the Chou Kou Tien cave. Vast quantities of fossil bones have been found. The most interesting types, apart from *Sinanthropus*, are the big beaver (*Trogontherium*), the primitive water-buffalo (*Bubalus*), and the strange deer (*Euryceros*), whose extremely thickened jaws and facial bones and short, flattened antlers are perhaps the most characteristic of the fossils found at Chou Kou Tien. *Machairodus* is exceedingly rare.

The fossils are scattered in the layers filling the cave from top to bottom, and all belong to the same geological age. While a few of the bones may have been introduced into the deposit by a brief flood action (*Bubalus*, for example), most of the material was clearly left (or brought in) by animals living in the cave. The fossiliferous material was set by a slow process of weathering under humid conditions (water infiltrations and occasional brief flooding), but without any torrential action. Although a stream flowed near the cave, there are no true river-deposits. The characters of the breccia and of the fossilised bones indicate that the site was not an underground, water-drained fissure, but an ancient, gradually filled, open-air cave.

SUCH was the home of *Sinanthropus*. The conditions arouse more reasonable hopes than can be entertained in the cases of *Eoanthropus* and *Pithecanthropus*, not only of finding other parts of the skeleton, but also the objects used by Peking Man. It is surprising that no implements have yet been found in the cave. Mr. Pei recovered an angular piece of quartz—a type of stone not found naturally—within a mile of the cave. Similar quartz-fragments have been found from time to time during the course of the excavations, but in none of them has any recognizable trace of artificial breaking been found. It is inconceivable that any creature which had attained human rank could have failed to make some sort of tools of stone. Yet Peking Man occupied this cave for a long time, and does not seem to have left with his bones anything beyond some unworked quartz!

Alongside the skull of *Sinanthropus* was found the complete skull of a rhinoceros, with its lower jaw in position. Mr. Pei ends his reports with this passage, which excites the liveliest anticipations of what next summer may bring forth: "The layer below the one just described is exceedingly rich in fossils, which are so crowded together that but little matrix separates individual bones. Not only are the fossils rich in quantity, but their quality is extraordinarily good."

Arcs of Art

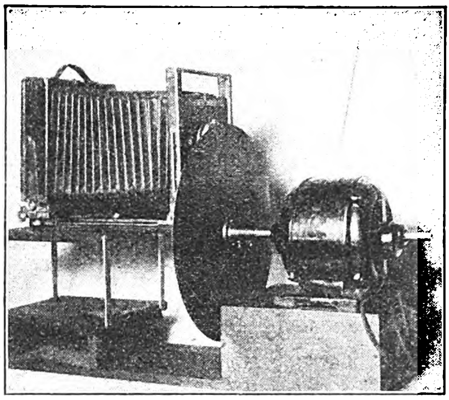
The Camera Analyzes the Electric Arc

By HENDLEY N. BLACKMON

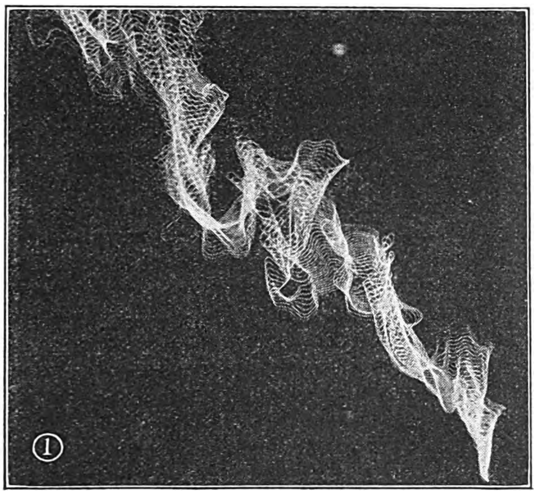
General Engineer, Westinghouse Electric and Manufacturing Company

SOME electric arcs form a most exquisite tracery—a weird gossamer picture of bright and dark bands of light emerging from a misty halo. These striated arcs are made by bringing one end of a 150,000-volt wire close enough to the other terminal for an arc to jump across. Once started, the arc hangs on until it is "stretched to death" when the terminals are pulled far apart.

In order to find out what happens at various points on the changing voltage wave, an electrically timed camera was used. This camera has a synchronous shutter consisting of a motor-driven disk with four radial slots, rotation of which times the camera to take pictures of the arc at any desired portion of the voltage wave. The pictures it makes show the physical characteristics of unleashed electricity and have helped scientists in solving the problem of the behavior of electric arcs.

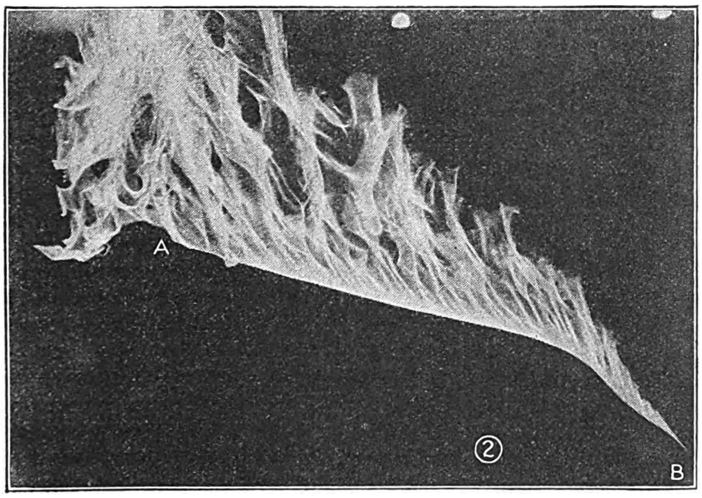


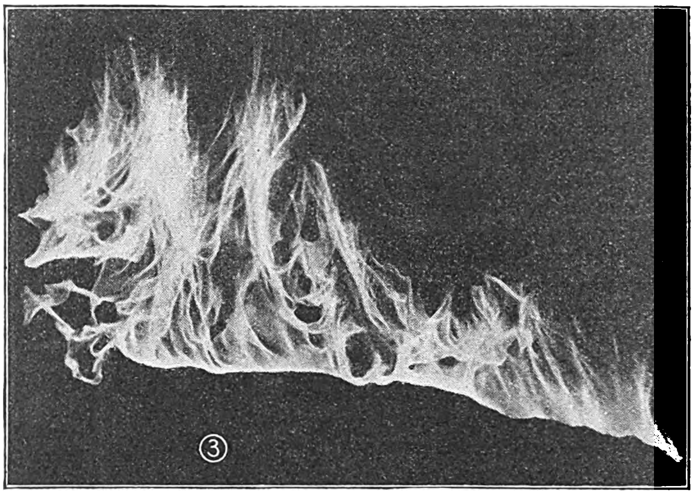
The arc-photographing camera with its motor-driven disk shutter

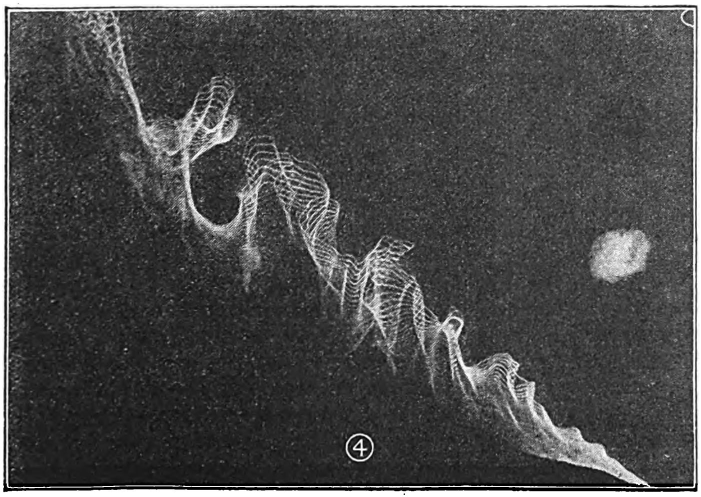


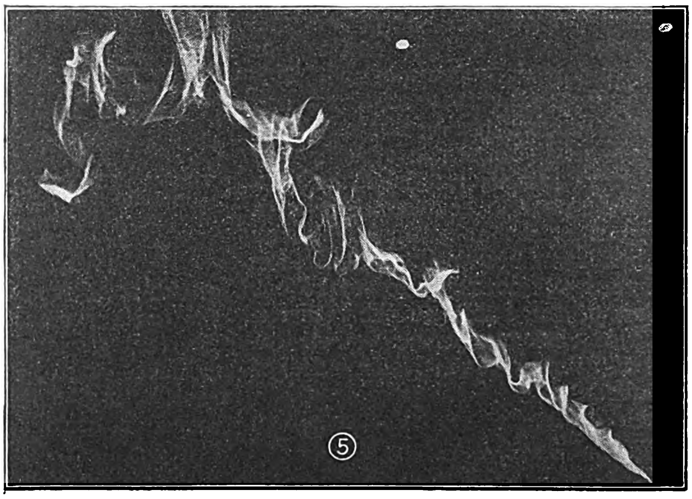
In the accompanying illustrations, Figure 1 shows how the halos are masked out by the synchronous shutter. Figure 2 shows what happens in the life of the arc: the arc began at "A" when the electrodes were 1½ feet apart, and was stretched 8 feet so that it finally went out at "B." The arc trailed off like a comet because at the left the electrodes were close together and more power was produced. As the arc was drawn out, the heated air carried the flame upward, the flame decreasing as the air gap was widened.

Figure 3 shows the sort of picture obtained by not opening the camera shutter until the arc has been drawn out quite a distance. Figure 4 was taken under the same physical conditions as Figure 1, but the halo is not masked out entirely; note the halo at the bottom and the sharply defined layers at the top of the arc. Figure 5 is a snaky specimen of the striated arc.









The Pattern of Evolution

By W. D. MATTHEW, Ph. D.

Professor of Paleontology, Chairman of the Department of Paleontology, and Director of the Museum at the University of California

A Criticism of Doctor Austin Clark's Thesis†

A GREAT many people are talking about evolution nowadays. Most of them do not know much about it and, generally speaking, the less they know about it the more it horrifies them. The theory of evolution, when you come to know it well, is not only of marvelous and inexhaustible beauty, but is an inspiration to a higher type of idealistic living than any orthodox religion.

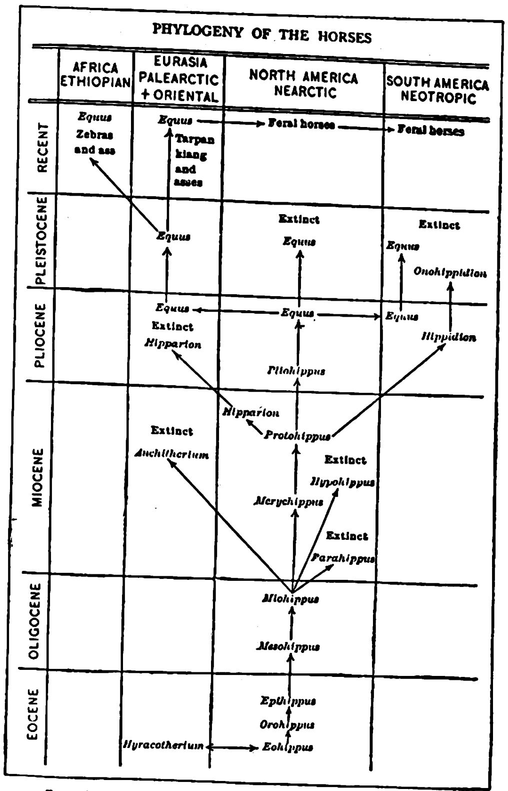
Doctor Clark, as a distinguished biologist and a specialist in certain groups of modern invertebrate animals, is very distinctly one who does know what he is talking about, and his views and conclusions about evolution are entitled to very careful and respectful consideration. If in the following pages I find it necessary to criticize and modify his statements of evidential fact, it should be understood that it is because they lie for the most part in a field that is my specialty but not his, the field of paleontology, and especially of vertebrate paleontology. In a scientific discussion the facts and the immediate interpretations that may legitimately be placed upon them are usually matters that must rest largely upon the authority of specialists. The soundness and validity of the conclusions drawn from these facts are matters of logic on which any reasonable man can and should judge for himself.

IN attempting to explain the principle of evolution (for it is a principle, not a theory, to the paleontologist) as it has actually worked out in the past history of life, certain aspects and effective illustrations have necessarily been selected from the record. These have been popularized and stated in some detail, while other parts of the evidence, often equally convincing but less readily explainable or of less general interest, have been omitted or briefly and casually summarized. This other evidence is quite necessary to any complete understanding of the nature of the record, but much of it is very difficult to get at, published only in technical papers scattered through numerous scientific journals. Much of it has never been printed at all; the specimens and records are stored out of view of the public in the research rooms of various museums, their existence known to the merest handful of specialists.

Such evidence, not yet assembled nor made available to the general student, yet serves to color the thought of specialists and control their interpretation of the better known data. Its existence, and, I may add, its controlling importance in the interpretation of our problems, is the reason why, in the free democracy of science, we may grant "authority" to individuals in their special line of research.

I do not agree with Doctor Clark's conclusions in this essay, because I think he has not fully understood the paleontological evidence, nor the geological and geographical background against which it must be viewed for correct interpretation. But he has quite properly pointed out certain neglected aspects of the evidence which make it less convincing as commonly presented than it really is when fully known.

These lie in two fields. First, that of the fossil record of the evolution of the various races of mammals in the Tertiary period—my own particular subject—and of the different orders of reptiles and classes of vertebrates in preceding periods. Second, the broader problem of the relationship and origin of the great phyla or branches of animal life, of which the vertebrates are one.



In the evolution of the horse there were several branch lines, none of which has survived, as shown in the cut

As concerns the first, I am obliged to take exception to his presentation of the evidence, as incomplete and in this connection misleading, and to his interpretation of it as failing to take into account the geologic and geographic background which controls its significance. He gives a brief and fairly correct summary of the record of the evolution of the horse, tracing it from the little four-toed *Eohippus*. But he does not mention that such diverse animals as the rhinoceros and the tapir are likewise traceable to small four-toed ancestors contemporary with the Eocene four-toed horses, and so like them that the most expert specialists have not always been able to distinguish the one group from the others.

Moreover, he speaks of the equid series as though it were a single line, and has elsewhere spoken of it as "an example of linear evolution." But it is not; there were several branch lines more or less clearly defined, running into parallel or partly diverse adaptations, none of which has survived to the present day. And in each stage of the main line of evolution of the modern horses there were several species, some more, some less in the direct line of descent. The record has, in fact, the familiar form of the phylogenetic tree, continually dividing up into branches and twigs of more or less importance, and the series customarily presented is merely the direct line leading up to the modern horse. From the same common ancestral stock are derived other lines of specialization, each one similarly branched, and two of them surviving today in the rhinoceroses and tapirs.

MOREOVER, the actual record of fossil perissodactyls [hoofed animals with odd number of toes. —ED.] as known to us to-day is obviously a very incomplete one if we view it in the light of geology and geography. The living members of the horse family consist of a number of related species—wild horses in Asia, wild asses in Asia and north Africa, zebras in Africa—scattered over considerable parts of the earth's surface, different species in different regions. The rhinoceroses are similarly distributed in southern Asia and Africa the tapirs in Malaysia, and Central and South America. Each family had a much wider distribution at the end of the Tertiary period, and during the Tertiary they were widespread, numerous, and varied through all the northern continents, the living members of the group being a few widely scattered, specialized survivors of a disappearing group, all probably on their way to extinction.

---

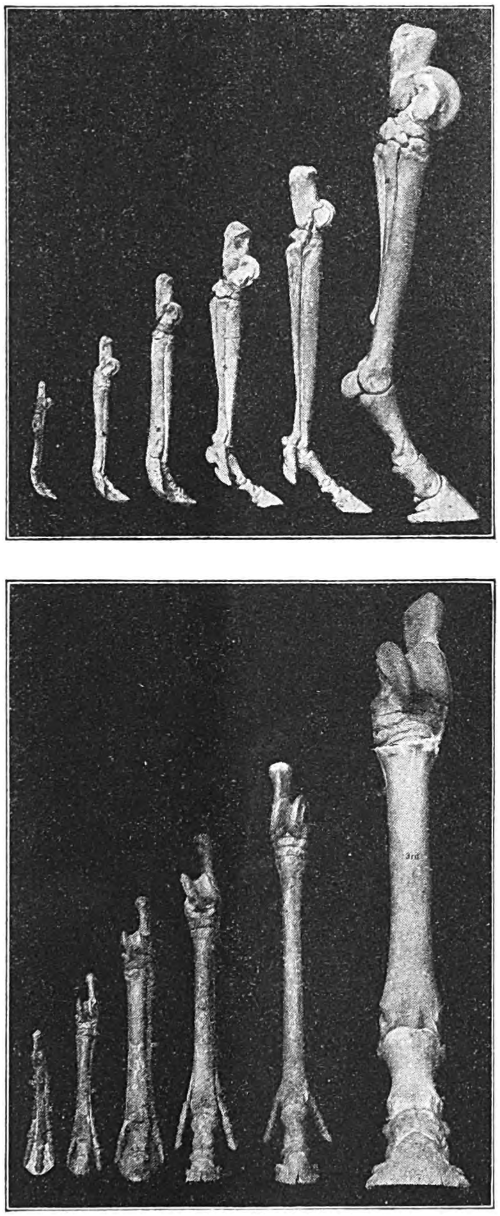
†SCIENTIFIC AMERICAN, August, 1930, Page 104

At each successive stage in their evolution, at each epoch of the Tertiary, there must have been numerous different species of "horses," as also of rhinoceroses and tapirs, living in various parts of the northern continents (Europe, Asia, and North America), some ranging over considerable parts of the continent, some confined to restricted areas, slowly shifting their range, becoming more abundant and widespread or less so, as similar animals do to-day.

OUR fossil record, though derived from many places, represents only the animals from small localities, scattered here and there over the continental regions, most of it from a few areas in the middle-western United States and certain parts of western Europe. Out of the dozens or hundreds of species of the family that were living in different parts of "Holarctica" (the aforesaid northern continents) at any one epoch or stage in the evolutionary history, we actually know only a few, and of these one appears to be more directly intermediate than others between the earlier and later stages. It is the closest known approximation to the direct line of evolution.

Our record, then, while it gives a correct picture in a broad way of the evolution of the race as a whole, reduces to a series of approximations more or less close to the detailed and exact phylogeny of any one line of descent. This is the explanation of the "gaps" of which Doctor Clark speaks, and which he thinks, as many other biologists have thought, must be due to some sudden great or considerable change in structure of the same nature as the "sports" with which Darwin and all breeders of plant or animal races were familiar in the last century, and which, under the name of mutations, have been so thoroughly and profitably studied by the geneticists of this century.

But it is not probable, in view of the nature of our fossil record, as outlined above, that the gaps in our evolutionary sequences are many, if any, of this nature. For they are very directly proportioned in numbers and in width to the scantiness and inadequacy of our record. Where the records are most abundant, and especially where we have reason on various grounds to believe that they come from points in or near the center of evolution and dispersal of the race, the habitat of the most progressive species, there these gaps almost or entirely disappear. In general it may be said that the more complete our record of any race the nearer it comes to being continuous, or separated by gaps which, although definite, are not beyond the limits of ordinary individual variation in a species.



Courtesy American Museum of Natural History

Side and front views of the evolution of hind feet of the horse. The smallest is *Eohippus*, then come *Mesohippus, Miohippus, Merychippus, Hipperion*, and *Equus*, the modern horse

The nature of these variations is much better understood than it was in Darwin's time, thanks especially to the researches of T. H. Morgan and his school. Some of them are inherited according to certain definite laws. They are "mutations" of the same nature as the larger, more conspicuous and more occasional mutations which the geneticists have studied in detail. Others are the non-heritable differences between individuals, due to slight or considerable differences in their environment and growth history.

Now it is to be observed that almost any major or conspicuous departure from the normal in an individual would have little or no chance of giving rise to a permanent change in the race. In almost all cases it would be immediately fatal or seriously detrimental to its chances for survival. For each animal is closely adjusted in habits and environment to a particular adaptation, a particular mode of life. With any important single change in its structure it would cease to be an efficient working mechanism. With any conspicuous change in appearance it would become a stranger to its fellows and as unpopular with them as strangers usually are. And even if it succeeded in leaving a few descendants, the chances that these would possess any superiority to their numerous normal competitors would be infinitesimal. Practically all cases in all combinations with the normal would result in an inferior mechanism, sooner or later to be eliminated by natural selection.

WITH the minute heritable differences these disadvantages would not exist. We are familiar with them in our own species and with all animal and plant races.[1] And moreover, the various correlated small differences in other parts of the organism necessary to make an efficient working mechanism can be and are adjusted by individual growth. This is a temporary adjustment, repeated generation after generation until it can be replaced by the appearance of the necessary inherited variations, thenceforward a permanent though small step forward in the evolution of the race.

We must think of each species as it is in nature, each race as it always has been in nature, as a complex of interbreeding strains, each having certain slight differences in inherited characters, intercrossing over and over again until some profitable combination of variations occurs, to be preserved, increased, and finally made universal by natural selection, and disadvantageous characters and combinations eliminated in the same manner. It is a process of almost inconceivable slowness. To change one species of horse into another seems to have required something like half a million or a million years—two or three hundred thousand generations. No appreciable change would occur in a few thousand years; but in the larger view of the geologic time scale it is seen to be cumulative, resulting in a slow progressive change in adaptation to equally slow changes in climate and environment.

---

[1] Men slightly taller than the normal are common, and are apt to excel in many lines of athletics. Seven- or eight-foot giants are rare, and are always more or less crippled and handicapped by their abnormal height, its lack of adjustment to other proportions and to the world they live in. They seldom live to old age and find employment difficult except in the circus. So with any wide and conspicuous variation from the normal. It is of relatively rare occurrence, and *it is a handicap, not an aid to survival.*

Large changes, conspicuous mutations, can play little or no part in this slow process. A three-toed sport from a four-toed horse would be a cripple. He would not have the numerous correlated adaptations necessary to make of him a good working mechanism, all of which are present in the three-toed horses. No sport that I have ever seen or heard of is at all analogous to such a great series of differences as those that separate the four-toed from the three-toed horses. Very few of the sports and conspicuous mutations would have any chance of survival in competition with the normal members of their race. Still fewer would be those that would be at all likely to give rise to new races. Yet there are a few isolated and exceptional instances among modern animals where certain peculiarities can best be explained as due to such heritable variations of considerable amount. It is the rare exception, and there is no reason to suppose that it played any part in the recorded evolution of the horse.

THE entire history of the perissodactyl order resolves itself then into a branching out from a common ancestry very nearly represented by the *Eohippus* into such diverse specialized types as the horse, the tapir, and the rhinoceros, with various other specialized races that have not survived; and each branch in turn has its minor branches and twigs of which in the horse only one has survived and has itself begun to branch out into horses, asses, zebras, and so on. The record is fragmentary, but no other reasonable interpretation can be placed upon it than to see it as a slow, gradual change quite analogous to the growth and branching of a tree, and like it conditioned in direction, amount, and character of growth, by the circumstances and advantages of the environment, and by the continuity of life. And this is the general pattern of evolution, which we see illustrated in every race of animals and plants whenever our record is adequate to show its real character. The more complete the record, the more precisely it conforms to the pattern.

After a "bone-digger" has studied and compared all the known material, fossil and recent, old and new, in a group of animals, and found them all to fit into this pattern; after he has gone into the field and secured new fossils from new formations and previously unknown stages, and found them also fitting into the pattern and filling some of its gaps; when he has repeated the operation on group after group, and learned from reading and conversation that it is identical with the pattern determined by his confrères in various other fields of paleontological research; that it has stood the test of a century of criticism as to its theoretical as well as practical soundness—he gets to feel that the phylogenetic tree as the true pattern of the history and evolution of life is a pretty fundamental and certain matter, that it has taken this form because, short of miracles, it could take no other. In so far as the record goes it definitely does take this form. Where the record is absent, we should assume the same pattern unless there is convincing evidence for a different interpretation of existing life.

Doctor Clark states, however, that this is not the case with other groups whose fossil record is at least partially known, and instances the cats and dogs as an example. Cats were cats and dogs were dogs, he tells us, and as far back as their history can be traced there is no approach between them. I do not know where he got this information, but it is quite incorrect.

Let us look for a moment at the facts. Cats are among the most highly specialized of the Carnivora in the reduction and special adaptation of the teeth, but are very generalized and much like the older extinct and more primitive living Carnivora in the limbs and feet. Dogs, on the other hand, have retained a comparatively primitive dentition, but have specialized considerably in the limbs and feet for swift running. Both have a high type of brain among the Carnivora, and a variety of minor special characters are found in one or both.

Now we can trace back the cats and dogs through a fairly complete series of stages to the Oligocene epoch of the Tertiary, and the dog ancestry is a pretty close series beyond that to the beginning of the Eocene, but little is known of the earlier ancestry of the cats. The Oligocene dogs are but little different in the teeth from their modern descendants, but the limbs have much more nearly the cat proportions, the feet have five toes, like cats, and the claws are partially retractile. The Oligocene cats on the other hand are much like modern cats in limbs and feet, but have more numerous and less specialized teeth.

When first found, these Oligocene ancestors were not recognized as cats and dogs, as the names of the earliest discoveries testify. *Cynodictis* (i.e., dog-toothed weasel), *Daphœnus* (devourer, i.e., glutton or wolverene) are now recognized as ancestors of the dogs, *Aelurogale* (i.e., cat-marten) and *Dinictis* (i.e., terrible weasel) as ancestors of the cats; but these relationships were not at all clear to the experts who first described them. Not until the intermediate series were discovered could the real affinities be demonstrated.

IT appears, therefore, that Doctor Clark is wholly mistaken in supposing that cats and dogs make no approach as we trace their ancestry back. They are already distinct in the Oligocene, but most of the wide differences that separate them today have not yet appeared. Could we trace the cats back through the Eocene, we should presumably find them gradually merging into a common ancestry with the dogs, which we can so trace, and whose Eocene ancestry is merged in exactly this fashion with that of mustelids (otters, minks, skunks, and so on) and bears and raccoons and civets. It is identically the same pattern as we have seen in the horses, tapirs and rhinoceroses, and goes step by step along with it in time. (See cut.)

I fully agree with Doctor Clark—and with Darwin—that the selection and differentiation of the various domesticated breeds of animals affords the most important illustration of how natural selection has operated. But I can not at all agree with his statement that there are no intermediates between the principal breeds of dogs as he cites them, nor with his implication that they all appeared suddenly in their modern stage of specialization. Any dog-fancier or student of the history of the breeds of dogs could set him right on that better than I can, but I am sure from what I have read that the different breeds, while originating in part as sports, have been largely developed and modified through centuries of selection and inter-crossing. The whole subject of variation under domestication has been very thoroughly treated by Darwin and others, and its relationship to natural selection is largely affected by the fact that most of the breeds as at present developed, while useful to man for certain purposes, would have but little chance for survival in nature. Some of them are probably based upon wild species, and would doubtless revert to type in time if they ran wild; but there is no reason to suppose that these wild species were evolved in any but the normal manner.

How the mammals deployed during the Tertiary period. Despite the indicated gaps a careful study of the subject will point to a common ancestor of all the mammals. Note under "Carnivora" (at the top of the cut, just to the right of the center) the dog-cat ancestry mentioned by the author

Concerning the evolution of man, Doctor Clark does not say much, but again I must take exception to some of his statements. He emphasizes the distinctness between man and the great apes "in every bone of the skeleton," and assures us that "the differences seem too great to have ever been bridged by intermediate types," and that "of all the fossils that have been found not a single one represents indubitably a missing link."

I do not know how far he is acquainted with the demonstration made by Huxley and confirmed by many subsequent writers, that the anatomical gap between man and the anthropoids is less than between these and the monkeys, less than between monkeys and lemurs, and that the differences are very largely superficial adaptations. But if by a missing link he means any intermediate stage or stages, I can not see how he would explain away the characters of the Neandertal man, which differs from modern man in a dozen or more obvious distinctive characters of teeth, skull, jaws, and skeleton, every one of them except his "taurodonty" constituting a definite approach to the anthropoid apes. Or the characters of the recently discovered Peking man and of the Piltdown man, both early Pleistocene, older than the Neandertal man, and making a further approach in most, although not all, characters to the anthropoids—the Peking man having more human teeth but a very ape-like jaw, the Piltdown man so apelike both in teeth and jaw that some authorities have insisted that the jaw could not have belonged with the skull, which is still dominantly human. Or of the Taungs skull from South Africa, related to the chimpanzee, but making an unmistakably nearer approach towards the human type. Or the classic *Pithecanthropus* of Java, which has a skull-cap and brain construction about half-way between ape and man.

If these are not intermediate stages, what are they? If Doctor Clark means that they are not "missing links" because they are no longer missing, I quite agree, and only wish that more could be discovered, and that all of them were as fully known as the Neandertal man is today, thanks to Marcellin Boule.

Again Doctor Clark makes a great deal of family life and the dependence of women, of articulate speech and the use of tools and fire, as fundamental distinctions between man and all other animals. But there is a pretty wide difference between man and man in these and most other distinctions, physical or mental. It is not especially rare among primitive races of man, or civilized races under primitive conditions, for a woman to bear and rear offspring without the help of man; nor do I think it is wholly the custom among apes, as it certainly is not among various other animals. The great apes are not "promiscuous," nor indeed the monkeys, although they are not monogamous; and various degrees between polygamy and promiscuity are not particularly uncommon among the lower races of man. Is the difference between an animal that has a dozen or more sounds expressive of definite concepts or feelings and a savage who has at most a couple of hundred, so very much greater than between the latter and a man of science with a vocabulary that runs into the tens of thousands?

THESE are all matters of degree, as are all the distinctions seen by science between man and animals. If indeed Doctor Clark had declared for the presence of a soul, as do the orthodox, as the fundamental and impassable gulf between man and animals, I would have nothing to say. As a man of science I know nothing one way or the other about souls, and my religious convictions I do not think it necessary to express in the SCIENTIFIC AMERICAN. But so far as scientific evidence and the fossil record are concerned, it appears to me that it fits very clearly and convincingly into our pattern of evolution, and that the descent of man and the anthropoid apes from a common ancestry is far better proved than many things that we implicitly believe. There is, I am well aware, a divergence of opinion among eminent scientists as to how far back that common ancestry should be placed and just what relationship should be assigned to the apes.

Turning now to what Doctor Clark has called *eogenesis*, that is, the origin of the great branches or phyla of animal life, as he fully recognizes, the origin of these great branches must be carried back toward or beyond the beginnings of the geologic record, while our fossil record extends back only through the later half of that record. The rest is inference. If it were true, as he gives us to understand that it is, that each great branch appears in the Cambrian period as clearly distinct, as fully differentiated and specialized as it is today, then it would be a reasonable inference, although far from being necessarily or even probably true, that that degree of distinctness continued on back indefinitely. The alternate view would be that, having in the course of evolution attained the full degree of specialization that was of any net advantage to the organism, natural selection would cease to impel it any further and it would remain unchanged in the essentials of its machinery so long as it remained in the environment to which it was now completely adapted. If the environment changed, further changes might come about, not necessarily in the direction of progress. Otherwise it might well remain substantially unaltered from the Cambrian or a much earlier period, down to the present day.

I believe that that is pretty largely true of the lower groups of invertebrates, the groups with which Doctor Clark is especially familiar. Cambrian protozoa, Cambrian sponges and jellyfish, are much like their modern relatives, probably just about as much specialized *so far as the hard parts show.* The same is at least partly true of the echinoderms (star fishes, sea urchins, and so on). Whether it is true of worms nobody really knows. But when we get into the higher groups, the molluscs and arthropods (spiders, crabs, insects, and so on), and especially the vertebrates, it is very far from true. The Paleozoic era molluscs or arthropods do not have nearly the degree of diversity and specialization that can be found among the higher modern molluscs. The earliest insects have not taken on the important specializations that characterize the higher groups of the class; they compare only to the lower and more primitive groups. And the vertebrates, when they make their first appearance as ostracoderms in the Paleozoic era, have, as Stensio has shown, all of their essential organs in a more primitive stage of imperfect evolution as compared with even the most primitive of modern fishes, and are a long way behind the higher vertebrates in the perfection and specialization of their mechanism.

IT is quite true, then, that the great branches of animal life were already distinct in the Cambrian period, with the exception probably of the Vertebrata. It is by no means the case that they are as diverse from each other or as diversified within each group as they are today. On the contrary, the most advanced and specialized groups of the early Paleozoic era find their nearest relatives in the more primitive and generalized groups of today. Again taking our phylogenetic tree as an illustration, we may say that while most of the main boughs were already distinct when the tree was half-grown, and, while some of the twigs of different boughs today may be as near to each other as any in these branches were in the Cambrian period half-way stage of growth, yet the boughs as a whole have grown farther apart, are more fundamentally separate and distinct, as well as broader in scope. It is therefore altogether erroneous to conclude that the relationships between the branches have undergone no change at all since the Cambrian.

Our picture of the Cambrian tree of life is incomplete and sketchy, it is true. It is only the hard parts of these animals that are preserved to us (there are a few rare and partial exceptions), comparatively simple in structure in these lower types, and frequently of more or less doubtful position. They are identified chiefly through their likeness to corresponding hard parts of later and better known or surviving types. For the most part we do not know whether the far more important and complex soft parts were like those of modern forms. It is in this way that they are "at once recognized"—when they are—for the history of paleontology shows many decades of dispute over the real relationship of some of of the problematic fossils.

At all events, we can hardly question that the tree has grown enormously since the Cambrian, and in view of that fact I see no reason to adopt Doctor Clark's thesis that it came suddenly into existence at some moment in pre-Cambrian time. It is too much like the Indian juggler's mango tree trick, and, while the pre-Cambrian tree is hidden under a basket, under the cloak of our utter ignorance, I do not believe that such a miracle happened, or that its growth was otherwise than according to the natural processes seen in the subsequent record of the history of life.

Nevertheless there is, and will always remain, much obscurity as to the origin and early development of life on the earth, and a wide latitude for reasonable hypothesis as to its precise cause and course. I see no reason to adopt Clark's view that all the different branches originated at one time. Certainly the vertebrates must be excluded from any such hypothesis, for Stensio's studies have shown that the ostracoderms, although vertebrates, have the vertebrate organs and characters in a very rudimentary stage of development and make a very marked and significant approach to certain invertebrate groups.

IT is by no means clear that the other branches have a common origin. It is quite conceivable, and has been argued for half a century or more, that each branch may have evolved separately from inanimate matter at different times, passing through a similar but distinct one-celled stage, the identity of cell-structure in all modern animals being due to such fundamental laws of matter as make one quartz crystal like another in form and structure and composition and relationship of its component molecules. We pass here into the rarefied atmosphere of speculative hypothesis, far removed from the solid grounds of fact and record on which the paleontologist builds his lowly but tolerably permanent habitations.

And I confess that these higher flights, while interesting to watch, do not tempt me to emulation. My airminded friends may scale the heights of fancy as they will. Those of us whose temperament is more cautious and conservative will content ourselves with admiring their ingenuity and daring, and hope that they will not crash.

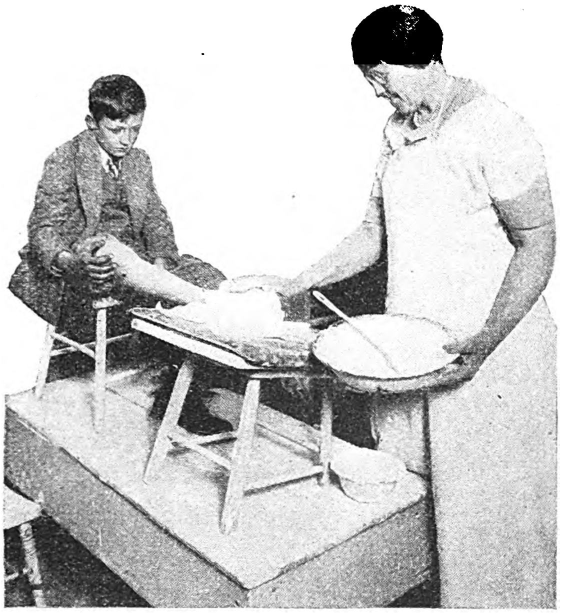
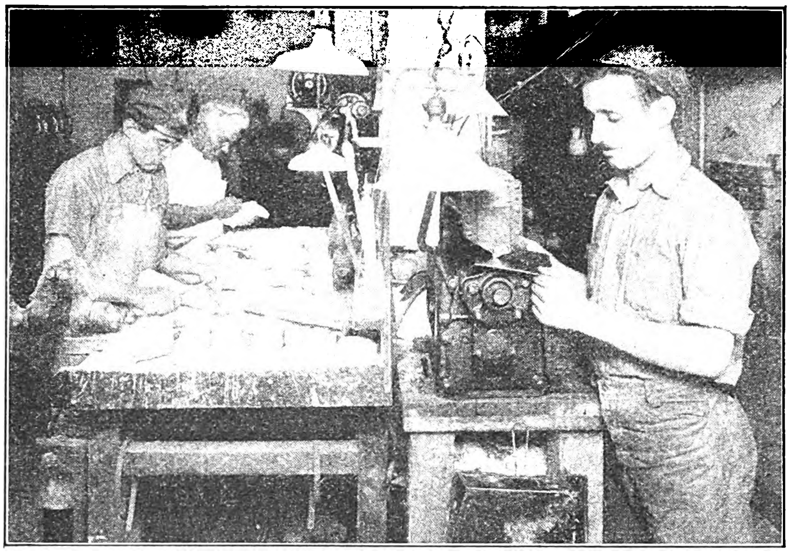
The phylogenetic tree, the true pattern of the history and evolution of life. The heavy horizontal line just below the center marks the "Cambrian period"

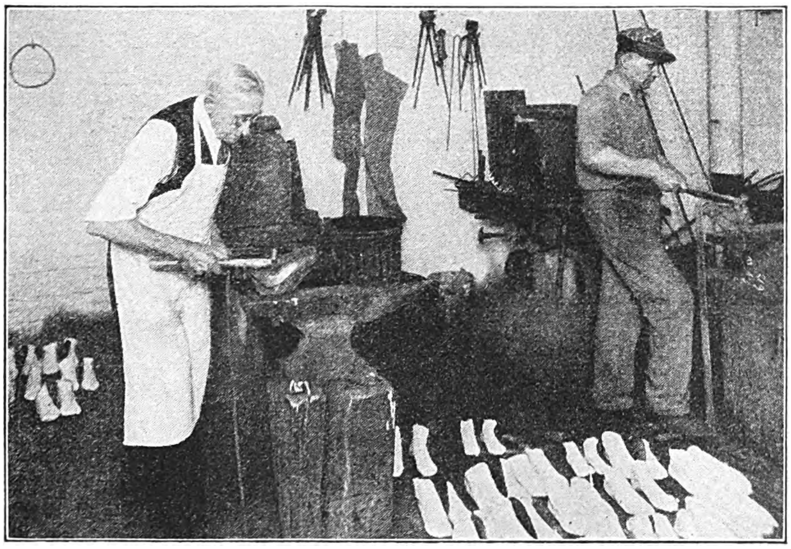


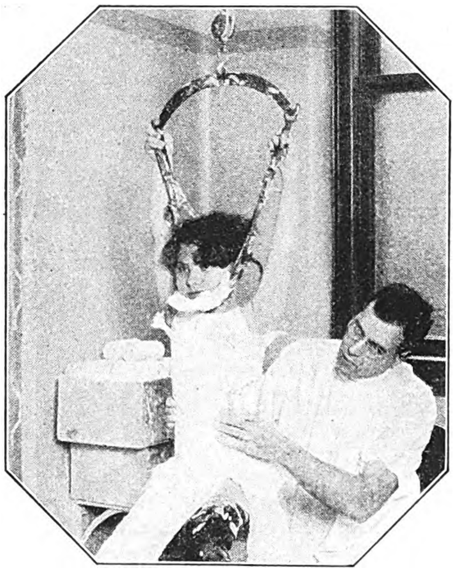
The first step in making a foot brace is a plaster impression, forming a mold for casting



A plaster duplicate of the crippled foot is cast in the mold, trimmed, and a piece of metal is cut to shape for forging

In this picturesque forge shop the iron plates are made to conform to the plaster replica of the foot made in the mold





Making a plaster jacket for the back. From this cast a mold is made which serves as a base on which to build a corrective corset

Modern Rehabilitation of the Cripple

By ALBERT A. HOPKINS

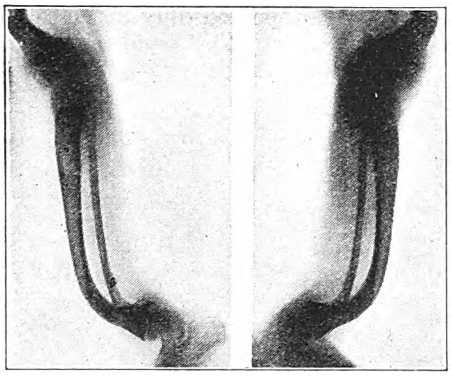
UNDER the shadow of one of New York's great home developments—Tudor City on 42nd Street—is the New York Society for the Relief of the Ruptured and Crippled, which devotes itself to orthopedic relief by surgery or otherwise. In the last quarter century great advances have been made in the treatment of cripples. There was a time when the patient was dismissed with a properly fitted truss or brace. Now the tendency is to try to relieve the sufferer by surgery, or by mechanical, electrical, or therapeutic treatments. We shall here consider only the non-surgical phases.

The hospital operates a vast clinic where treatment is free to the poor, and those who can pay are asked as little as 25 cents to one dollar. Those who are better off are generally glad to pay five dollars. The hospital originally occupied the plot on which the Commodore Hotel was built. The Grand Central Station improvements called for a new hotel and the hospital was moved a few blocks to the eastward into the heart of an extremely congested district.

Orthopedic surgery deals with the rectification of congenital and acquired deformities, particularly those of the

limbs and spine. It is a most interesting phase of surgery. Often as many as eight or ten operations are necessary before the patient is restored to society able to engage in life's struggle on a fairly equitable basis, handicapped perhaps, but vastly improved. This all takes time and it sometimes requires over a year to "make over" a child. A hospital of this kind is not a particularly cheerful place to visit, but on leaving you are filled with thankfulness that your limbs and your children's limbs are straight and that you have never been stricken by the dread infantile paralysis.

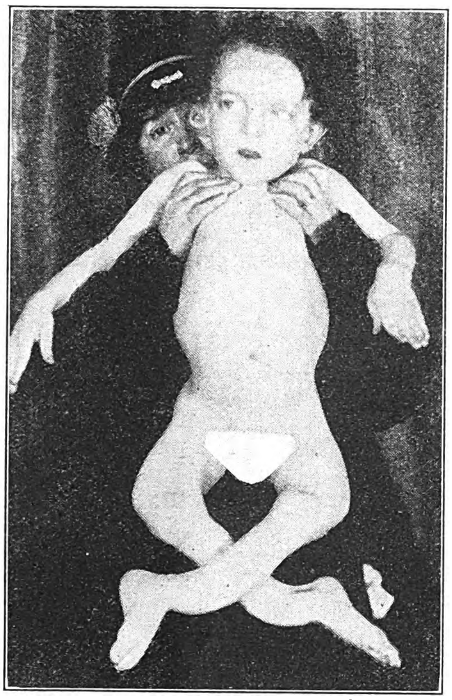
We cannot here go into the technique of orthopedic surgery with its power-driven bone tools, bone dowels, the reconstruction of bone ends and the introduction of transplanted or living tissue between the bone ends to secure movement, and dozens of other complicated and interesting operations. They can hardly be explained to the lay reader, so we will pass on to some of the other methods of treatment.



Correctional devices have always proved of great value with or without surgical relief. Foot correction occupies an important part of the work of this hospital. A cast is made of the foot and this serves as a mold in which to cast in plaster of Paris a replica of the deformed foot. This cast serves as a pattern to which a metal plate is conformed. This flat plate is cut out to form by a sheet metal working machine or nibbler. It is then contoured by blacksmiths who give a picturesque air to the shop with their time honored anvils.

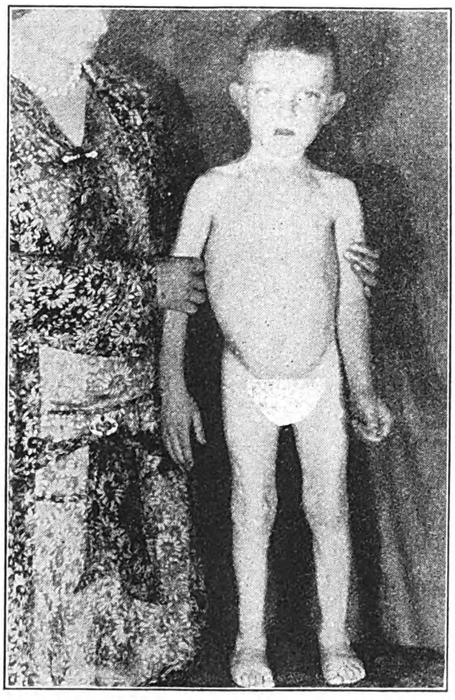
IN spinal deformities a cast is taken from the patient. A plaster jacket is made on the patient by winding wet crinoline bandages in which plaster of Paris is impregnated. This drys in a few minutes and becomes very hard. If a corset is desired this jacket is slit down the front, removed, and used as a pattern.

Various devices are employed for exercising the flabby and unused muscles and even used to help teach the patient to walk once more. Therapeutic lights of all types are employed and hydro-therapeutic treatments of all kinds are given. The therapeutic pool gives much relief from the effects of infantile paralysis, arthritis, congenital hip disease, and other diseases paralyzing the muscles. In effect, the treatment in the pool is similar to that given at Warm Springs, Georgia, which has been so strongly advocated by Governor Franklin D. Roosevelt of New York State, also a sufferer.



***Above:* A victim of rickets so deformed that he has never walked and his legs could not be untwisted. *Left:* X rays before operation**

The pool might be termed an underwater gymnasium but this would not be strictly correct. The principle is one of the most elemental in physics. Since a body submerged in water loses weight in direct proportion to that of the displaced water, patients assisted by this buoyancy are able to perform exercises while in the water, which they could not possibly do when not submerged. Dr. K. G. Hansson, of the hospital staff, conceived the idea in 1914 of indoor pools of heated water for therapeutic purposes and such pools now exist in New York City, Port Jefferson, Long Island, and in Los Angeles.

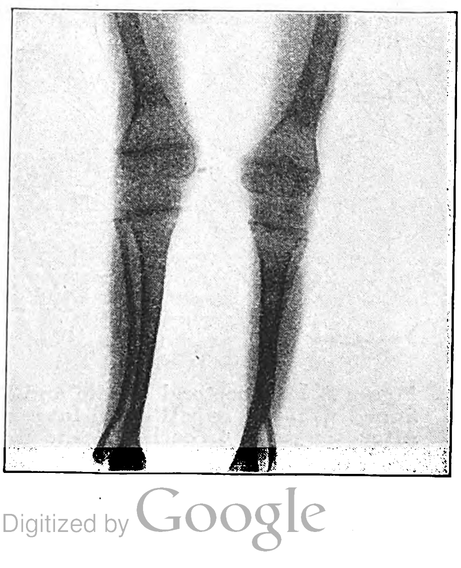


***Above:* The patient after operations had restored health. He can play, and his mentality has improved. *Right:* X rays after operation**

The patient is given a shower and then climbs up into the pool, which is waist-high and not sunk as is usual. The water is filtered and sterilized with ultra-violet rays. The pool is 26 feet long, 12 feet wide, and the depth varies from two to four feet. The tiles are of the "non-skid" variety to protect those who, at best, have difficulty in walking.

TWO of our illustrations show the "principle of Archimedes" worked out in actual practice. We also show a table submerged in the pool so that the patient may rest the torso on it and exercise the limbs.

Through the courtesy of Dr. Armitage Whitman of the hospital staff, we are enabled to present pictures of a boy whose whole life was changed by surgery. A social worker connected with another hospital visited a recently discharged patient who was a janitress in a tenement. There were no windows in the apartment and here the social worker found a child sitting with his legs crossed—tailor fashion, as in one of the pictures. He was a victim of rickets caused by lack of sunshine, proper food, and fresh air. His legs were consequently so deformed that they could not be untwisted. He had never walked and his feet had never touched the gound. The boy was removed to the Hospital for the Ruptured and Crippled and after four operations at proper intervals his deformities were corrected and he now walks normally and his mentality is improved.



Basic Patents in Evolution—II

By WILLIAM K. GREGORY

Professor of Vertebrate Paleontology, Columbia University. Curator, Departments of Anatomy and Ichthyology, American Museum of Natural History. Member of the National Academy of Sciences

IN Part I of this article we saw that the striped muscle fiber, a living elastic thread that contracts when stimulated by its minute nerve fiber, was the first "basic patent" or primary invention of the complex locomotor apparatus of vertebrates. The second step was the grouping of these muscle fibers into zigzag muscle segments arranged in tandem along either side of the body. Whatever may have been the still earlier stages, it is certain that at a very early period the vertebrate body as a whole had been modeled into some kind of "stream-line" form, with a blunt, rounded head and flowing contours dwindling to the rudder-like tail. This discovery of the advantages of the stream-line body-form, both for forward locomotion and for heading up stream, may well be reckoned as the third "basic patent," although of course the reader will understand that in nature such changes are more or less continuous and more or less simultaneous, so that it is arbitrary to assign a numerical order to certain changes which may more properly be considered as details in a drift or movement whose general direction is known.

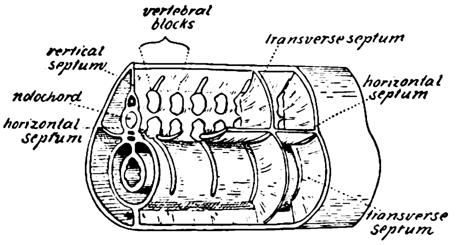


***Figure 6.* The basic patent of the vertebrate skeleton. The skeletal pieces (either cartilage or bone) arise as strengthening rods and blocks at the intersections of the longitudinal transverse and horizontal septa. After Goodrich, from "A Treatise on Zoology" (Ed., E. Ray Lankester), Part IX**

IN this connection it may be regarded as a well-established fact that the general course of evolution in the vertebrates from fish to man has been as follows: (1) a primitive chordate stage, typified broadly by the fossil ostracoderms of the Silurian age; (2) an early shark-like stage, with a relatively simple skeleton; (3) a lobe-finned stage of the Devonian age, provided with both lungs and gills and with paired paddles corresponding to our arms and legs; (4) an early land-living stage, typified by the earliest known amphibians of the Coal Measures; (5) an early lizard-like stage, known in the oldest fossil reptiles; (6) the stage of the mammal-like reptiles of the Permian and Triassic ages; (7) the early shrew-like mammals of the Triassic and Jurassic periods; (8) the first of the tree-living primates at the beginning of the Eocene epoch; thence (9) to the remotely prehuman stock that also gave rise to the Old World monkeys, perhaps at the close of Eocene times; (10) the predecessors of the anthropoid apes, some of the earliest of this lot giving rise to (11) the human line, perhaps in Miocene times.

Among other basic patents which were essential for the forward propulsion of an undulating stream-line body was the possession of a more or less elastic axial or functional backbone (Figure 6). In the first stage of its development this axis was unjointed and continuous and appeared in the form of the notochord. Later the notochord became surrounded by small blocks, clustering around the connective tissue partitions between the muscle segments, and still later these blocks combined in various ways to compose the different kinds of vertebræ that are found in amphibians, on the one hand, and in reptiles, birds and mammals, on the other.

At an early period steering was effected, as we have seen, by keel-like outgrowths from the body-wall, some of which eventually gave rise to the pectoral and pelvic paddles, which correspond to our arms and legs. At first these were supported only by rod-like pieces of cartilage that were laid down between the connective tissue mem-

branes that surrounded adjacent muscle segments. In the sharks the pectoral paddles are supported by a fan-like system of cartilaginous rods and basal blocks, which as a whole correspond to the skeleton of our hands and arms. By the time of the lobe-finned fishes of the Devonian period (Figure 7, A,) the skeleton of these pectoral paddles had begun to foreshadow the "tetrapod" or four-footed, land-living type, but they were still unable to support the full weight of the body on land. When at last certain of these air-breathing, lobe-finned fishes ventured to crawl out of the foul pools, in which in the dry season they were liable to suffocation, their pectoral paddles were drastically remodelled into the five-fingered tetrapod type (Figure 7, C) which even man retains in a somewhat modified form.

In a crawling amphibian or crocodile or in a running mammal, after the body is lifted up by the straightening of the limbs it falls forward, passing over an arc the radius of which is measured by the distance from the shoulder-joint to the base of the fingers. The pectoral and pelvic girdles are essential structures not only in transmitting the thrusts caused by the straightening of the limbs, but also in acting as slings for the support of the body. The pectoral girdle in front view is a U-shaped sling, consisting on each side of an inner core, the scapulo-coracoid arch, and an outer layer of bony sheathing plates, found in all fishes above the shark grade as well as in the earliest land-living animals up to the mammal-like reptiles.

In the air-breathing, lobe-finned fishes of the Devonian period the shoulder-girdle was a crescent-shaped structure that separated the gill-chamber in front from the muscular flanks of the body behind it (Figure 8, A). It consisted of two layers, an inner or primary shoulder-girdle, which

Figure 10. **Further history of the shoulder-girdle. (A) Typical early reptilian type, after the loss of the cleithrum. The coracoid plate is now subdivided by a vertical suture into two parts, of which the posterior one later gives rise to the coracoid process of mammals. (B) First phase of the mammal-like reptile stage, in which the front border of the scapula is reflected outward to form the "spine of the scapula." The arrows show the directions of the two upwardly-growing divisions of the supracoracoid muscle, which give rise to the supraspinatus and infraspinatus muscles of mammals. (C) Second phase of the mammal-like reptile stage, showing further progress toward the mammalian condition, in which the "acromion" projects from the spine of the scapula and the coracoid plate is reduced in size. (D) Shoulder-girdle of the gorilla (left half), showing complete agreement with that of man except for minor differences in the proportional size of certain parts. (E) Shoulder-girdle of man (left half). Of the original two-layered girdle the clavicle represents the outer or dermal girdle, while the scapula represents the primary girdle. The coracoid is reduced to a hook. After Gregory, 1928**

was more or less crescent-shaped, with the concave side directed forward, and a surface layer of bony plates following the same general direction and fastened above to the hinder outer corner of the skull. At first the outer or sheathing plates of the pectoral girdle predominated but when the weight of the body came to rest on the bent pectoral paddle, the stresses on the inner or primary shoulder-girdle increased, so that the scapular blade (Figure 9) grew upward and finally (Figure 10) became the dominant member of the series.

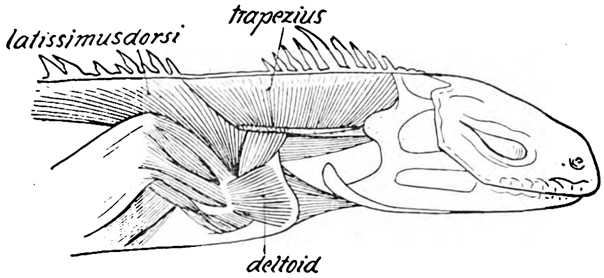

***Figure 11.* Musculature of the shoulder-girdle of a primitive reptile (*Sphenodon*). From Gregory and Camp, 1918, after Fürbringer, 1900**

In the course of many millions of years the outer dermal girdle as a whole gradually lost its functional importance, so that in the higher mammals several of its plates, namely the interclavicle and the cleithra of either side, have disappeared entirely. In the primates, including man (Figure 10, D, E) only the clavicles or collar bones remain as souvenirs of the outer or dermal shoulder-girdle; this was because the ancestors of man were tree-living forms in which the clavicles were important in suspending the weight of the body from the arms.

Meanwhile the inner or primary shoulder-girdle has likewise undergone many important changes (Figure 9). In the lobe-finned fishes (Figure 9, A) its lower prong, the coracoid, was not large. In the early amphibians it has broadened out into a large semicircular plate. In the mammal-like reptiles (Figure 10, C) it finally diminishes in size, while the scapular blade above it meanwhile becomes dominant; in the mammals (Figure 10, D) the coracoid undergoes progressive reduction and finally (Figure 10, E) dwindles into the coracoid process of the human scapula.

THE scapular blade has also been greatly modified and its history furnishes a beautiful example of the fact that during the course both of individual growth and of evolution, bone is not a rigid substance but responds to the changing forces around it by laying down "trabeculæ," or tracts of bone cells, in directions that stiffen the bone against the stresses developed within it. Thus the form of the bone changes from within in adjustment to external stimuli. In the lobe-finned fishes (Figure 9, A) the scapula is relatively small, but when the pectoral paddle had to support the weight of the body on the ground the stresses that were developed in it increased and it enlarged accordingly (Figure 9, B, C). At first its function was chiefly for the anchorage of the muscles that suspend the body, including those that run either downward and backward to the ribs or downward and forward to the sides of the neck vertebræ. The inner side of the scapula also serves as the anchor for a part of the subscapular muscle which tended to draw the humerus inward; its outer surface (Figure 11) was partly covered by the great deltoid muscle running downward to the outer side of the humerus, while its upper border served for the origin of muscles that passed inward to the top of the backbone. Thus the scapula or upper part of the primary shoulder-girdle becomes the platform for many important muscles that transmit the thrust of the backwardly extended humerus upward and forward, or prevent the collapse of the scapula upon the humerus, or hold up the body when the opposite limb is lifted from the ground.

THE subsequent changes in the scapula were dependent upon the change from crawling, with the elbows sprawling outward, to running, with the hands under the body and the elbows drawn in to the sides (Figure 12). When this happened, certain muscles on the outer side of the coracoid plate found themselves in a disadvantageous position and they accordingly gradually shifted upward (Figure 10, B, C), invading the outer face of the scapula from below and giving rise to the supra- and infraspinatus muscles of mammals. These muscles assist in moving the humerus back and forth but they are even more essential in cooperating with the subscapular muscles in preventing the collapse of the scapula upon the humerus. However, the original front border of the scapula had already been curled outward (Figure 10, B, C) by the stress of surrounding muscle and had given rise to the so-called "spine of the scapula" of mammals. Thus when the invading muscle from the supracoracoid mass grew upward, the rear fork passed behind the spine of the scapula and occupied the post-spinous fossa, while the front fork passed in front of this spine.

It has frequently been observed by all students of the skeleton of mammals that the presence of muscles and their tendinous sheaths frequently cause the upgrowth of ridges and crests from the bone that supports them. Consequently when the front fork of the upgrowing supracoracoid muscle found itself pressing against the scapula, it was soon able to evoke a supporting crest, which finally gave rise to all that part of the mammalian scapula which lies in front of the scapular spine. Hence we, in common with other mammals, owe the front part of our shoulder-blade to our remote ancestors, the immediate successors of the mammal-like reptiles, who first developed a ridge or crest in front of the spine of the scapula for the support of an upwardly prolonged slip of the old supracoracoid muscles.

When the limbs were drawn in at the sides (Figure 12, B) the joint between the humerus and the scapula was pulled outward and the coracoids were drawn out into narrow rods; then these lost their attachment to the breastbone or sternum and dwindled away into the hook-like coracoid process. This was retained only because it gave anchorage to the powerful biceps and coraco-brachialis muscles which flex the forearm.

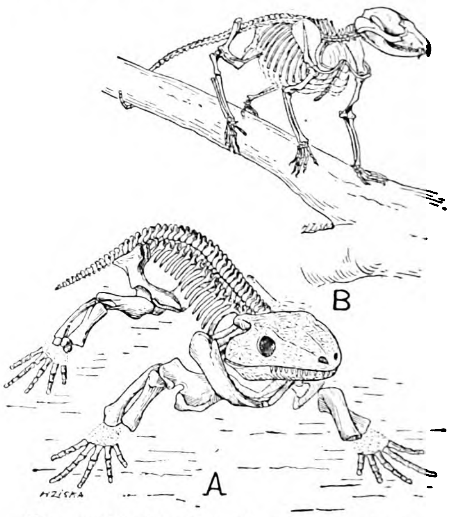

***Figure 12.* Contrast between primitive reptile (A), with sprawling limbs and typical mammal (B), with limbs drawn in at the sides**

In brief, the pectoral girdle of the ancestral fish served as the rear wall of the gill-chamber and as the anchorage for the pectoral paddles and body muscles. It consisted of an inner and an outer series of plates. Under the changed conditions of locomotion on land the inner or deep parts of the pectoral girdle gained the ascendancy and the outer plates finally became greatly reduced. Man inherits his shoulder-blade, or scapula, together with his now vestigial coracoid, from the inner series of the pectoral girdle of the fish; his clavicle, or collar-bones, represents its dermal plates.

Thus new advances require the sacrifice of old devices and the working out of new basic patents.

(*To be concluded*)

A Fish Factory At Sea*

THE outfitting of a ship, formerly in operation in the Orient, as a floating fish factory, has just been completed in England and she has left for a cruise in the waters off southwest Africa. The *Seapro*, as she was renamed, is provided for dealing with the many classes of fish in that locality and a fleet of motor boats for doing the actual fishing. These boats, it is anticipated, will bring to the parent ship from 60 to 100 tons of fish every day. Some of the fish that will be utilized are fit only for conversion into cattle, pig, and poultry feed; some are valuable for their oil content; others have livers that provide a valuable medicinal oil; and some are worth putting in cold storage for sale at a convenient market.

In such an enterprise as that of the *Seapro*, one of the first matters to be borne in mind is that the average content of water in fish is from 70 to 75 percent and that the ship must not be encumbered with so much valueless material. As a consequence, the greater part of the catch must be passed through dryers to drive off this moisture.

The coarser kinds of fish will be hoisted on deck from the fishing boats and dumped into hacking machines, one on each side of the vessel 'tween decks. These machines comprise two pairs of rolls made up of a series of toothed plates. The rolls rotate at different speeds and tear the fish into small pieces. The hacked material is then passed through a sterilizing chamber where the albumen is coagulated and any noxious bacteria killed by being subjected to steam. Then it goes into the drying machines, one of which is on each side of the ship.

THE drying is done in four parallel cylinders which are steam-jacketed. In the drying process, large quantities of steam are driven off and this contains a certain proportion of vapor of an offensive nature. This steam is, therefore, collected and passed through a series of three condensers which are cooled by circulated sea water. The condensate is discharged overboard. There remains a small amount of uncondensable gas which must be done away with, so this is sent up the boiler funnel for complete burning.

From the dryers, the meal is discharged into elevators, one of which is for "white" fish and one for oily fish. The white fish meal goes up elevator A—see diagram—to a cooler, then through a magnetic separator for taking out any scrap metal, into a grinder, and finally into bags ready for the market. The oily fish meal goes up elevator B into a large bin on the spar deck, from which it drops into one of two oil extractors, or digesters, on the deck below. Trichlorethylene, which is non-inflammable and recoverable in its entirety, is used for dissolving the oil. After the first wash of solvent has become saturated with oil, it is drained off and distilled. The condensers shown in the diagram condense the vaporized solvent. When all the oil has been recovered from the meal, steam is introduced into the extractors to recover any remaining solvent. The oil-free meal is then passed through the same process of grinding and separation as the white fish meal. The fish oil that has been extracted is pumped from the evaporator into tanks or barrels. The operations are all automatic, the machinery and conveyors being driven by electric motors.

In the after part of the ship there is a complete plant for making tins, boiling and canning such sea foods as crayfish; and another plant for boiling out the oil of fish livers. The refrigerating plant for carrying fine food fish to market is of normal design.

The start of the 1930 Indianapolis race. The cars in this, the first lap, are being paced by a stock Cord front-drive car. This lap is not a part of the race but is run only to bring the cars across the starting line at 75 miles an hour

Racing Cars of 1930

By WILLIAM F. STURM

A STUDY of the 1930 Indianapolis race is especially interesting in view of the greatly changed conditions under which the race was run. The race is run on a four-cornered track, 2½ miles around, and paved with vitrified brick. The four corners were built for a speed of only 90 miles an hour average for the lap. They are banked only 16.66 degrees for the first 50 feet from the lower edge of the track, and 36.66 degrees for the outer 10 feet—the rim—where cars never run except in case of a near smash with another car.

One thing that made for a good race this year—one easy on tires especially—was that the temperature at noon was 58 degrees, with a good breeze blowing, against the 87 degrees last year.

A resumé of the first five places in the race, with last year's average for each, follows:

First—Billy Arnold, Miller-Hartz, front drive, eight cylinders, 150.5 cubic inches displacement; 100.448 miles an hour (last year's average, 97.585).

Second—William Cantlon, Miller-Schofield, rear drive, four cylinders, 183 cubic inches displacement, 98.054 miles an hour (last year, 95.596).

Third—Louis Schneider, Seal Fast, rear drive, eight cylinders, 121 cubic inches displacement, 97.241 miles an hour (last year, 93.699).

Fourth—Louie Meyer, Sampson, rear drive, sixteen cylinders, 203 cubic inches displacement, 95.253 miles an hour (last year, 93.541).

Fifth—Bill Cummings, Duesenberg, rear drive, eight cylinders, 243.5 cubic inches displacement, 93.579 miles an hour (last year, 88.792).

SEVERAL matters rather definitely decided by the race were:

That the rules banning the supercharger and other so-called speed adjuncts were not destructive to the speed average of the race.

That stock cars, or modified stock cars, did not enter the race in as large numbers as expected.

That the highly specialized racing car is still supreme, winning, as it did, the first four positions; or, if we include the changed stock motor in fifth place, winning the first seven places.

That while these highly-specialized cars will continue to be built, the modified stock-car engine made a showing that warrants the belief that it will appear in next year's race in greater numbers.

A year ago the Indianapolis Motor Speedway Corporation issued a radically new set of rules for the 1930 race. For four years the drivers had been piloting 91½ cubic-inch racing cars equipped with centrifugal type superchargers and having one-man bodies. (See SCIENTIFIC AMERICAN, January, 1930.—*Editor.*)

The rules for this year's race provided for the abolition of the supercharger; limited carbureters to two; limited poppet valves to two per cylinder; raised the piston displacement limit to 366 cubic inches; and made mandatory the two-man body and a minimum weight limit of 1750 pounds, with the further provision that cars must weigh 7½ pounds per cubic inch of displacement.

The drivers naturally made a great outcry. Racing had not been especially good for several years and the new rules compelled the drivers to spend from 2000 dollars, which was the minimum price a new body with gas tanks could be built, to 10,000 dollars, or 15,000 dollars for a completely new car. The rules meant even more than that to the driver—they meant that the little 91½ cubic-inch cars were practically obsolete, since other tracks would, in the main, follow the Indianapolis rules.

A study of the entry list of the race shows that there were 10 four-cylinder, 2 six-cylinder, 23 eight-cylinder, and 2 sixteen-cylinder cars. It is an interesting note that the winning car was an eight-cylinder, built up and owned by Harry Hartz, but not driven by him. Hartz is recognized as one of the cleverest men in the business when it comes to getting cars ready for an Indianapolis race. He himself has won three second places and two fourth places in years past, but he is now definitely out of the driver's seat.

A further note of interest is that the race was won for the first time in its history by a front-drive racing car, with a front-drive mechanism that is practically a duplicate of that in the most popnlar front-drive car in America. Another front-drive won sixth place, while still another won seventh.

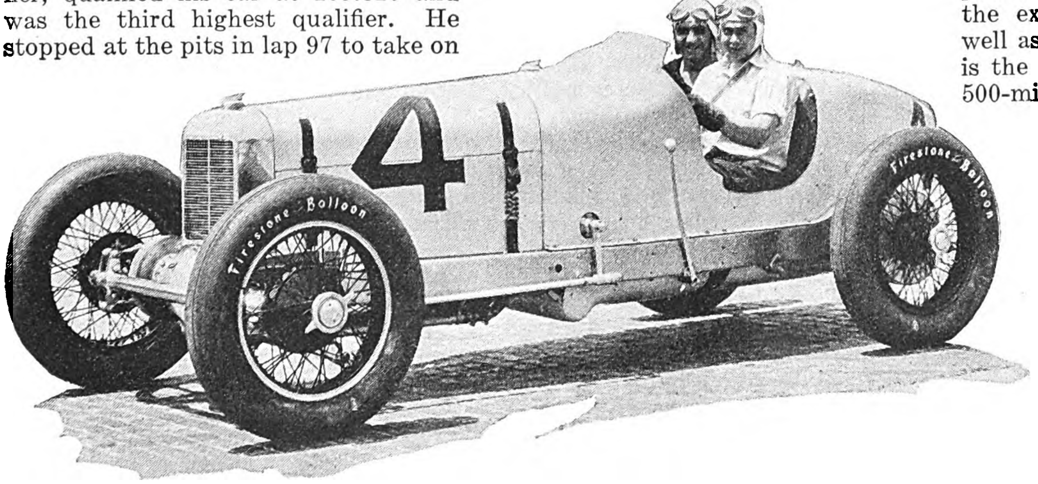
The average of the race—100.448 miles an hour—was the highest of any 500-mile race except one: that won by Peter DePaolo in a Duesenberg Special in 1925, when the average was 101.13 miles an hour.

THE race brought back into racing the four-cylinder car, and evidently it will stay because of its good showing. Ten of the drivers went to the four-cylinder because these motors could be obtained with large piston displacement from a west coast maker who knew engines thoroughly. The fact that the limit of two carbureters might make carburetion difficult for multi-cylinder cars no doubt was another factor, as the drivers of the fours were certain of good carburetion with two carbureters to four cylinders.

Louie Meyer's carburetion on the sixteen-cylinder Sampson Special, however, with two downdraft carbureters, was very good; so good, in fact, that he had the greatest acceleration on the track and qualified his car at 111.290 miles an hour for four laps of the two and a half mile track, next to the fastest qualification made. The racing drivers handled their carburetion well on the eights.

In qualification, Arnold, the race winner, averaged 113.268 miles an hour. He took the lead after Louie Meyer and his Samspon Special had held it for two laps and after that was never headed. Arnold stopped in the 111th lap for right and left front tires, oil, and gas, taking three minutes. He made no more stops until the finish of the race, and had no mechanical trouble.

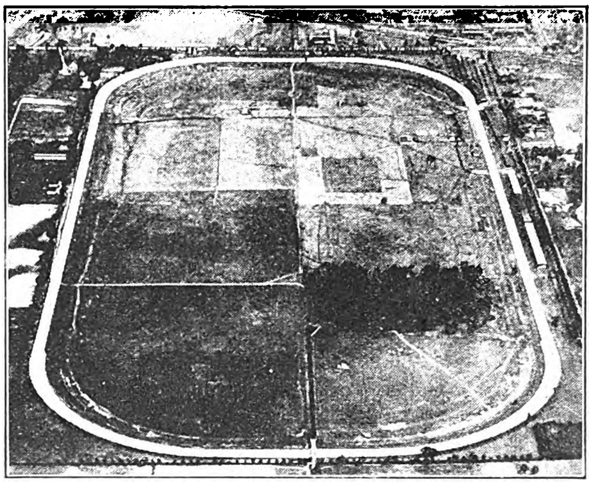
William Cantlon, second place winner, qualified his car at 109.810 and was the third highest qualifier. He stopped at the pits in lap 97 to take on a right front and right rear tire, water, gas, and oil, and gave up his wheel to Herman Schurch, relief driver. The time at the pits was 2 minutes 15 seconds. Schurch stopped in lap 151 for 25 seconds and Cantlon took the wheel.



Billy Arnold, the youthful winner of the 1930 Indianapolis Speedway classic. His Miller-Hartz two-man racing car is the first front-drive to have won this annual race

Louis Schneider, in his Jones-Maley Special, had no mechanical trouble. He stopped at his pit in lap 102 for 1 minute 20 seconds for a right rear tire, gas, and oil. In lap 184 he stopped for 40 seconds for gas and to tighten up a shock absorber.

Arnold's car develops approximately 150 horsepower; while Cantlon's develops approximately the same. For those interested in gear ratios and engine compression, Cantlon's four-cylinder car pulled a 3.9 to 1 gear and its compression ratio was 10 to 1. This is the highest compression ratio used in the race, the average being between 6 and 7 to 1. The gear and compression ratio of the winning car could not be ascertained.



The round-cornered, brick track on which the races are run, as it appears from an airplane

ARNOLD wound his engine up to a peak of about 6200 revolutions per minute. Cantlon's peak was about 5000, while Schneider, the third man wound his to between 5600 and 5800. Louie Meyer wound his sixteen-cylinder car to a top of 6100.

The Sampson Special of Louie Meyer is unique in construction. Its two banks of eight cylinders are placed vertically and each has its own crankshaft, cooling system, and oiling system, only the gasoline system being a common one. Even the radiator is separated in the center, there being no connection between the two sections. Each water cooling system holds approximately four gallons. Each of the two crankshafts has a gear on its front end and these two are connected at the front of the motor to a like gear on a shaft which runs between the two banks back to the transmission. The motor was reversed, to obviate the necessity for a change in the transmission and rear-drive assembly. It had a total displacement of 203 cubic inches and was the highest priced car in the race, representing an investment of approximately 16,500 dollars.

The outstanding performance in the race was that of a Jones-Stutz Special. This car was entered by Milton Jones, a private owner, of Cleveland, Ohio, and was driven to tenth place by L. L. Corum. It was stock in every particular except that its oil and gas tanks were made larger for the sake of fewer pit stops for fuel and oil, and the fenders and running boards were removed.

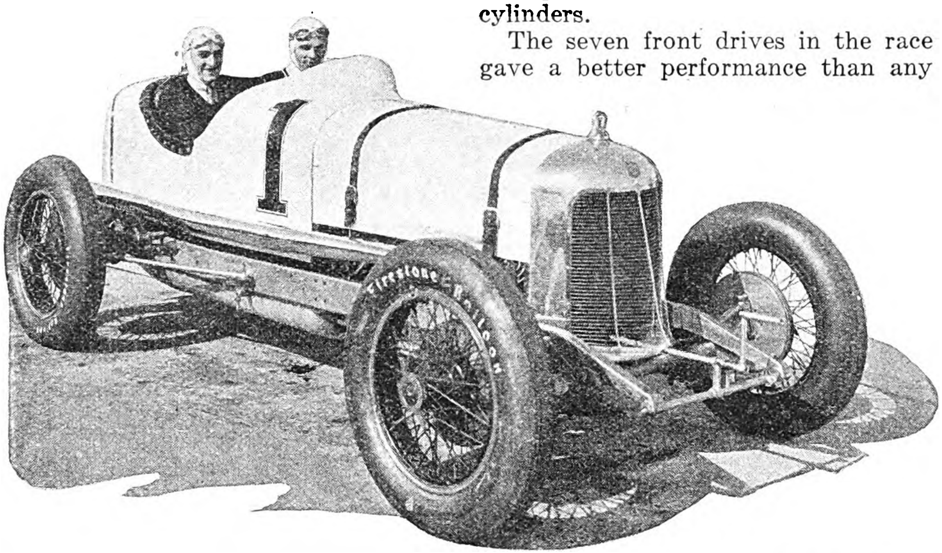
THIS car weighed 4600 pounds at the starting line. It ran the entire race without the hood being lifted except to add two quarts of oil. In spite of its great weight it made no tire changes, the four original ones going through in perfect shape and with so little wear that they evidently were good for thousands of miles more of ordinary usage. The tire wear and performance of the car is a tribute to the excellent balance of the car as well as its mechanical perfection. This is the best stock car performance the 500-mile race has ever seen, even in the days when modified stock car racing was the vogue.

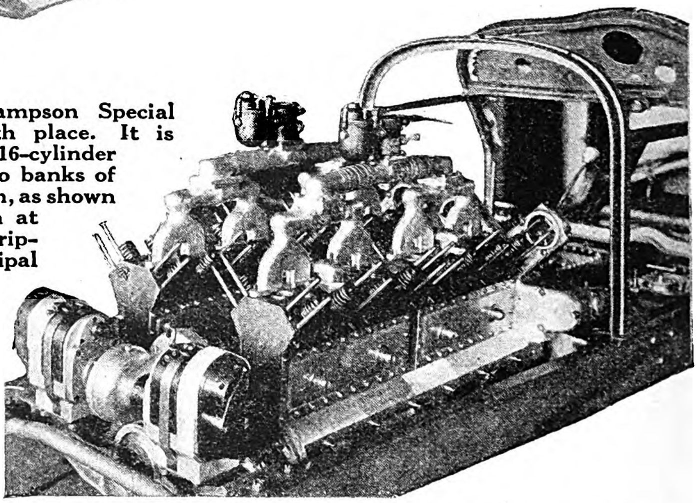
It was unfortunate that the duPont Special, the only factory-entered car in the race, had a smash-up and was put out of the race. This car's performance would have been watched with interest because of its near-stock set-up.

Bill Cummings' Duesenberg Special had a motor that formerly was in a Duesenberg stock car. A new head, not stock, was made for the race.

Dave Evans' Jones-Maley

front-drive was, in part, the second front-drive of modern times, it being one of the two cars built by Harry Miller for the 1925 race at Indianapolis. It is a peculiar commentary that it sat in its garage throughout the race in 1925 because DePalma, Duray, Bennie Hill, and other big drivers of that time decided they did not wish to handle it through a race.





Louie Meyer's Sampson Special which took fourth place. It is powered with a 16-cylinder motor built in two banks of eight cylinders each, as shown in the illustration at the right. A description of its principal features is given in the text. In it, Meyer made an average speed for the race of 95.253 miles per hour, and had no trouble with his carburetion

Meanwhile, the other front-drive went ahead, driven by Dave Lewis, Harry Miller's brother-in-law, and won second place in the race at 100.82 miles an hour—faster than first place in this year's race.

In winning seventh place with a Coleman front-drive, the entry of the Coleman Motors Corporation, of Littleton, Colorado, Phil Shafer demonstrated the correctness of the theory of the Coleman. Its front end embodied many of the features of the Coleman four-wheel-drive truck on a smaller scale. The Coleman broke all racing tradition and calculations by carrying most of its motor weight unsprung, the front motor support being on the front axle. The Coleman differs from other front drives in that it has only one front axle, the driving one, and not a subsidiary one to carry the weight as is the case with others.

SHAFER, in averaging 90.921 miles an hour with his car, which has a top speed of about 103 miles an hour, miscalculated the speed at which the race would be run and held resolutely within striking distance of 93 miles an hour, his estimate of the winner's average. The motor used in the Coleman was a 183 cubic-inch Miller four-cylinder. Another Coleman, driven by Lou Moore, was in a crash and did not finish the race.

The car to finish in eighth place has a stock Studebaker eight President motor; and many of its chassis parts, including the frame, are stock. Snowberger's performance was noteworthy. His top speed was approximately 104 miles an hour but a broken shock absorber stud caused him to decrease his speed and he lost his chance to win.

Leslie Allen's Allen-Miller Products car was strictly a racing car, with a four-cylinder Miller engine of 183 cubic inches. The remarkable part of Allen's average of 85.749 miles an hour was that he put a valve through one of his pistons, with more than 100 miles to go, yet he drove to the finish at a speed of 80 miles an hour on three cylinders.

The seven front drives in the race gave a better performance than any other group in Indianapolis race history, where they have been performing since the 1925 race. With the exception of the two Colemans, all of them were of the Miller-made type, basically identical in construction of their front-drive units and used eight-cylinder engines.

The eleventh-place car was entered simply as a V-eight. It was in reality an Oakland V-eight engine, being the only V-eight in the race. It made a highly creditable showing for a motor that was all stock except its pistons, according to its entrant, Ira Vail. It had qualified at 97 miles an hour.

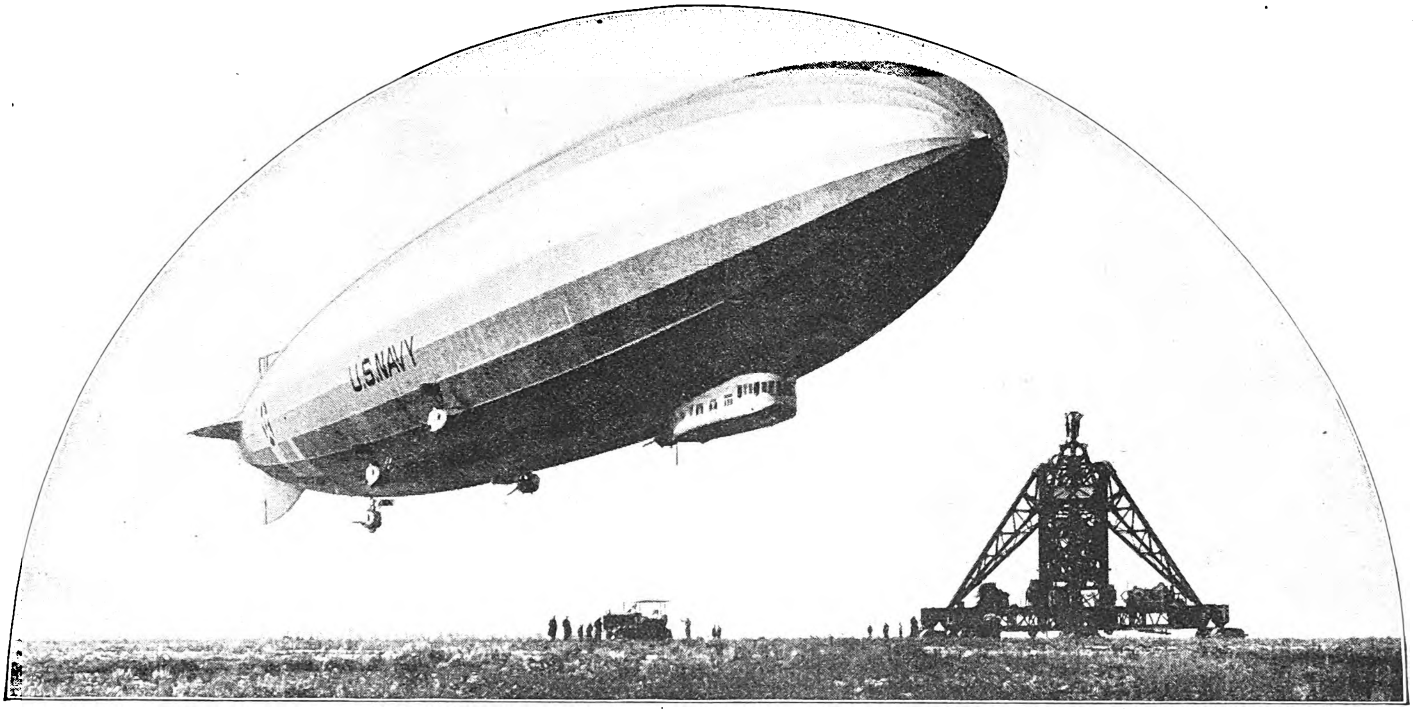
The twelfth car to finish, the Maserati eight, driven by Letterio Cucinatto, of Italy, was the only foreign car to finish, the other one, a sixteen-cylinder Maserati, stopping in the early part of the race with motor trouble.

The car running in thirteenth position was a Fronty Special. This little car, made up of Model T and Model A Ford parts, did especially well. Its transmission and clutch are Model A. The engine is Model T, with special Fronty head. The crankshaft, connecting rods, and pistons are non-stock. The chassis is Model T, including the transverse springs, front and rear. This car qualified by doing four laps of the track at 97 miles an hour. It was running the race at between 85 and 90 miles an hour, when the technical committee member in charge of the recording of car conditions, saw that the eye of the front spring was broken off when the car came in for gas. The driver explained that it had been that way for an hour and, beyond making the car difficult to handle on the turns, no serious difficulty could result. The technical man was obdurate, however, and insisted that something be done. Accordingly, Stanley Reed and Tom Mulligan, entrants of the car, ran into the infield at the track and turned the first Model T Ford they came to up on its side and took off the front spring. They put it on their car, after the Fronty had been delayed 41 minutes. After the car finished the race they hastily jerked the spring off, and put it back on the car from which it had been borrowed, Reed says, without the car owner being any the wiser.

THE fourteenth, and last, car to be running, was the Butcher Special, entered by two Butcher boys of Wilmington, Illinois, one of whom drove while the other acted as mechanic. This car was a big Buick motor mounted in a small Buick chassis, cut down to a wheelbase that would do for racing conditions. It ran throughout the race, but at a very low average.

There were 37 cars entered in the race, but only 14 were running at the close of the race.

There were numerous car failures due to such causes as cracked cylinder heads and broken wrist pins, gas tanks, connecting rods, valves, water jackets, and clutches. Several serious smash-ups occurred.



The *Los Angeles* makes ready to tie up at the new mast

Mooring Dirigibles Mechanically

New Stub Mast and Other Equipment at Lakehurst Facilitate Mooring and Housing

A FEW weeks ago there occurred at the United States Naval Air Station at Lakehurst an event which marked the passing of another milestone in the development of rigid airships. The *Los Angeles*, having been landed from flight, was secured to mechanical devices near the hangar and with about 60 men attending various stations on this equipment the ship proceeded under mechanical power to her berth in the hangar while over 200 other members of the ground crew stood by in unaccustomed leisure and watched this performance in which they have usually had to participate so forcefully with brain and brawn—largely the latter. The first demonstration of practically the full mechanical system for docking airships had been successfully conducted.

Every since the inception of American development of the rigid airship, it has been realized that the field of terminal facilities and other auxiliaries represented a weakness in airship operation. The success of airship operation, both military and commercial, depends very largely on the achievement and provision of adequate, efficient, and economical terminal facilities. From the very beginning airships had been handled in and out of sheds by groups of men placed at strong points of the ships to haul against direct winds and gusts, man-power, of course, having the virtue of being highly flexible. As the size of ships increased, ground crews grew to several hundred men.

Lakehurst, being rather unfavorably situated from a meteorological standpoint, has from the very beginning impressed our airship personnel with the fundamental necessity for improvements in airship mooring and handling.

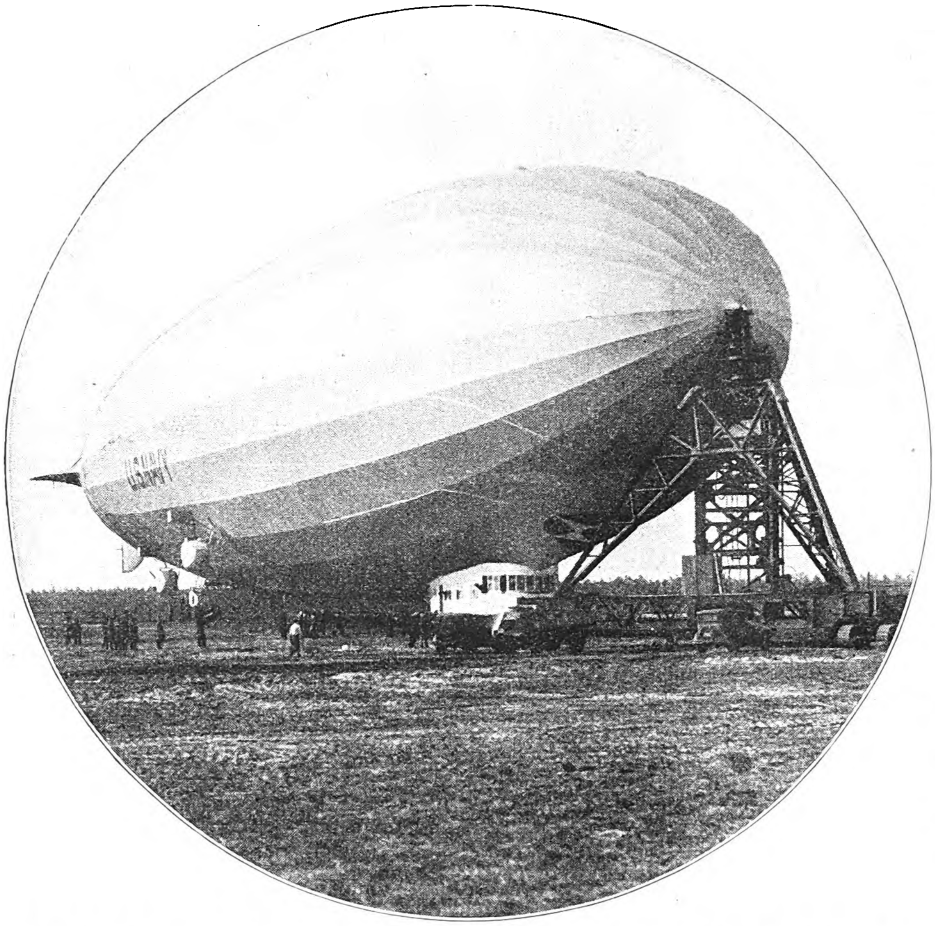
SHORTLY after the World War, the British developed an airship mooring mast which materially added to airship progress in making it generally possible for airships to remain at the mast until favorable conditions permitted housing them without difficulty, should housing be desired. One British airship remained based on a mast for a period of about six months.

However, this "high" type of mooring mast is not a "cure-all" for every airship need. Large ground crews are needed at some time or another when housing or unhousing becomes necessary. Consequently some unit other than the high mast had to be developed.

The method of housing and unhousing airships at first was to employ only men in groups about the ship, in a manner similar to the tugs around an ocean liner. Then there were added "docking rails" projecting along the sides of the hangar and extending out on to the field and over which there traveled trolleys, two on a side, attached to the ship by suitable lines. Additional groups of men steadied the ship against the wind as she had to be moved parallel to the hangar. Such was the extent of the "airship handling project" when taken up at Lakehurst.

The mooring and handling problems resolve themselves into three phases: (a) landing the airship from flight; (b) mooring the ship out or "anchoring" it to ride, ready for flight, as a surface vessel anchors or swings to a buoy; (c) housing or unhousing the airship just as a surface vessel docks or undocks. The problem was one of combining, if possible, these three functions in one set of equipment and making that equipment as efficient and simple as possible. Two phases of this problem have already been proved practical; the third is still in the process of development, but present indications give promise of early solution.

In landing from flight, an airship formerly proceeded over the landing point and was pulled to the ground by man-power using ropes dropped from



Anchored to the stub mast, the *Los Angeles* will safely outride winds of more than ordinary velocities. The cabin, it will be noted, is close to the ground

her bow. In landing to a mooring mast the process is that of being pulled down against her buoyancy by mooring wires dropped from her bow and connected to corresponding ground wires which are then hauled in by power-driven winches. One of these wires pulls the ship downward while two others, leading aft at an angle to the ship, steady her against yawing tendencies arising from gusty wind conditions. These same two wires also prevent the ship from over-riding the mast and thereby possibly fouling her hull against the mast. By means of these three wires the steel cone on the nose of the ship is maneuvered into a steel cup on top of the mast where it is firmly locked.

ALTHOUGH this original method of mooring to a mast has been successfully used a great many times, it does not fully overcome the irregularities of the wind. It has been demonstrated repeatedly that there exists the necessity for providing an additional force to overcome the tendency of vertical gusts to drive the ship downward. Such vertical tendency may, of course, be overcome to some extent by making the ship more buoyant, but there is a practical limit to this measure and, therefore, there exists the necessity for providing a corrective force outside the ship.

The solutions of these several problems worked out at Lakehurst center largely in the demonstrated success of a low or "stub" mooring mast some 60 feet in height as opposed to 171 feet and even 201 feet in modern examples of the "high" mast.

The principal unit employed in the new mechanical system at Lakehurst is a low mobile mast capable of movement over the ground. This mast not only acts as the principal unit of the handling equipment, but also serves as a mooring device to which the ship may be moored for indefinite periods. It incorporates a telescopic feature enabling its height to be adjusted to suit different airships.

To utilize the mast for "anchoring" purposes there is provided a mooring site or circle in the precise center of which the mobile mast can be placed. Surrounding the mast is a circular, standard-gage railroad track on which runs an especially devised car to which the after portion of the airship is secured. In this way the mooring airship is secured at two places, that is, with the bow in the mooring mast cup and the after portion of the ship attached firmly to the car which moves with great facility along the circular railroad track thus allowing the ship to answer fluctuations in the wind directions just as does a weather-vane.

At this low or stub mast, which is an American idea, the lower part of the airship is held within a few feet of the ground, thereby expediting repairs, transfer of loads and personnel, as well as keeping the ship close to the ground where winds are of lower velocity than at levels of the "high" masts. When riding to a high mast the free stern of the mooring airship is practically always going through vertical and horizontal oscillations due to irregularities in wind flow and to temperature changes which temporarily influence the ship's buoyancy. At the American stub mast, the ship, while free to answer horizontal fluctuations, cannot acquire any vertical motion whatsoever and, therefore, the crew of the ship are not continuously flying the ship as is the case when she is moored at a high mast. This stub mast idea has had very successful practical demonstrations at Lakehurst and it is felt that if further results continue to be uniformly successful this type of mooring equipment will not only be developed to a point of increased efficiency, but will at the same time reduce mooring and handling costs materially.

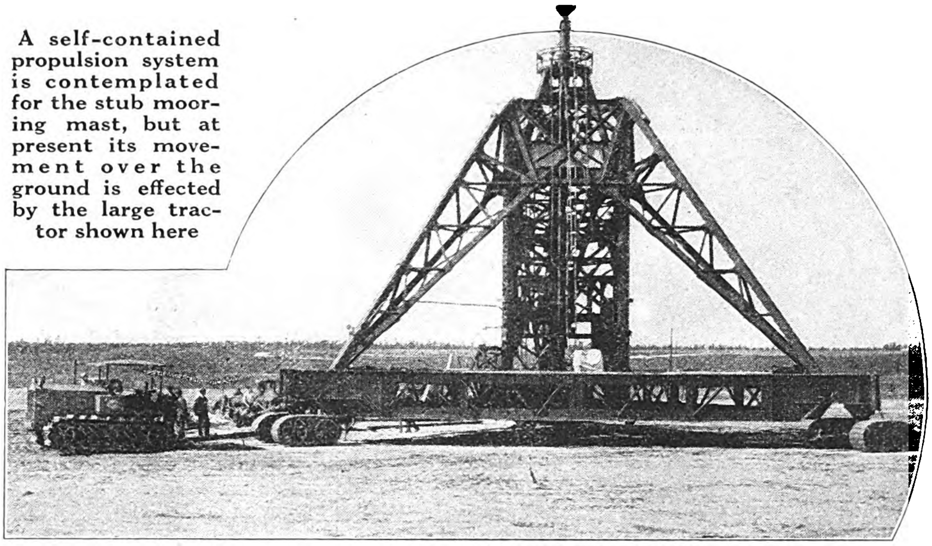
IF after landing from flight, it is desired to house the ship in the shed, the ground servicing connections at the mooring circle are disconnected from the mast and the after portion of the ship is freed from its car. The mooring mast then gets underway with the ship's nose remaining secured just as when moored. Under the stern of the airship, however, there is placed a pneumatic wheel device capable of castering in any direction as well as of furnishing smooth rolling contact with the ground while the mast, with the airship riding to it like a flag, travels from the mooring site to the vicinity of the shed in which the ship is to be docked. A specially devised "tail drag" attached by a line to the ship's stern, follows the ship over the field, but resists any tendency of the stern to lift vertically, by adding its weight to the ship as automatic ballast. Furthermore the mobile mast's own pump and tanks can furnish the ship water ballast if needed as it moves over the ground.

Having reached the docking rails which lie in the prolongation of the hangar direction, the mast comes to rest temporarily. The after part of the ship is secured on each side by an endless wire system which leads from four points on the ship to mechanical trolley systems which operate in the docking rails. These systems are provided with winches to haul the ship up against the wind load in case the wind direction is across the hangar, and enable the airship to be centered between the two docking rails. Held securely in this position, the mast, ship, and trolley systems get underway together and proceed into the shed. In undocking, of course, the reverse system is employed, the mechanical trolley bridle systems holding the ship against a cross wind until clear of the hangar where, by slacking off, the stern of the ship is allowed to swing until it finds its natural position of "nose into the wind." Signal lights similar to traffic lights, and a loudspeaker system mounted on the mast, provide the means for passing orders and information to units and personnel.

Having cleared the hangar, the ship can then either take to the air from that location or be towed to the mooring site or circle and remain there safely until its scheduled time of departure. The limitation on the wind force in which an airship can be docked and undocked by this mechanical means is dependent upon the strength of the airship itself.

IT would not pay nor is it necessary to build an airship structure strong and heavy enough to be capable of withstanding great forces in any direction or at random points. The *Los Angeles*, for example, was not constructed with any idea of mechanical handling devices being applied to it and still we find that the strength of the ship is adequate to allow it to be housed or unhoused in beam winds up to 20 miles per hour velocity. It would be, of course, expensive and complicated to change the structural characteristics of the *Los Angeles* to permit handling in higher winds. When, however, airships are originally constructed with a view to mechanical handling they can, of course, be made adequately strong for handling in greater wind velocities if desired.

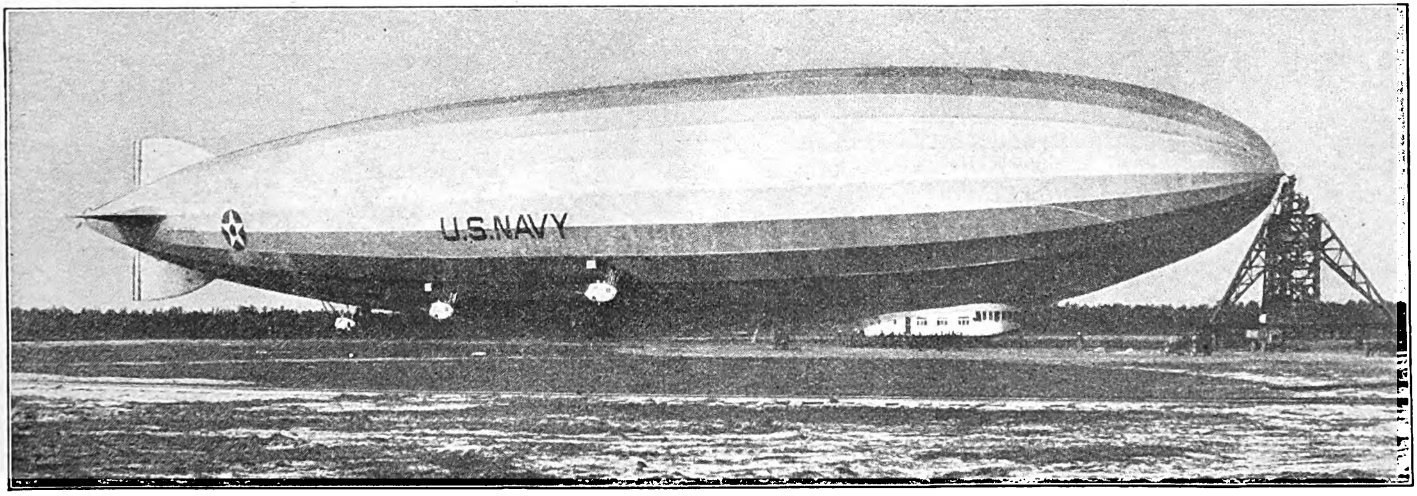
This mechanical handling system is not as yet a fully refined product. It will continue to be modified and perfected, perhaps for years, but fundamentally it has been proved correct. The "iron horse" of the mechanical handling system (as the mobile mast is often referred to) has already during its development period been used in handling the *Los Angeles* on over 30 occasions during the last few months, and by its use the *Los Angeles* has been housed and unhoused in cross-hangar winds of 17 to 20 miles per hour velocity; and it successfully handled the *Graf Zeppelin* while that ship was at Lakehurst last spring. At present its movement over the ground is by a tractor but a self-contained propulsion system for the mast is a contemplated refinement for the near future.



A self-contained propulsion system is contemplated for the stub mooring mast, but at present its movement over the ground is effected by the large tractor shown here

THE stub mooring mast, its mobile features, and other units of the mechanical handling system herein described have been devised, built, and operated by personnel of the United States Navy, principally through the efforts of the Bureau of Aeronautics, the Bureau of Yards and Docks, and the personnel at Lakehurst. No one else in the world has yet attained such solutions except the United States Navy which has been engaged in this arduous task for the past several years. Others, however, are now working on the problem. Recent press reports, for example, indicate that the British Air Ministry is now engaged in the provision of a mechanical handling system for airships, which, according to the announcements, appears to be almost identical with that developed at Lakehurst.

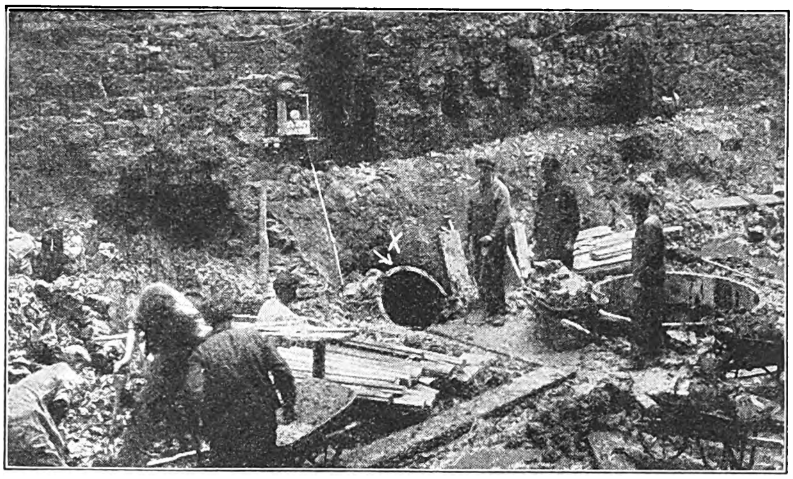
The mechanical handling system is but one of a number of most important airship projects and experiments being conducted by our Navy through the wise provision by Congress of funds for this most important pioneering work. By the continuation of sufficient funds for further experimental work, our Navy will undoubtedly soon contribute other very valuable features to airship operation and thereby expedite the attainment of the high value which the rigid airship potentially possesses not only for naval uses, but for commercial employment as well. With these developments, airship operation can be made practical and economical. We shall have added greatly to the naval usefulness of airships to our fleet. With our natural advantages, such as our helium resources and our great engineering resources, these recent developments should enable the establishment of an aerial merchant marine capable of carrying the American flag to the corners of the earth. In this as in many other pioneering fields, the way will have been pointed out by the Navy.



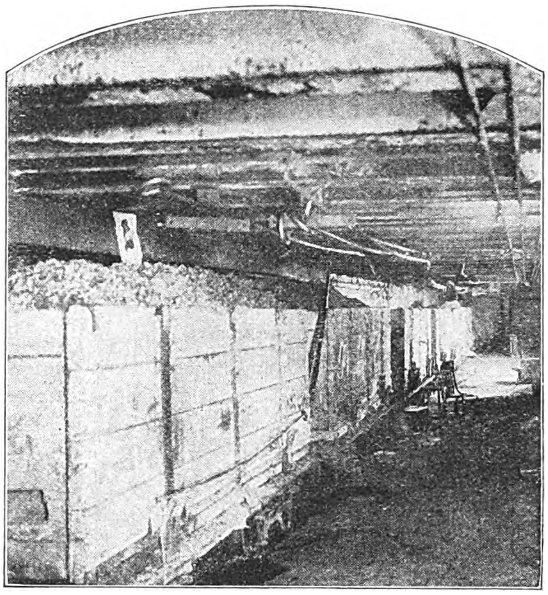
Swinging low enough for the convenience of passengers and for making repairs

distant as even the Field Museum. There are 3304 cars and 150 electric locomotives in use. The merchandise transported yearly amounts to 589,761 carloads, without counting coal, cinders, and excavated material.

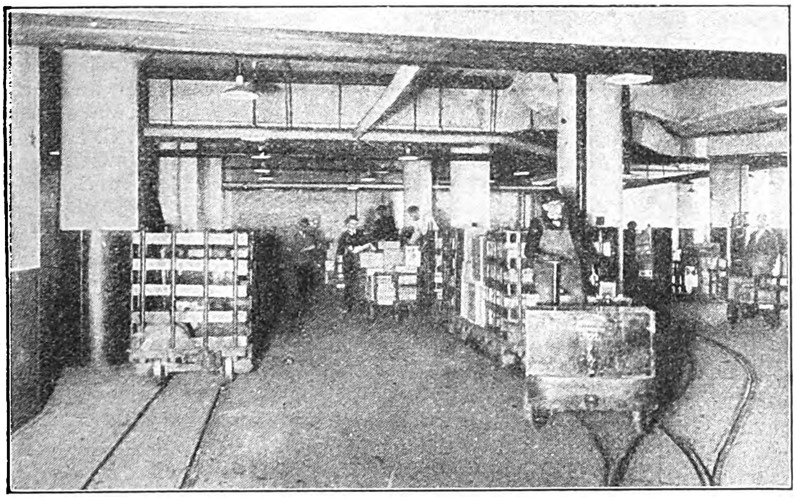
Freight is received at public stations, or directly from the railroads or from connected buildings anywhere along the routes. Ninety-six elevators give access to the tunnel level, the cars themselves being raised and lowered on them. As an example, let us consider a world-famed department store. All its coal is delivered, the ashes removed, and much of the merchandise received and shipped without turning a wheel on the streets. What would New York give for a similar system? The movement of package freight between freight terminals is one of the most important functions of the system. The tunnels are also assisting the new World's Fair by taking quantities of excavated material to the lake front. Our illustrations give an excellent idea of the tunnel, its size (gage 24 inches, size of tunnel 6 feet by 7 feet 6 inches) and its uses. We are indebted to Mr. J. H. Burke, Traffic Manager, for a private view of it.



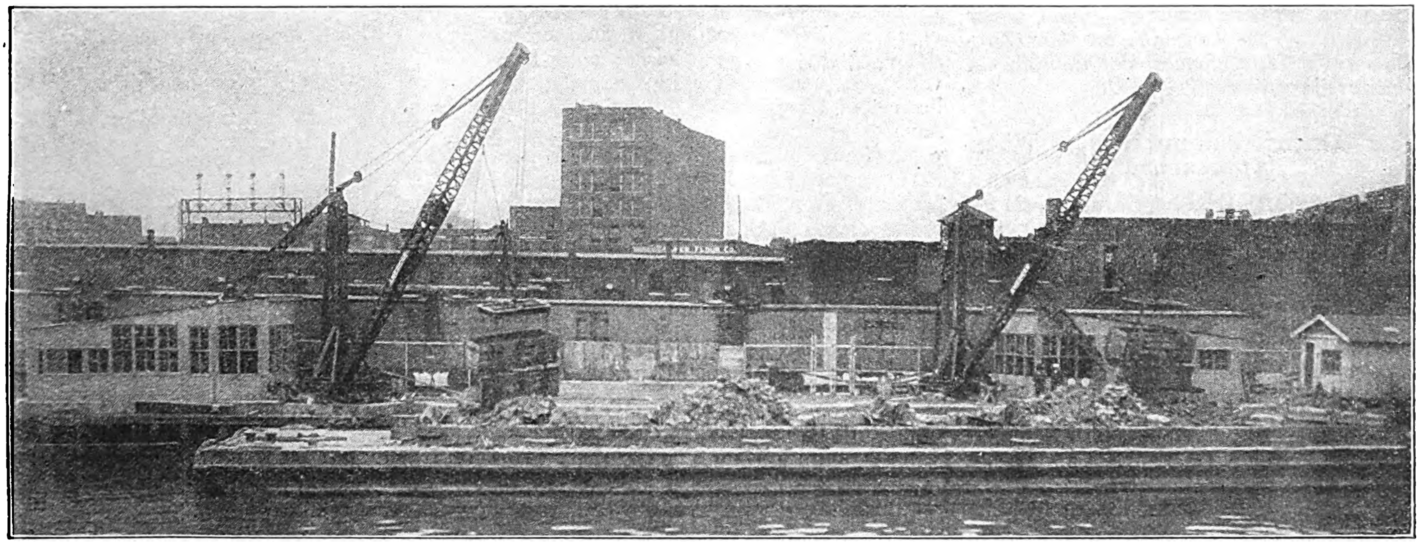
Excavation is easy in rockless Chicago if you are near the tunnels. You bore a hole and shoot the spoil through a chute to the waiting tunnel cars for ultimate disposal



The tunnel takes away the ashes for disposal by dumping them into the lake



Shipping room of a large commercial house showing how freight is loaded on to tunnel cars



Here we have the refuse disposal station where excavated materials, cinders, and other wastes are loaded on barges which are towed far out in the lake for dumping. A total of 102,179 car loads were disposed of in a period of one year

The Scientific American Digest

Conducted by F. D. McHUGH

Suspended Observation Car

THE Materiel Division of the Army Air Corps has employed a very simple, yet useful idea in connection with dirigibles. An observation car was suspended below an airship by a windlass and cable. By ordinary telephone, communication was successfully maintained with the pilot of the airship. Such a device would be invaluable in fog or in low ceiling work. The airship would hover aloft, while the observer reconnoitered, and then gave instructions for safe landing. Such a car was used by the Germans on their Zeppelin raids, and should be valuable in commercial operation.—*A. K.*

A valuable application of the photoelectric cell. It opens this restaurant door automatically

Door Opens Automatically When Approached

HARD-WORKING hotel waiters, struggling through kitchen doors with heavily laden trays and performing like circus acrobats to make the passage safely, need no longer suffer these agonizing evolutions, for the photoelectric cell has come to the rescue. The General Electric Company recently demonstrated an automatic door-opener by means of which, without conscious human effort, a door can be made to open swiftly and silently—and, what is more, to close in the same manner.

A ray of light focused on a photoelectric cell passes in front of the door. When this ray is interrupted it sets a hydraulic door-opener to work, through the agency of a photoelectric relay. The cell and light are placed several feet from the door and, as a person approaches, his body interrupts the light ray directed at the cell.

The current, hardly great enough to be dignified by the name, is amplified through three large vacuum tubes, the last a power tube. It then sets in motion a small motor which operates the hydraulic device, thus actually opening the door. A lever, comparable to those found on ordinary door checks, forces the door open. A suitable time then elapses before the door closes. When the ray of light is again focused on the tube, the device is again ready for operation. The length of time during which the door is held open can be changed by adjusting the control

Largest Gas Tank Known

SUPPOSE you had 200,000,000 cubic feet of natural gas that you couldn't use immediately? Where would you keep it? The novel answer to this "poser," evolved by the Canadian government experts, is as simple as it is ingenious. They could think of no container big enough to hold such a quantity of gas except the container from which it came originally, namely, the bowels of the earth. Accordingly, they have determined to pump the gas from a producing field back into the earth in a field previously exhausted. This plan has been approved by the Minister of the Interior, the Gas Conservation Committee, appointed jointly by the Federal and Provincial Governments, and the Premier of Alberta.

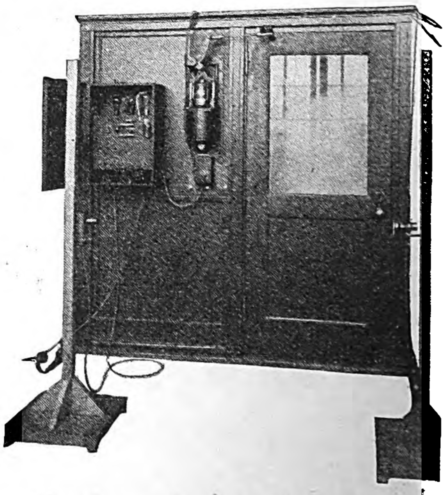
Among the conditions set out in the Order-in-Council under which the reservation has been granted, is the requirement that the company shall commence the actual injection of gas into the depleted sands not later than May 1, 1931, and the amount of gas to be so injected each year shall be not less than 200 million cubic feet until the maximum pressure has been reached and maintained.

The Bow Island gas field, in which the interesting gas storage experiment is to be made, is located about 140 miles southeast of the Turner Valley and a slightly greater distance from Calgary. Prior to becoming depleted it was the principal source of the natural gas supply for the city of Calgary. Now it is proposed to rejuvenate the old wells by bringing gas from Turner Valley, where great quantities are being wasted at the naphtha wells, and to store this gas so that it may be used whenever the peak loads on the company's gas lines may require such reserve supplies.—*A. E. B.*

Ragweed Pollen

THE vast majority of cases of hay-fever occur in people who are sensitive to ragweed. In the fall ragweed pollen is exceedingly prevalent in the air and hay-fever sufferers journey hither and thither attempting to avoid it. Dr. O. C. Durham made a survey of the entire United States during 1929 to locate the boundaries of the ragweed district. He says that the potential ragweed district is the portion of the United States east of the Rocky Mountains, except the south end of the Florida peninsula. In all parts of the area, from one to seven species of ragweed are found.

Thus the actual part of the United States affected seriously by ragweed is little less than three fourths of the total area of the country, but this three fourths contains nine tenths of the population. For each section of the ragweed distric



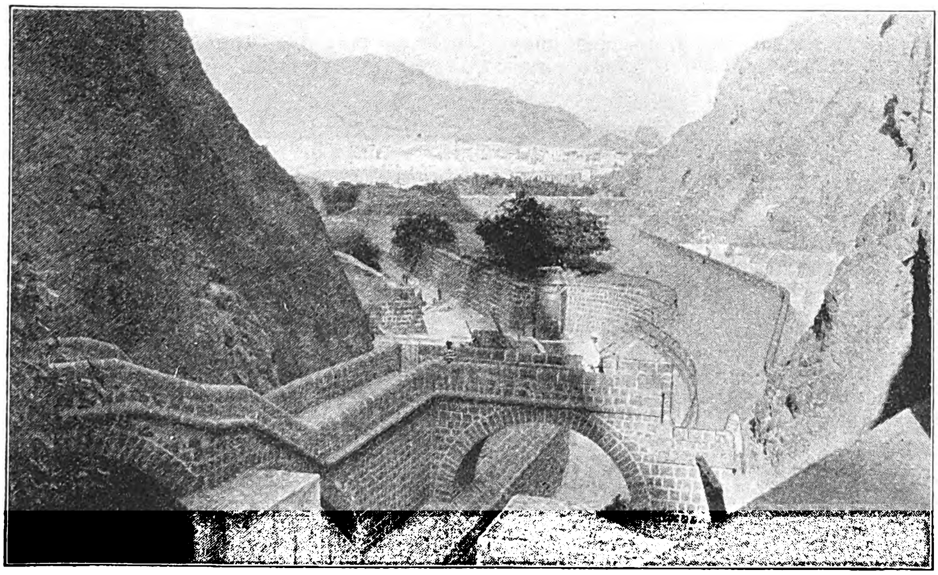
Experimental set-up of the photo-electric cell door opener. Light source is at right near knob and cell is directly opposite at left

the almost rigid dates of onset, climate, and termination of the season are being established, and it will soon be quite possible to tell the hay-fever sufferer exactly what day his symptoms are likely to commence in any definite region and almost the day on which they are likely to terminate. It will then be possible for him to move from the district or to take the necessary preventive measures exactly as they are needed.—*M. F.*

Elaborate Ancient Reservoirs

ADEN, on the Arabian peninsula, is a barren spot, for on the mountains and flat sections of this region there is not a spear of green growing things. Near the city of Aden, however, an elaborate series of 12 reservoirs collect what little rain falls and this is used for irrigation. The water quickly becomes foul and cannot be used for drinking purposes.

The reservoirs which empty into one another were partly excavated out of the solid rock many years ago. Of Persian origin, they were discovered in 1884 by a British officer and restored to the condition shown in the accompanying illustration.



Beautifully built ancient masonry reservoirs near the city of Aden

The Hearts of Athletes

FOR years it has been known that intensive athletic effort places a severe strain upon the heart which may result in chronic disability or even in immediate fatality. It is generally thought that the strain produces enlargement of the heart and cases have occurred in which acute dilatation has resulted. Recent investigations made by Dr. T. K. Richards indicate, however, that in the majority of instances after a hard race the heart is small.

When the athlete collapses he seems to be utterly exhausted, gasping for air, and unable to take a full breath. He complains of abdominal pain and lies on his side with his legs doubled up. Although he perspires freely, his body feels cold. In order to determine the condition of the heart, arrangements were made to look at the heart by means of the X ray before and after the race. Members of Harvard's varsity and freshman cross-country squads and individual distance runners of national fame were studied for the purpose. After a race, the hearts were constantly smaller than before the race. Moreover, the hearts of distance runners who had had many years of competition showed the greatest decrease in diameter after racing. As the man's condition improved, the excursions of the heart became greater and sometimes after an hour more the heart seemed to be dilated.

The theory as to these changes that occur is that the contracted heart of athletes is the result of some form of muscle cramp due to excess of lactic acid in the muscle. The cramp can be relieved by inhaling carbon dioxide which sets free the lactic acid. It seems likely that the general collapse is due to the fact that the contracted heart is unable to supply the brain with sufficient blood and that the collapse is therefore due to some form of anemia of the brain.—*M. F.*

The "storage battery" hydro-electric plant described in the accompanying text. During periods of low power demand, the pumps in this plant draw surplus power from the line and pump water uphill into the reservoir to furnish a head sufficient to run the generators during peak load periods

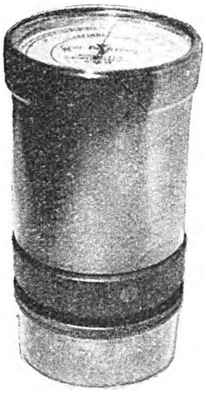
A "Storage Battery" Hydro-Electric Plant

ON the Housatonic River near New Milford, Connecticut, the Rocky River hydro-electric plant of the Connecticut Light and Power Company pumps a river uphill in order to store up a sufficient head of water to run its own generators. It is the first plant in America to pump water for power generation. In general, the pumping is done when there is a surplus of power at other hydro-electric plants in the system. This water supply is used when there is a peak load on the system.

One 30,000-k.v.a. hydro-electric generating unit and two pumps, the latter driven by 8100-horsepower electric motors, have been installed. The head on the units varies from 200 to 230 feet, depending upon the level of the water in the reservoir.

Each of the two pumping units, which were designed and built by the Worthington Pump and Machinery Corporation, has a capacity of 112,500 gallons per minute, or 162,000,000 gallons per day. They are of the vertical-shaft, single-inlet, single-stage, bottom-suction, volute type.

On each pump, the driving motor is mounted directly on top of the casing. These motors are General Electric synchronous motors rated at 7900 k.v.a., 13,200 volts, and run at 327 revolutions per minute.

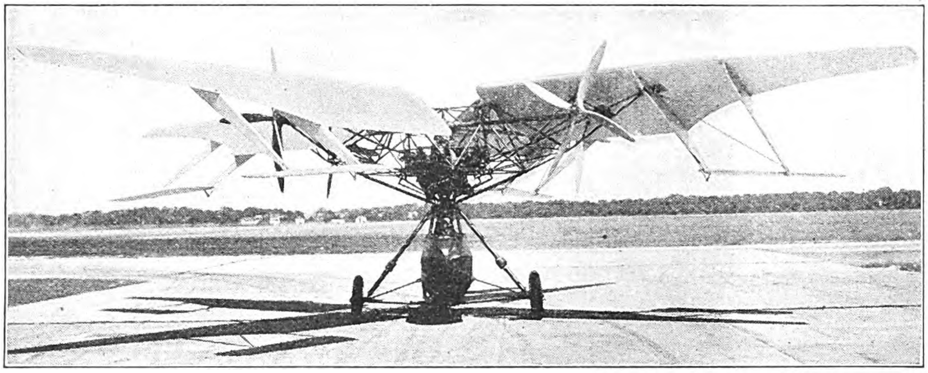


The indicating gas detector

Indicating Gas Detector

IN various industries there has long been an urgent need for a gas detector which reads directly the amount of gas in an atmosphere being tested. Such a device has been developed in Austria and has been put on the market by the Bureau für Wärmewirtschaft, Laboratorium für Brennstoff-Untersuchungen, of Vienna.

This detector consists of a flexible metal membrane, resembling the case of an aneroid barometer, which is closed by a porous clay plate on one end. When the device is brought into an atmosphere containing diffused gas, the gas penetrates the porous clay and fills the space between the clay and the metal membrane. The pressure therein is increased so that the membrane, which is connected to a pointer on an indicating dial, is distended. As the pointer moves, it indicates on the dial the approximate amount of gas in the air.



First of the experimental helicopters to give some promise of successful vertical flight in taking off and landing, designed by a young aeronautical engineer

Navy Enlists Gas to Build War Ships

GAS has been enlisted by the United States Navy to play a large part in the construction of future vessels, according to reports from the Mare Island Navy Yard.

Although it was used in the past to cut up old battleships, gas played a larger part in building the recently launched U. S. S. *Chicago.*

The 1,500,000 rivets required were all heated in specially designed gas ovens because the uniform heat produces stronger rivets and prevents oxidizing, according to the report. All the zinc used to galvanize the inner bottom of the cruiser for machinery foundations and for her fresh water tanks was melted in gas-fired vats. Gas was also used to bend all copper pipes installed and for much of the welding.

The Curtiss-Bleecker Helicopter

THERE is no doubt that the helicopter has possibilities of usefulness. It is unlikely ever to compete with the airplane on the score of speed or load carrying, but it might well act as an auxiliary to the airplane, bringing passengers, for example, from the heart of a city to the transport terminal. The helicopter also has military possibilities, such as for observation work in very rugged country where the airplane itself would be helpless. Such services by the helicopter have long been admitted as plausible, and great ingenuity and vast sums of money have been spent on the development of various types of direct ascent machines. Unfortunately, the history of the helicopter has been marked by a succession of failures. In many cases a reasonable conception has been ruined by insufficient fundamental research. Inventors have been too eager to build and fly their craft.

Now the Curtiss Aeroplane and Motor Corporation has entered the lists with a young engineer, Maitland B. Bleecker, as the inventor and designer of a helicopter. The Curtiss company cannot be reproached with too hasty construction. Systematic research was begun as early as 1927. This has covered aerodynamic work in the wind tunnel, investigations on the cooling of the engine, and so forth. At least we have here a brilliant young engineer, supported by a great company and with all technical aids at his command.

Brief descriptions of the helicopter have appeared in the daily and technical press. The writer has had an opportunity to examine the novel craft. The Curtiss company, however, has been chary of issuing adequate descriptions so far and the following remarks, although carefully considered, must be ragarded as reasonable conjecture for the most part.

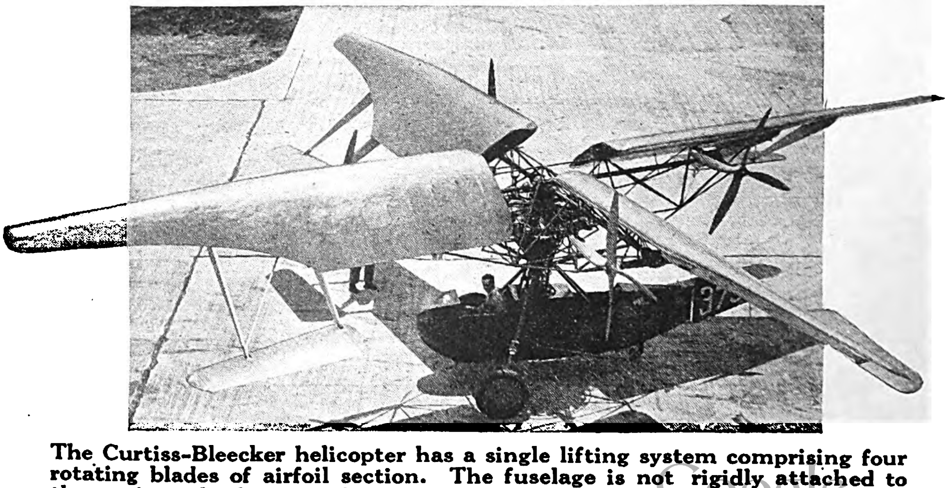
The Curtiss-Bleecker helicopter has but a single lifting system, comprising four rotating blades of airfoil section. With a single rotating system, if the engine were rigidly mounted to the fuselage or nacelle, then the fuselage as a whole would turn in space (action and reaction being equal and opposite) to the great discomfort of the pilot. This difficulty has been met by having the engine free to rotate in suitable bearings in the nacelle. The engine is mounted somewhat above the nacelle and behind the pilot.

The question of transmitting power from the engine to the main rotating blades is a difficult one. Nothing would appear simpler than to gear down from the engine to a vertical shaft, which would, in turn, rotate the blades. Unfortunately, a large speed reduction is necessary. The engine must revolve at high speed—2000 revolutions per minute or thereabouts—while the lifting elements should, for maximum lifting power, revolve slowly, say 150 revolutions per minute. The problem of gearing down and transmission without excessive weight, is a formidable one.

Again, the rotating blades must vary their incidence, or pitch, as they move along their circular path. The pitch must be varied rapidly for control or for descent with power off. The design of a good transmission system is complicated by these additional requirements. To avoid these difficulties, Mr. Bleecker has hit on a novel method of attack. He connects the engine through shafting to a number of small propellers, which, in turn, pull the lifting blades around, but leave the lifting elements more or less free from the transmission machinery. The central vertical shaft running from the horizontally placed Pratt and Whitney Wasp air-cooled engine is geared to four horizontal shafts, which again are geared to four, four-bladed propellers of relatively small diameter. The transmission system is external to the main lifting elements which are rotated by the thrust of the small propellers.

Another difficulty in the single-lift-screw-system helicopter is that, in forward motion, the blade advancing into the wind is meeting the air at a greater speed than the blade moving away from the wind. Therefore if the pitch on both sides is the same, the blade advancing into the wind will have a greater lift than the blade retreating from the wind. The result is a powerful rolling moment tending to bank the machine about its main or longitudinal axis. Such a rolling moment would be difficult to resist by the controlling means placed at the pilot's disposal, and even if met by the pilot would leave him dangerously little lateral control.

To meet this situation it is necessary to vary the pitch or angle of incidence of the blades automatically, as they whirl round. Herein lies the function of the auxiliary vanes or "stabovators" as they are termed by the Curtiss company, disposed at some distance behind the main blades. The area of the wings is 322 square feet and the stabovators have an area of 12½ square feet each. The main blades are presumably hinged at such a point along their chord that they tend, under a gravity moment, to increase their angle of incidence. When the stabovater is moving rapidly into the wind, its aerodynamic moment becomes greater in proportion to the gravitational moment. Therefore the stabovator tries to bring the wing down to a smaller incidence or pitch. If the whole delicate situation is correctly adjusted, then the decrease in pitch of the advancing blade balances the effect of the greater speed, and the lift on each side of the airplane is equalized. The dangerous rolling moment disappears. We believe this explanation to be an entirely plausible one; but later disclosures may modify it.



The Curtiss-Bleecker helicopter has a single lifting system comprising four rotating blades of airfoil section. The fuselage is not rigidly attached to the engine; the latter is free to rotate in suitable bearings in the nacelle

The designer of the helicopter has also worked out a system of control about all three axes. The directional control, or rudder, is mounted at the rear of the short nacelle. Contrary to practice with the conventional rudder, the helicopter rudder is hinged about a longitudinal axis. This is evidently so as to provide steering when the helicopter is either climbing vertically or soaring. Under such conditions, the rudder is in the downward slipstream of the main blades. If it were hinged about a vertical axis, nothing would happen. With the rudder hinged about a horizontal axis at its top edge the craft will turn to the right when the lower edge of the rudder is swung right. Our readers will no doubt agree with this supposition after a little reflection. For lateral control and longitudinal control, an ordinary "joy stick" is placed in the nacelle. The joy stick is so connected with the rotating blades that the pitch can be changed either on the right or left side, or ahead or behind the pilot. We imagine that a system somewhat analogous to the floating aileron is employed. Thus a complete control system is provided for.

All the main blades can also have their pitch changed simultaneously. This means that they can be given a negative pitch when the engine fails. The blades will then continue to rotate as a wind-mill, providing lift for either vertical descent or descent on a steep path. Ability to change the pitch is also important from the point of view of maximum climb and forward speed. In vertical climb the pitch should probably be somewhat greater than in forward flight. To secure forward flight, the elevator system is employed to tilt the machine slightly down by the nose, so that a part of the lift now acts to give forward pull.

A great deal of thought has gone into the power plant system. Gasoline and oil tanks are mounted so that they rotate with the engine. Electrical connections are taken off the rotating system through the use of a commutator. Through an ingenious system of gearing the pilot has normal throttle control available. A tripper device allows the gasoline feed system to be shut off while the rotor is in motion. To cool the engine, since it is *not* in the slipstream of the conventional propeller, a 32-inch diameter propeller-type fan is placed above the engine, with special baffles to guide the air all around the engine.

The landing gear is more or less conventional but the travel of the oleo struts is exceptionally large, to allow for vertical descent with power off. The tail wheel is of the caster type.

The gross weight of the helicopter is 3400 pounds. The useful load is small and some 20 percent of the gross of this useful load—180 pounds—is in fuel.

The main criticism of the helicopter is complication and the fact that there are so many transformations of energy to be reckoned with. The engine drives shafting. The shafting drives the small propellers. The propellers pull the main blades round. The main blades tilted forward provide the forward pull for the entire craft. Each of these transformations spells a loss. There is no doubt, however, that the Curtiss company will proceed with the utmost caution and will persevere, meeting difficulties as they occur and improving the machine step by step. We wish them every success.—*A. K.*

Exports of Farm Machinery

EXPORTS of agricultural machinery and implements in 1929 amounted to 140,800,000 dollars compared with 116,000,000 dollars in 1928. This increase of 21 percent over the high record established in 1928 is of importance to business, as it relates to one of the great industries that is a large employer of labor and an extensive consumer of raw materials. Barring unforeseen calamities to the crops, the outlook seems to be for a continued increase in these products both at home and abroad.

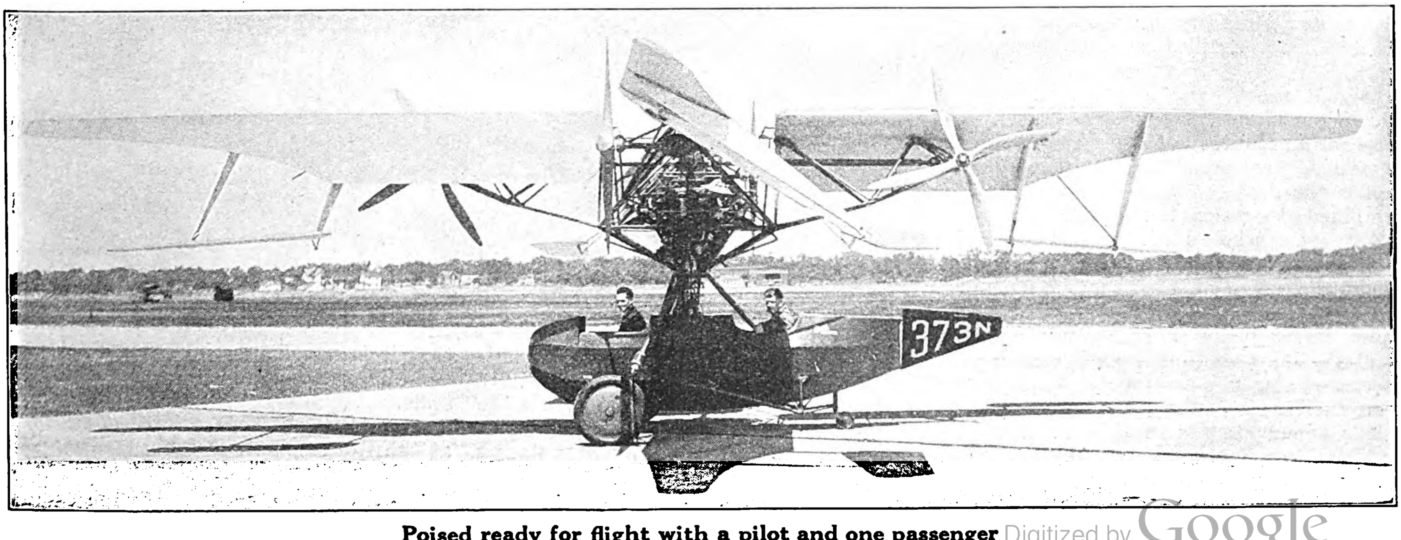
The manufacture of farm machinery and implements in 1928 accounted for 2,200,000 tons of steel, or 6.5 per cent of the total consumption of steel in domestic industry. As the railroads used 16 percent of the country's steel, the farm-machinery business called for 40 percent as much as the railways. This business also called for almost exactly the same tonnage of steel as was exported. Sales of this type of machinery in 1929 were larger than in 1928, due in part to the increase in exports. Thus the export field demonstrates its importance in maintaining one of our great manufacturing industries.

The great increase in power-farming machinery shipped out of the country shows that the trend towards the mechanization of agriculture is not an exclusively American feature. Canada and Argentina, great export wheat-growing countries, and Russia, a "hope to-be" exporter, are the leaders in this kind of machinery. Tractors are one of the features of these exports to the wheat-growing countries. Doubtless our new plan of "farm relief" by reducing acreage and raising less will receive the enthusiastic endorsement of these three countries that stand to profit by taking whatever trade we shut ourselves off from supplying.

Of those countries, Canada, Argentina, and Russia offer great possibilities for power farming. Canada's prairies are especially adapted for it, and the great increase in such heavy machinery taken in the past year shows that the farmers there are appreciating the value of mechanized agriculture. All such methods of production as this decrease the cost and make it possible to sell wheat at lower prices in the world markets. When crops are fairly good, therefore, it stands to reason that this line of manufacture will prosper both at home and abroad.—*Barron's.*

Refrigerating Fresh Fruits

FRESH Georgia peaches at Christmas-time are the latest triumph in food preservation by freezing. Advances in refrigeration practice accompanying the freezing, distribution, and display of frozen food-stuffs were featured at a recent meeting of the American Society of Refrigerating Engineers, held in Atlanta.



Poised ready for flight with a pilot and one passenger

Plans for the production of frozen Georgia peaches on an extensive scale were described by W. R. Tucker. Sliced peaches packed with sugar are to be quick-frozen in one-pound waxed paper containers and then held to supply the "out-of-season" high quality demand.

Extensive experiments covering more than two years preceded the plans for large-scale production. Unsatisfactory for canning because of the very delicacy of cellular structure that is their chief asset from a flavor standpoint, Georgia peaches have presented a difficult over-production problem. Flooding of the market during the brief season in which they reach maturity could be avoided, Mr. Tucker said, by withholding in a frozen condition a sufficiently large part of the crop.

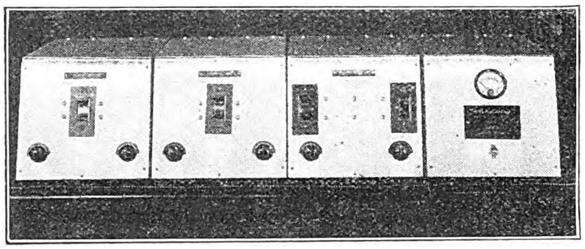
As a result of experiments made last year, the most satisfactory varieties, the proper freezing time, freezing and holding temperatures, and container size have been determined definitely. More than 10,000 pounds of peaches were frozen by Mr. Tucker and his associates at the height of the producing season last year, and stored until Christmas time. Then they were packed in solidified carbon dioxide and sent to leading hotels, representative peach growers, home economics bureaus, and other interested individuals. An amazing unanimity of opinion to the effect that these peaches were indistinguishable from freshly picked products resulted from this test. With the plans that have been developed, large-scale production will make it possible to market frozen peaches at a price that is considered reasonable for such high-quality products. It is planned eventually to effect national distribution throughout the period when fresh fruit is not available, Mr. Tucker said.—*A. E. B.*

The Trend to Short Waves

THE growing use of low waves for broadcasting is creating a demand for low-wave receivers, which is being met by several manufacturers, one being C. R. Leutz, Inc., makers of the short-wave Model C receiver illustrated in these columns.

The Model C is of unit construction, allowing maximum flexibility; either two, three, or four units may be used together as a complete receiver. The simplest combination is the detector stage and audio unit combined, to which the first and second RF stages can be added. Since each unit is in a separate aluminum cabinet, double shielding is effected, each radio frequency stage, the detector stage, and the three audio stages being in separate compartments. The resultant isolation between the tuned stages is an important factor in the performance of the set.

The tuned circuits in this receiver are designed for maximum and uniform efficiency over the entire frequency range. Ordinary short-wave adapters obtain a wide range by the use of small coils and a large tuning condenser. Vacuum tubes, being voltage operated, require maximum inductance and low capacity, to meet which demands a higher manufacturing cost than is the case with the first-mentioned method of obtaining width of range. But in the Model C short-wave receiver, efficiency displaces cost as the determining factor. Of course, the receiver is unsuited for ordinary broadcast wavelengths, but its efficiency on the short waves is very high. The condensers are of fine construction and of the low loss type; the various tuned circuits are completely shielded; and there has been provided an elaborate system of chokes and by-pass condensers, which confine the radio frequency currents to their proper paths.



Panel of the four-unit Model C short wave receiver. Either two, three, or four units may be used as a complete receiver

One of the problems of short-wave receivers using few tubes is to secure sufficient amplification in the detector circuit to operate properly the powerful audio amplifier. To meet the requirements, the Model C receiver has two tuned radio frequency stages. The push-pull audio amplifier has been purposely omitted since the extra input signal required to secure full output cannot always be conveniently obtained in a short-wave circuit. A receiver employing push-pull would operate well enough on strong signals, but the weak ones would be entirely lost. The sensitive cascade amplifier guarantees loud speaker volume.

The Model C short-wave receiver is sold without coils, which may be purchased separately to cover any desired bands or wavelength ranges.

Mineral Oil and Cancer

BECAUSE of the publicity given in recent years to the possibility of producing cancer in human beings by contact with lubricating oils, Dr. Francis Carter Wood of the Columbia University Institute of Cancer Research undertook a study to determine definitely whether or not the ordinary mineral oil used for laxative purposes might have any effect in stimulating the growth of cancer. It is well known that "mule spinners" in the cotton industry, whose clothes are saturated with lubricating oils from the machinery which they use, develop cancers at spots where the skin is irritated by the clothing saturated with oil.

It has also been well established that cancer may be produced in mice by rubbing them with tar. It was found that painting the skin of mice with heavy lubricating oil would produce irritation and overgrowth, but painting the skin of mice of the same type with mineral oil of the kind used for laxative purposes did not produce anything resembling cancer. Feeding of mice with mineral oil did not produce any changes in the intestines or stomach, neither did the feeding of rats with such oil have any cancer-producing effect. It is well known that the skin of the albino mouse is just as sensitive to irritation by oil as is the human skin, and that both albino mice and rats may develop spontaneous cancer of the intestines.

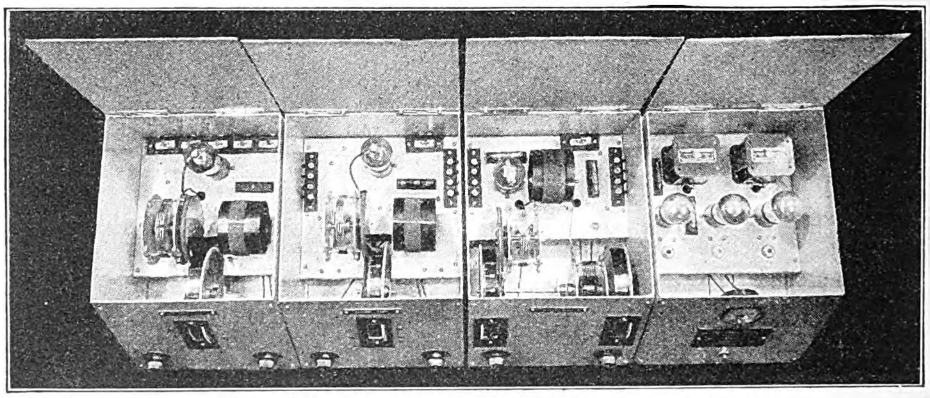
Hence there is no reason to believe that mineral oils, as used in modern life for the treatment of disease, have any cancer producing effect.—*M. F.*

Air Trespass Over Private Property

WE pointed out in an editorial in our May issue that the old theory that a property owner's rights extend to the skies has no basis in fact. A federal court, sitting in Cleveland recently, apparently concurred with us in this opinion, but the decision of the court did give to the property owner "possession" of the air up to a height of 500 feet above the land he owns. This is an interesting commentary on the growing need for study of the many legal problems confronting aviation today and, so far as we can learn, is the first really definite legal opinion that a plane may be actually liable for trespass even though it does not touch the ground over which it illegally flies.

Salvaging Everything but the Rattle of Derelict Cars

FOLLOWING the systematic wrecking of more than 18,000 antiquated motor cars, the Ford Motor Company recently announced that the salvaging of materials obtained in this manner is practical and that it is now increasing its facilities for continuing the work on a more extensive scale.



Interior view of the radio receiver illustrated above

At the present time a force of 120 men at the Rouge plant, Dearborn, dismantles these apparently worthless hulks at the rate of 375 cars every 16 hours. Many parts, such as tires, are salvaged in their entirety and other materials are being converted into useful articles, while the steel is remelted in furnaces to do its bit in the manufacture of Ford cars and Ford trucks.

The derelicts are bought from dealers at a fixed price of 20 dollars a car. There is no restriction as to make, age or condition, except that all cars must have at least some semblance of tires and a battery.

The salvaging of cars that have outlived their usefulness serves three ends. It will rid highways of motor menaces that are dangerous both to life and traffic; it will, to a large extent, free the landscape from unsightly junk piles; and it will convert into usefulness material that would otherwise go to waste.

The present method is, first, to drain the cars of gasoline and oil, both of which are salvaged. Grease is also saved. The cars are then hauled into the building and placed on a progressive conveyor. The headlight lenses and lamp bulbs are recovered. The spark plugs and battery are taken out. All glass is removed. That which is whole or may be cut to useful sizes is utilized for glazing in Ford plant buildings. The broken bits are sent to the Rouge glass factory for remelting. Floor boards travel to the box factory to be used for crate tops.

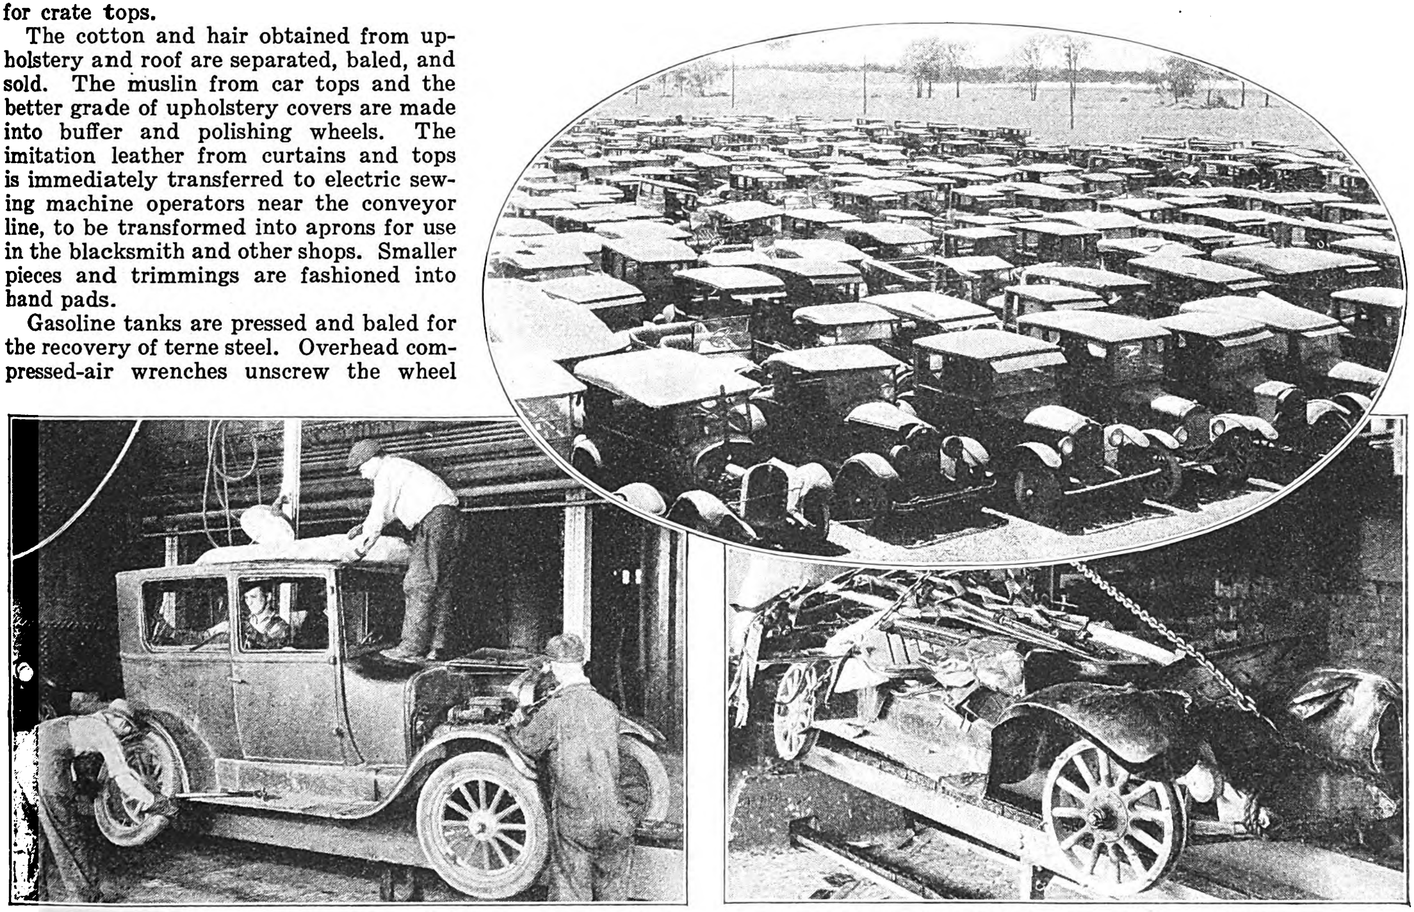
The cotton and hair obtained from upholstery and roof are separated, baled, and sold. The muslin from car tops and the better grade of upholstery covers are made into buffer and polishing wheels. The imitation leather from curtains and tops is immediately transferred to electric sewing machine operators near the conveyor line, to be transformed into aprons for use in the blacksmith and other shops. Smaller pieces and trimmings are fashioned into hand pads.

Gasoline tanks are pressed and baled for the recovery of terne steel. Overhead compressed-air wrenches unscrew the wheel nuts. When the wheels are removed the tires are inspected. If the tread is good they are sold as used tires at the commissary; otherwise the entire unit is placed in automatic shears which sever both tire and rim. The tire is quickly stripped and tossed into a waiting cart to be sold as old rubber. The rims join others for use as furnace scrap.

Horns are salvaged. Likewise hubcaps for aluminum, ignition wire for copper, oil cups for brass, bushings for bronze, and other bearings for babbit. All metals are kept separated by depositing each kind in steel barrels.

As the conveyor-propelled, and now all but dismantled, cars reach a station near the end of the salvage line, men with oxygen torches burn the motors loose from the frames. Overhead compressed-air hoists are attached to the motors and they are swung to a washer. This bath of boiling water and soda ash expels them from the opposite end free from grease and dirt. Meanwhile what is left of the cars continues on the conveyor into a 22-ton press which crushes them. The remains are then transferred to the third conveyor which carries them to the furnace doors.

All Model T engines are conveyed past the washing machine to a group of specially designed presses where they pass through a special process of disassembly.



In the three views above, the oval shows a section of the receiving yard at the Ford plant where old cars are stored awaiting junking; below at left, workmen are stripping the car; at right, car pressed after stripping

553 Hours in the Air

In the refueling endurance record flight of John and Kenneth Hunter, which ended late in the afternoon of July 4, the engine was put through the most grueling test to which an airplane engine has ever been subjected. The Hunter brothers remained in the air for 553 hours, 41½ minutes.

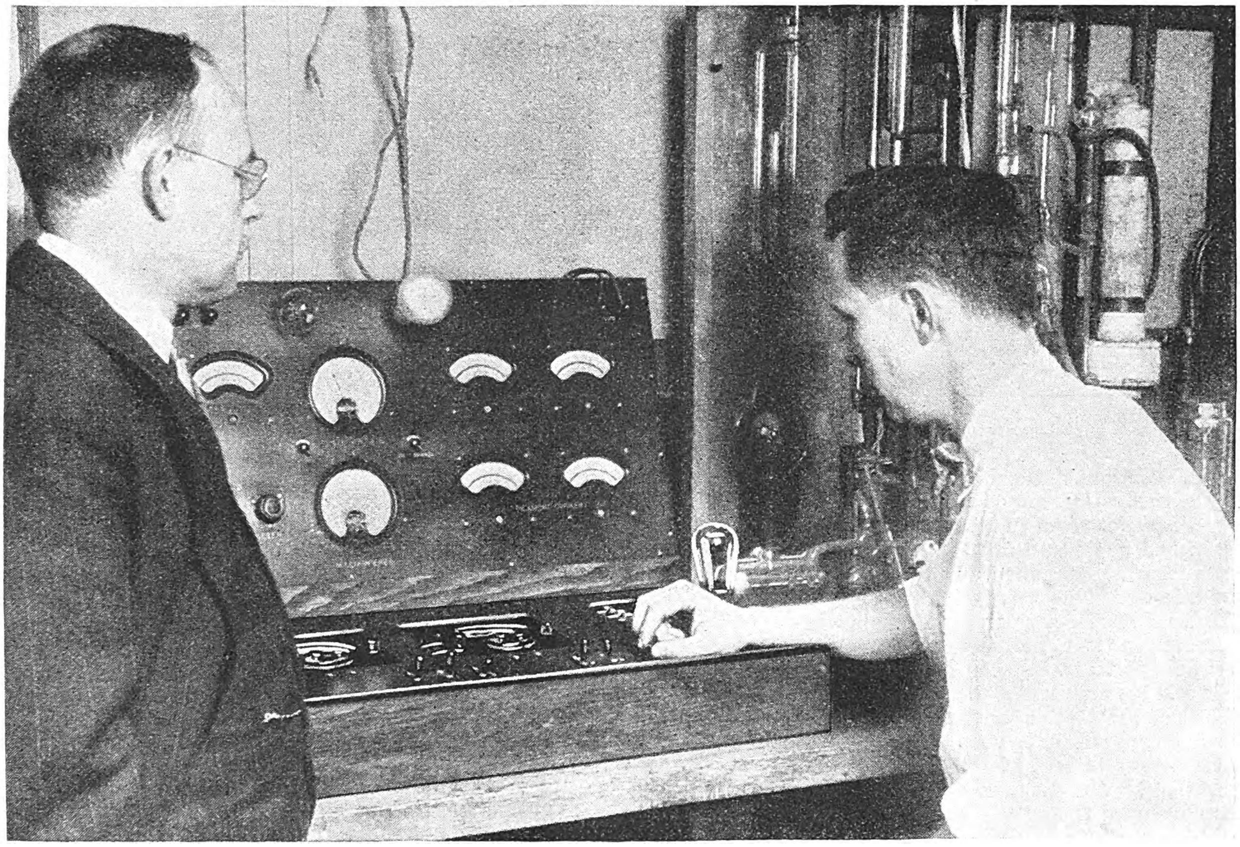
The engine used was a Wright Whirlwind 300, which, before the beginning of the flight, had already had 300 hours service. During the endurance flight, the plane flew approximately 40,000 miles, non-stop, around and around in the vicinity of the airport. This figure, however, is small in comparison to some of the performance statistics of the flight. The revolutions made by the crankshaft were 52,000,000; each valve opened and closed 26,000,000 times; strokes made by each piston were 104,000,000; each piston traveled 9025 miles; and the revolutions made by the supercharger amounted to 405,600,000!

Brain Changes After Gas Poisoning

Poisoning by illuminating gas containing carbon monoxide is one of the most common conditions in modern life. So wide are the uses of gases that the hazard is almost constant. Only the high development of modern plumbing keeps the gases within reasonable limits. Moreover, there is also a hazard from carbon monoxide due to the amount of the gas contained in the exhausts from automobiles. Many cases occur every year due to running the car in a closed garage.

The immediate symptoms after gas poisoning are unconsciousness; if a sufficient amount of the gas has combined with the red coloring matter of the blood death promptly ensues. If the patient recovers, nausea, vomiting, headache, and weakness are not infrequently seen. After the patient recovers, even from severe cases, he may develop secondary conditions, including pneumonia, gangrene, and particularly changes in the nervous system. The nervous system of the human being is such a delicate structure and so highly developed that it is particularly sensitive to poisonous influences.

In a case described by R. P. MacKay, a locomotive fireman 29 years of age who was found unconscious in his garage due to inhaling exhaust gas from his car, developed serious disturbances of the nervous system and symptoms like those of shaking palsy, his speech became monotonous, and his hands and head were subject to tremor.



"SUBSTITUTE NICKEL *for* PLATINUM! we can do Better *than that*..."

When the radio industry was young and only a few thousand technically minded enthusiasts were hooking up receiving sets, radio tubes were a laboratory product. The use of costly platinum-iridium for their filaments was not a handicap. For comparatively few tubes were in demand.

Westinghouse engineers, however, foresaw a serious situation. When millions of radio sets came into use there would not be enough platinum available to make the tubes they would need. A substitute material just as satisfactory must be found. Westinghouse laboratories set out to find it.

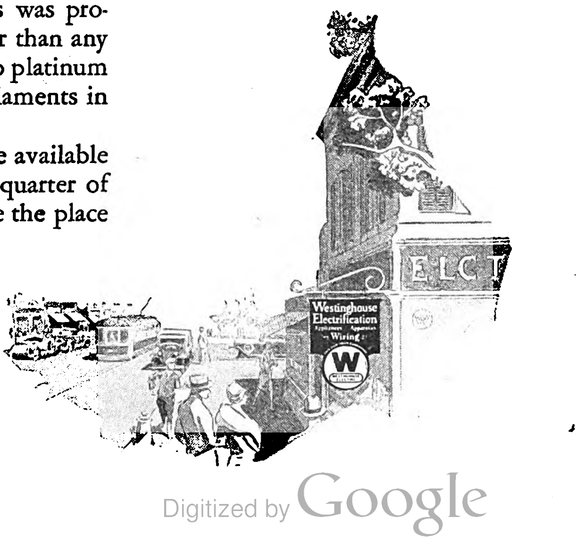
Soon a young engineer reported that nickel would meet the requirements. From a practical standpoint it made as good filaments as platinum. It would do. But Westinghouse engineers said: If a pure metal is as good as platinum, it should be possible to produce an alloy that will be far superior.

Months of tireless research and experimenting followed — development work that called into play the broadest scientific knowledge. Eventually the ideal combination of metals was produced, Konel metal, stronger than any alloy steel, and far superior to platinum as a core for oxide-coated filaments in radio receiving tubes.

If sufficient platinum were available it would take more than a quarter of million dollars worth to take the place of the Konel metal used in vacuum tubes each month. And vacuum tubes are only one of its possible applications. Konel metal meets severe service requirements such as those confronted in gas engine valves and spark plugs. Its commercial possibilities have only been touched.

Tune in the Westinghouse Salute over WJZ and the coast-to-coast network, every Tuesday evening.

Westinghouse



Calcium chloride in its new "flake" form, is also finding growing application in the construction of concrete highways. It may be coated on the surface of the finished paving or added to the concrete mix. In the former case, the calcium chloride cures the concrete by supplying moisture—from the air—for the surface of the new road, thus preventing premature drying of the base as well as the surface. When the chemical is added to the concrete mix—two pounds, in solution, for every 100 pounds of cement—it eliminates all other forms of curing, such as straw covering, and gives a pavement that may be opened to traffic in one half the time required by the old methods.—*A. E. B.*

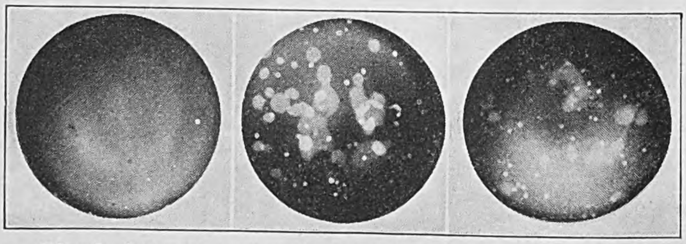
Calcium chloride, a snowy white chemical, coaxes moisture out of the atmosphere when it is spread on dirt roads. This deliquescence keeps the dust down because of the wetness. The chemical is also mixed with concrete to eliminate the costly process of watering the laid concrete or covering it with straw. Above is shown a calcium chloride spreader in action and at right a concrete mixer where the chemical is used

The Germ in the Blood

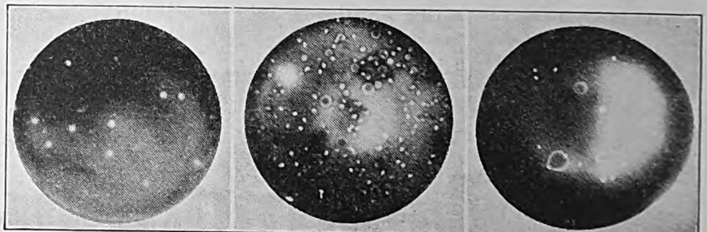
ORDINARILY the blood is free from germs. One may take specimens of blood and put them in a bacterial medium again and again and fail to grow a single germ from the specimen. In times of serious infection, however, germs get into the blood. Since the germs vary in their virulence and in their character it is, of course, desirable to know as soon as possible the type and the numbers of the germ involved. In order to settle this fact, various bacterioologic techniques have been developed, one of the most interesting having been devised recently by Dr. Reuben Ottenberg, who has developed the system called "differential blood cultures."

In system, blood is taken directly from the internal jugular vein, or from the arm vein, or perhaps from a vein directly draining the spot at which the germs are supposed to be developing. Another specimen is taken from a vein at a distant point and the number of germs in the blood taken from two or three places is compared on blood culture plates. If, for example, there is a severe infection of the mastoid or of the blood vessels on either side of the skull, the blood taken from the jugular vein on that side will contain many more germs than the blood taken from the arm vein or the leg vein in the same patient.

As is shown in the illustrations, the method works out satisfactorily and is of great value in making the diagnosis and in determining the procedure to be followed. Doctor Ottenberg applied the method in 29 cases with satisfactory results. Of course, the failure to find the germ in any of the cultures does not absolutely indicate its absence but may indicate the necessity for making a further study one or two days later.—*M. F.*



Blood plates ot a case of thrombosis of the left lateral sinus, showing: left, blood culture from left jugular; middle, from the right jugular; and right, from arm



Plates from a case of thrombosis of right lateral sinus, showing: left, culture from right jugular; middle, from left jugular; right, from arm—white spots are bubbles

Launching and Picking-up Seaplanes

SO far, in using a seaplane in conjunction with a steamship, attention has been concentrated on specially prepared runways or on catapults. For picking up a seaplane from the water, cranes have been employed. *The Aeroplane* (London) points out that long runways are difficult to install, catapults are expensive, and fast steamers are not supposed to stop in the middle of a run.

Therefore an entirely new method of launching and picking up seaplanes, invented by a German engineer named Kiwull, is of decided interest.

The Kiwull "Watersail," as it is called, consists of a spread of canvas about 98 feet long and 33 feet wide, with spreader booms on the under side. One end of this canvas runway is attached to the deck over the stern of the steamship and the other end terminates in a kind of drogue made of wide-mesh netting. This end is attached to the ship by two ropes. The action of the drogue is to cause the water to roll in over the end. This makes it easy for the seaplane to taxi behind the steamer and run onto the trailing runway. When the seaplane is once on the runway, the floats are attached to skids and the whole machine is hauled up the inclined canvas slope. The process may be be reversed for launching.—*A. K.*

Hen Changes to Rooster, Then Changes Back Again

AHEN that became a rooster and then exercised the prerogative of her former sex and changed her mind, becoming a hen again, is the freak fowl described in the *Journal of Heredity* by Drs. R. A. McCance and A. Walton of the pathological department, King's College Hospital, London.

The bird, a light Sussex pullet, was hatched with seven other pullets in March, 1925. In October of the same year all eight commenced to lay and continued to do so until the spring of 1926. All then moulted and while the normal birds soon put on their new plumage, this freak remained practically nude all summer and autumn.

Early in 1927 she slowly assumed male plumage and grew spurs, but no comb. She also put on additional height, becoming two inches taller than her sisters.

She (or "he") commenced to rule the farmyard. She called the other hens to food, escorted them to the nest boxes, shepherded them about the yard, and in general conducted herself like the "cock of the walk." And she laid no eggs at all. In the autumn of 1927 she failed to moult with the others.

During the following spring she was seen going to the nests and clucking. A dozen eggs were placed under her as an experiment. Still wearing her male feathers, she faithfully sat on them, hatching out 11 chicks and proving an excellent mother afterwards.

Subsequently, still in male disguise, she began to lay eggs again. That autumn she moulted, resuming female feathers, but keeping her spurs. Throughout the winter of 1928 and spring of 1929 she laid regularly, mostly doubled-yolked eggs.

Usually when a hen reverses her sex, an examination of her internal organs will disclose some diseased condition, most probably in her ovaries. But when this hen-rooster-hen was killed and all of her glands subjected to minute examinations, nothing whatever could be found wrong with them. She remains an unsolved physiological riddle.

The editor of the *Journal of Heredity* adds a note telling of a somewhat similar case recorded a couple of years ago in this country. A hen assumed male feathers, but continued to lay. While she was still disguised as a rooster she was mated to a real White Leghorn male bird, and produced fertile eggs. She did not, however, raise her own family. Subsequently she moulted and her new feathers were those proper to her female sex.—*Science Service.*

Calcium Alloys Find New Uses

NEW commercial calcium alloys have been studied by Prof. J. Meyer, of Breslau, Germany, and are finding various uses. They are rather sensitive to air and moisture, forming a dense white smoke when burned. For some purposes the activation of calcium by sodium is of significance.

Chemical and Metallurgical Engineering reports that experiments by A. von Antropoff at Bonn have proved that minute quantities of metallic sodium at the surface of calcium can incite its reaction with nitrogen. Calcium filings can be activated by precipitated sodium fumes. The same investigators likewise report on the reaction of calcium and nitrogen in the presence of the rare gases, by which argon, for example, can be quickly and completely freed of nitrogen. The use of this process for the extraction of helium from natural gas seems to offer interesting possibilities.

Measuring Height in Seaplane Landings

A CABLE from London to the *New York Times* reads as follows:

"Experiments carried out at Calshot make night flying possible for seaplanes by means of small searchlights fitted beneath each wing. The rays converge at a predetermined distance from the plane, forming a large patch of light on the water and revealing exactly how far the pilot is above the surface when he is coming down."

It is quite difficult to estimate the height above water even in the day time, because definite points of reference are lacking. At night this is well nigh impossible. The cable needs a little interpretation, however.

If the small searchlights are placed under

Miles and Miles of Yellow Strand

This is the age of big projects—the deepening of waterways; the digging of great canals for transportation and drainage; the erection of mammoth dams to impound water for irrigation and power.

It is no mere coincidence that miles and miles of Yellow Strand Wire Rope are constantly employed in these enormous construction projects. The excavating and handling machinery are of the largest capacities obtainable—and each year finds them larger, putting ever increasing strains on their wire ropes. Only such rope as Yellow Strand can stand the gaff—economically.

Yellow Strand is designed and made especially for heavy duty. Its wire is drawn to our special specifications, from steel of Swedish origin. And over fifty years of wire rope making experience go into its manufacture.

One strand of yellow is its *visible* difference from all other ropes and enables you to *see* that you get Yellow Strand when you specify it.

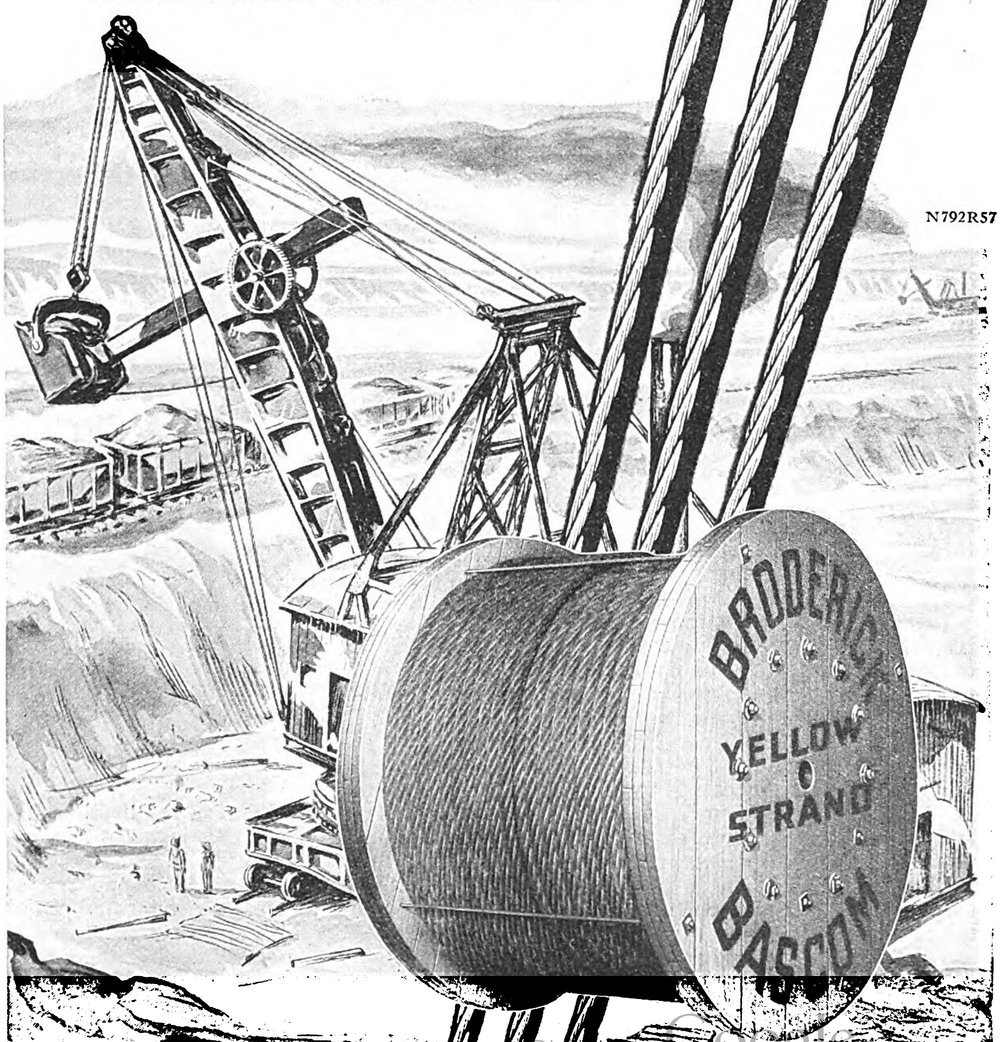
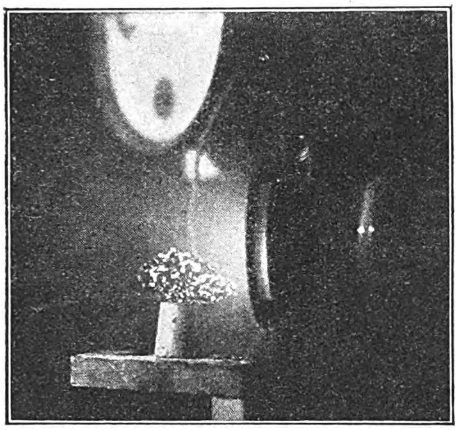
N792R57



each wing tip, at the proper angle to one another, their lights will indeed converge at a certain fixed distance from the wing. If the distance between the searchlights and the angle between them are both known, this distance is readily calculated. Now suppose that, by means of an inclinometer, we can tell the inclination of the plane to the horizontal. Then we can calculate its distance above the water. The naviagtor in these experiments probably sights the patch of light, reads the inclinometer, and picks off the height from a large and clearly visible chart mounted on the dashboard in front of him.



How minerals glow when subjected to the influence of cathode rays

The device is only in its experimental stage, but is evidently correct in principle, and may be very helpful in the night flying of seaplanes.

Cathode Rays Detect Synthetic Jewels

SYNTHETIC sapphires can be detected readily from the natural stones by means of the cathode-ray tube. The use of the tube in this work is the first commercial application of the apparatus which was developed in the research laboratory of the General Electric Company by Dr. W. D. Coolidge about four years ago.

Sapphires, next to diamonds in hardness, are used by the company at the rate of more than a million and a half a year as jewels for bearings in meters and other delicate electrical instruments.

Trays of sapphires, both natural and synthetic, are exposed in a dark room to the powerful rays of the tube for a few seconds. All glow or radiate colors while exposed to the rays, but when the rays are turned off, the natural stones cease to glow whereas the synthetic stones continue to glow.

In addition to sorting the natural from the synthetic sapphires, the rays also help determine where both the natural or factory-made gems come from, an important advantage according to engineers.

"Should sapphires from Montana be mixed with stones from Australia, we could find this out with the cathode rays," B. W. St. Clair, of the company's standardizing laboratory at Lynn, Mass., explained. "In the case of synthetic stones, in most cases we can determine which factory made them by the different hue of the glow while the rays are on.

"We have one particular kind of natural sapphire which does not glow at all. In this case, the lack of glow under the rays immediately tells us its origin."

Tests have been made with diamonds and it has been found that synthetic stones turn decidedly brown when placed in the rays, whereas there is no change in natural stones. However, these tests have been but meager and no definite conclusions have been reached.

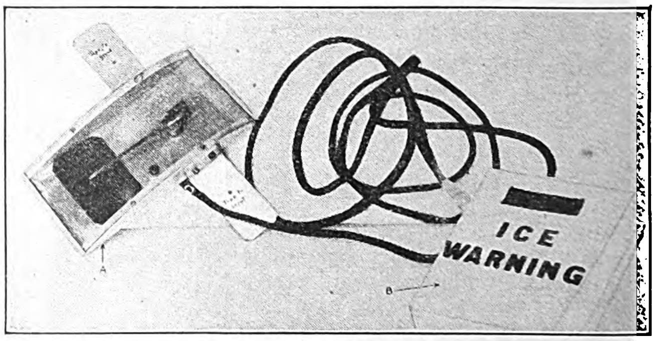
An Ice-Warning Thermometer

IN our July 1930 issue we described the very interesting experiments of Dr. Geer of Ithaca, whereby rubber, oil-impregnated airplane "overshoes" seem to have met the danger of ice formation. It still remains to be seen whether practical aviators will resort to these overshoes. Airmen have a horror of gadgets, and operators may fear that the added cost and a possible decrease in aerodynamic efficiency will be prohibitive. In the meantime it is the concensus that it is a very sound plan to warn the pilot that he is flying in a danger zone, namely where temperatures are between -4 degrees and 0 degrees, centigrade, and when he had better proceed to a zone of higher or lower temperature. A special instrument designed to warn the pilot of this danger zone is described by H. B. Hendrickson in *Instruments*. It is shown in the photograph. Essentially it is a temperature-actuated switch which controls a red light on the instrument board of the airplane.

Rough sapphires, synthetic and natural, are sorted by cathode rays

The thermal switch A is placed on the strut or other exposed part of the airplane, while the indicator box B is installed in a convenient place in the cockpit. The light behind the window in the indicator appears only at the above mentioned temperature range, -4 degrees to 0 degrees. For ease in installation on the ship, the instrument is made up in a unit with its own battery, using pocket flashlight cells of standard size, located in the box B.

The unit A in the illustration at the right is the thermal switch of the ice-warning thermometer. The box B is the indicator, and contains the battery



A bi-metal coil moves the switch, as the temperature decreases or increases and expands or contracts the coil. The contact points are made of coin silver. The lower contact is made crescent-shaped so that the switch arm can easily ride over it without jamming. When the temperature is in the danger zone, the switch assumes such a position that the circuit is closed and the battery lights the lamp.

Although the bimetal coil and contact points are enclosed to provide protection against the weather, tests show that the lag is not appreciable. Severe vibration does not interfere with the instrument.—*A. K.*

Mechanical Exercisers

DURING the past year there has been a great vogue for vibration and shaking of various portions of the body by the use of machines especially built for the purpose. These machines have been sold with claims that they would reduce weight, increase health, and in many ways take the place of exercise. Actually the machines are simply devices for producing passive motion in some part of the body. Moreover, cases have occurred in which the machines have been used by people with ulcers of the stomach and intestines or with swollen gall bladders, and the results of the agitation have been to burst the ulcer or to increase the inflammation and thereby to cause serious illness if not death of the patient.

The Council on Physical Therapy of the American Medical Association has recently issued a report governing the use of these devices. The Council argues that the point of view which their use develops in the patient is wrong. The advertisements and the instructions for their use often convey the impression that the machine will do the work necessary to cure the patient and that the patient does not have to work. Volitional effort is not encouraged, and the machine often is regarded as the only factor in the cure. The more expensive the apparatus or installation, the more this thought will be developed. These machines do not develop volitional effort of any kind—the work being done for and not by the patient. This develops a poor mental attitude in a patient and will react to his detriment.

These machines do nothing that can not be accomplished equally well by simpler apparatus or none at all. For example, many of these machines are sold to reduce excessive abdominal adipose tissue. In these cases the same results could be accomplished by leg and abdominal exercises without apparatus, with the patient giving himself heavy kneading massage at the same time that he is taking his exercises. In most cases, for general weight reduction, much better results could be attained by a walk or a slow run in the fresh air.

These machines treat only one part of the body at a time and do not have the advantages of general exercise in developing other parts of the body. Vibratory massage of the abdomen with a strap attached to a motor for 10 minutes can not give as much benefit as does a 10-minute fast walk with conscious effort given to pulling in the stomach. The benefit of deep breathing, exercise of many muscles, and increase of circulation is actually obtained under the latter conditions.

The use of apparatus is stereotyped and monotonous. The physician prescribing one of these machines is making the same mistake that he would by prescribing only one form of massage or exercise. The patient will soon tire of its use. This form of massage vibration and shaking has little place in treatment, and better results could be secured by definite exercises varied enough to prevent monotony or by occupational therapy to prevent loss of interest.

The physiologic effect of mechanical exercisers is the same as of that form of massage which gives vibration and shaking. The effect of this form of massage has not the same effect as active exercises and can not have the same benefits.

The mechanical exercisers are often actually dangerous. The Council on Physical Therapy has records of severe injuries caused by these machines—ruptured appendix, hernias, ruptured bladder, ruptured duodenal ulcer, pleurisy with effusion, and torn penis.

The Council on Physical Therapy of the American Medical Association therefore condemns the sale of these mechanical exercisers to the public for the following reasons:

1. Volitional effort is not encouraged.
2. The same results could be accomplished without an apparatus.
3. Treating only one part does not give any of the advantages of general exercise.
4. The use of such apparatus is monotonous and the patient loses interest in treatment.
5. The effect is that of massage and lacks the physiologic benefits of exercise.
6. Such apparatus is definitely dangerous.—*M. F.*

Could Pave Broadway With Silver—But Won't

THE world production of silver for the entire period from 1493 to 1927, inclusive, has been over 14,000,000,000 ounces, or about 14 times the weight of gold produced in the same period, according to the United States Bureau of Mines, which has conducted an economic survey of the subject. This amount of silver would make a cube measuring 114½ feet on an edge; or it would pave Broadway, New York, six inches deep, from the Battery to Central Park, a distance of over four miles. Since 1888, more silver has been produced in the world than in the period 1493 to 1887; in other words the production of 396 years has been exceeded by the production of the last 39 years.

In spite of the greater relative increase in the production of gold than that of silver, the price of silver has declined. This decline in the price of silver has been a result of a lessening demand rather than an ab-

A GUARANTEED INCOME FOR LIFE

$250 a month
beginning at
Age 55, 60 *or* 65

THE Phoenix Mutual announces a new Retirement Income Plan under which you get not only immediate protection for your beneficiaries but also, for yourself in later years, a guaranteed income you cannot outlive.

What a $25,000 policy, payable at age 60, will do for you

It guarantees to you when you are 60

A Monthly Income for Life of . . $250.00 which assures a return of at least . $25,000.00 and perhaps much more, depending upon how long you live. Or, if you prefer, a cash settlement of $33,750.00

It guarantees in event of permanent total disability before age 60

A Monthly Disability Income of . . $250.00 and payment of your premiums while disabled.

It guarantees upon death from any cause before age 60

A Cash Payment to your beneficiary of $25,000.00 Or a monthly income as long as your beneficiary lives.

It guarantees upon death from accidental means before age 60

A Cash Payment to your beneficiary of $50,000.00 Or a monthly income as long as your beneficiary lives.

Send for the Facts

The plan above is for an income of $250 a month, payable at age 60. You may arrange to retire at other ages than 60 if you wish. You may provide for yourself a Retirement Income greater or smaller than $250 a month. Plans for women are also available.

Other things you can provide for by this program are: Money to leave your home free of debt. An income for your wife in case she should outlive you. Money to send your children to college. Money for emergencies. Money for special needs. There is hardly a financial problem which cannot be solved by this plan.

A Retirement Income does not have to be paid for all at once. It is usually paid for in installments spread over a period of 20 years or more. Naturally this makes the individual installments comparatively small.

One of the great advantages of this plan is that it goes into operation the minute you pay your first installment. As you continue to invest, the fulfillment of your life plans is guaranteed.

Even though you should become totally disabled and unable to make another payment, your payments would be made by us out of a cash reserve provided for that purpose. Your home would be left clear of debt, just as you had planned. Your children would go to college, expenses paid, if you had planned it so. And, beginning soon after you were disabled, you would have $250 a month to live on so long as the disability continued, even if it should last the rest of your life.

We should like to send you an interesting 28-page book called "How to Get the Things You Want," which tells all about the Retirement Income Plan and how it can be exactly suited to your own special needs. No cost. No obligation. Send for your copy of this free book today.

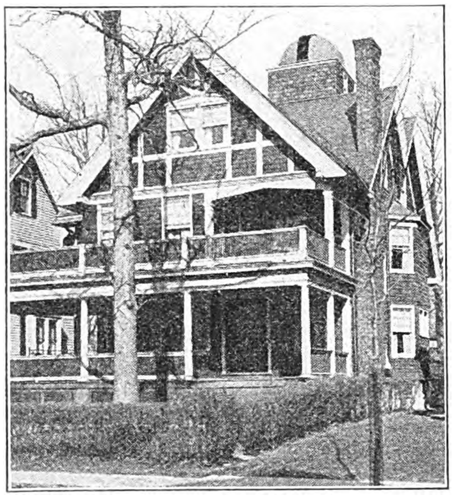
The Amateur Astronomer

Conducted by ALBERT G. INGALLS

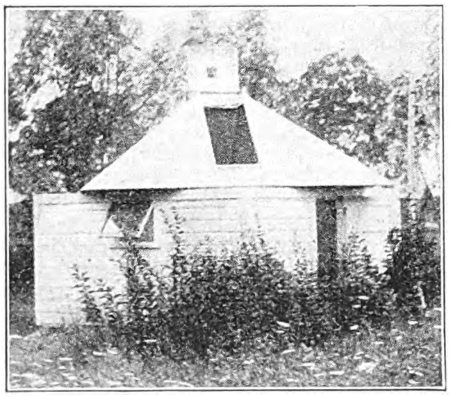
NOW that cooler days to work in are in sight, it may be about the psychological time to think of building a private observatory to house the telescope for more comfortable use in the cold months. It seems odd that more amateur telescope makers have not thus equipped themselves.



Pickering's housetop observatory

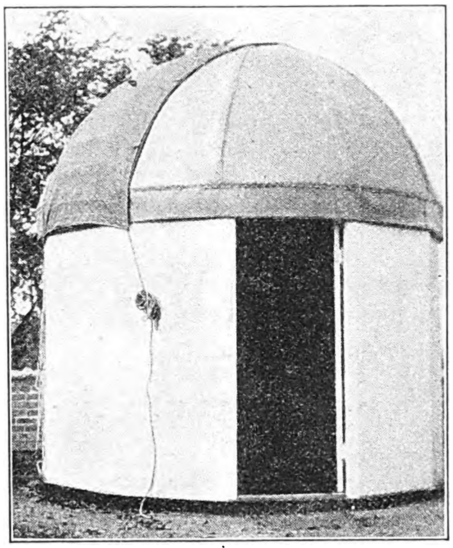
One of the best observatories is the simple straight-sided box type, equipped either with a slide-off roof or a traveling gantry roof as shown on the opposite page. However, there is this to be said: None of these straight-line "chicken-coop" types of structure look much like an astronomical observatory. The amateur may perhaps be pardoned if he prefers his neighbors and townspeople to know that the structure he creates houses a telescope.

To build the hemispherical type of dome requires no particular skill, though admittedly it involves considerable fussing and fitting. Designs vary widely. Usually the dome proper consists of a horizontal wooden ring and a number of upright curved ribs, covered with some kind of roofing and provided with a slot opening for the telescope. The whole dome is mounted on rollers and turns on the plate of the fixed building.



Yalden's design, turned cornerwise

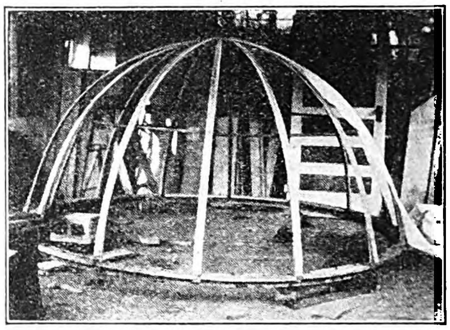
This building may be round or square, but many of those who have "been there," and who speak from actual experience, will swear by the square type of building, because its four corners give room for a small built-in desk, for built-in seats, cabinets, bookshelves, and for a parking place for visitors, who sometimes get under foot in the more constricted, round type of observatory.



One of Schroeder's designs

THE roof-top observatory of D. B. Pickering, of East Orange, New Jersey, the well-known variable star observer, is a good illustration of the square type. There is no mystery about the building proper, exclusive of the dome; it is simply a square structure built on top of the house. Note that the entrance is not through a trap door in the floor but from the roof through a door. This leaves the floor clear. Pickering did not run a masonry pier to the ground, as many think imperative, but rested the telescope pedestal on cross timbers attached to the roof. Will the vibrations of the house not destroy the good seeing? Pickering's success in variable star observing says at least, "not necessarily." The same bogey was faced when a large telescope was placed on the roof of a 13 story building at Columbia University, but the predicted ruination of seeing due to vibration did not materialize (*Popular Astronomy*, June–July, 1928; also same, Oct., 1926). Pickering saw to it, however, that the immediate flooring of his observatory did not touch the support of his telescope; he also insulated the floor against heat from the house below.

Another square type of observatory is that of George Waldo of Fairfield, Connecticut, designed by J. Ernest G. Yalden of 120 Woodbridge Place, Leonia, New Jersey, a variable star observer. This has a pyramidal "dome" which rotates on a circular track. The side shutter lifts off, while the small level truncation at the top has a lid that tips back. By the way, the shutter should be at least 24 inches wide; a narrower one is a nuisance. It may, if one prefers, be made in two halves, like a sloping cellar door, opening outward.



Light weight dome (by B. W. St. Clair)

ALBERT F. SCHROEDER, 1075 Forest Cliff Drive, Lakewood, Cleveland, Ohio, kindly let us see some drawings from which several observatories, including one

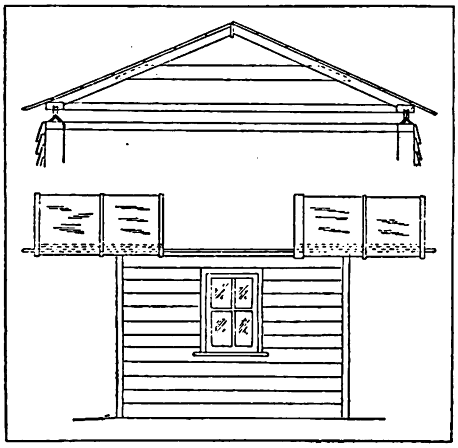
Assembly of a typical observatory dome, after Schroeder in China, have been made. The original drawings can not be reproduced but the accompanying sketches based on them may serve to give ideas concerning a good structure. The main elements are: A solid circular track, for which wood, if leveled well, will do; about eight good rollers (Charles D. Higgs of Fontana, Wisconsin, used roller skate wheels—see *Popular Astronomy*, Aug-Sept. 1928); some kind of device or guide to keep these rollers on the track (here Mr. Higgs used eight more skate rollers bearing sidewise, while the sketch shows Schroeder's method); something to keep the dome from being lifted off by the winds, (Mr. Schroeder uses simple iron hoop stock bent to embrace but not touch the dome ring, as shown on sketch). The maker may juggle and recombine or revise these or other elements to suit his own taste. Past experience with amateur ingenuity in telescope construction gives promise of a wide variety of new ideas; some of which will be good and a few better yet. The average amateur dislikes being pinned down to a standard, inflexible design to copy. He prefers to do most of his own designing.



Courtesy *English Mechanics*

W. R. Evans' design—gantry type

A good dome ring can be made of ⅞-inch pine stock cut to proper radius, lapped alternately, glued and screwed together. The vertical pieces are made in the same way. This makes a heavy dome, but one that will "stay put" in all weather. Any kind of roofing will do, from unsupported canvas, giving the "starved dog" effect, to sheet metal—suit your own skill, taste, patience and pocketbook.

SOME good hints and a few plans will be found in Bell's "The Telescope," Chapter 10, and others in various back numbers of *Popular Astronomy* (see A.T.M., page 260). In the average case, however, an ingenious amateur will prefer to "roll his own," thus giving him the right to take credit for the whole job. We have no "blueprints, instruction pamphlets, or set specifications" of any kind. Those who expect to hire a carpenter to do the job may need these, it is true, but if anyone plans to have it done in that manner the best thing is to go to a professional designer of observatories. The above, which is not too precise a description, was written for the fellow who enjoys doing his own jobs.

Amateur telescope making fans may be interested in knowing that the hobby is still going strong—stronger, in fact, than at any time since 1926. This is the first year in which interest has not dwindled to a tricklet during the hot months.

Statler service

awaits you in six cities

So you get "Statler Service" here, from employees trained in an interested helpfulness to guests.

You get the comforts of radio in your room, a morning paper under your door, running ice water, a bed-head reading lamp, and other "extra" conveniences for which you aren't charged extra.

You get the benefit of rates which are fixed and unchanging, regardless of conditions — and every room's rate is posted, in plain figures, in that room.

And you get a guarantee of your satisfaction, from the time you come in the door.

In any of six cities you can have "Statler Service."

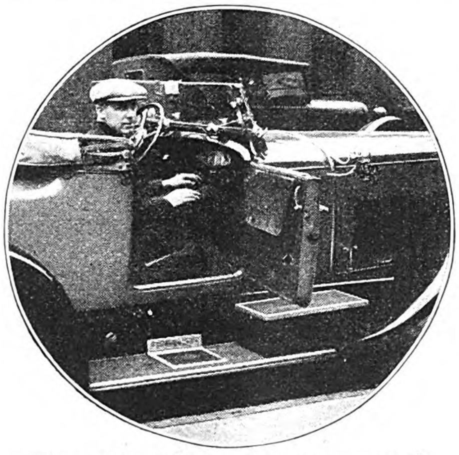
The Scientific American Digest

(*Continued from page* 223)

normally increasing supply. The lessening demand has been due very largely to demonetizing of silver during the latter part of the 19th Century by the principal nations of the world. Demonetization became possible through the enormous increase in gold production that followed invention of the cyanide process in 1887 and development of the gold fields of South Africa, yet a number of countries still retain the silver-gold standard. Most orientals use silver as a medium of exchange almost to the exclusion of gold. Silver may thus be regarded as a second line of defense for the maintenance of the metallic foundation of monetary systems, but the future of its production will be influenced largely by the production of gold.—*A. E. B.*



The auto-radio receiver is mounted in a box on the running board

Gas Is Big Factor in Aviation Safety

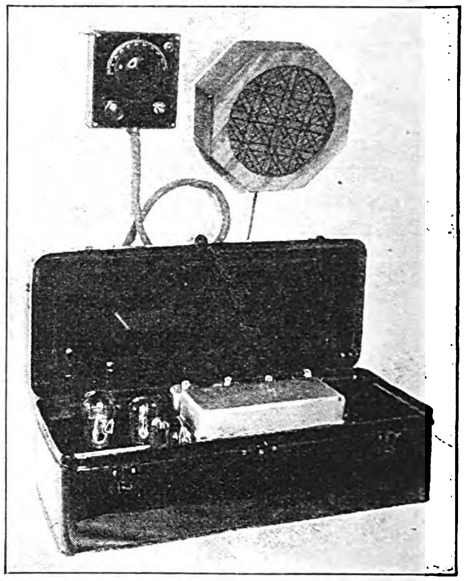
In aviation a man's life literally "hangs by a thread," but the strength and importance of this "thread" depends on gas, according to *Industrial Gas*.

The manufacture of tie rods and tie wire for heavier-than-air machines relies largely on the steady, intense heat of huge gas-fired ovens. These parts, the "threads," are subjected to a temperature of about 300 degrees for six hours for the purpose of driving off any hydrogen that may have been absorbed by the steel wire. This process makes the wire strong and slender in order to assure the least possible air resistance.

Auto-Radio Kit

Practically all of the automobile radio receivers that have appeared so far are intended for concealment behind the instrument board or under the engine hood. A new set in kit form, recently placed on the market by the Pilot Radio & Tube Corporation, is rather unusual in that it is designed for mounting on the running board, or possibly in the rumble seat of roadsters or coupés. The new outfit, bearing the name "Auto Pilot," is supplied in kit form and must be assembled, wired, and installed by the individual purchaser, who will find the work easy, interesting and enjoyable.

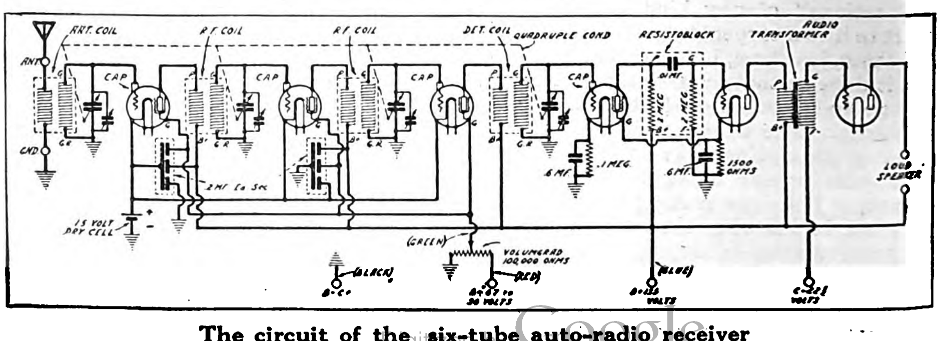
The receiving unit itself is contained in a black japanned steel case. This is 22 inches long, 8 inches wide, and 6⅞ inches high, flat enough to let the doors of all makes of cars clear it by a comfortable margin. The set is controlled from the inside of the car by means of a flexible cable which terminates at a control box 5½ inches square and 2 inches deep. The cable is six feet long and is enclosed in a protective sheath of waterproof fabric.



The assembled auto-radio in its box; the control panel that is placed in the car; and a small loudspeaker

The movement of the tuning dial on the control panel is transmitted to the shaft of the variable condenser by means of two brass chains fastened to pulleys at both ends. These chains slide in separate flexible tubes, and run smoothly in spite of their length. The other devices on the control panel are the usual pilot light, volume control, and filament switch. The volume control is a potentiometer that regulates the voltages to the screens of the R. F. tubes.

Electrically, the receiver is of simple but reliable design. It makes use of three stages of tuned R. F., a screen-grid detector, one resistance-capacity audio stage and one transformer stage. All the parts are mounted on a formed and drilled



The circuit of the six-tube auto-radio receiver

aluminum chassis or foundation unit. Six tubes are employed: four 224's, one 227, and one 245. Plate voltage is supplied by three 45-volt "B" batteries.

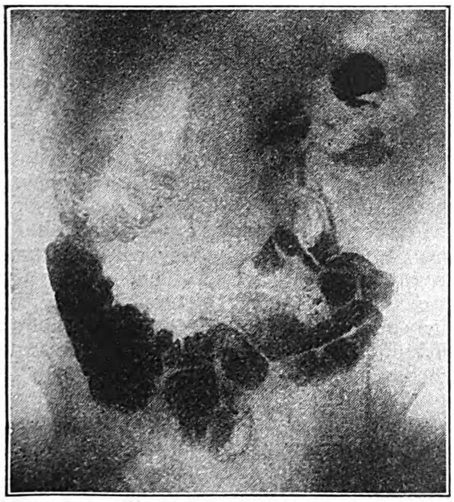
The radio-frequency gain in this receiver is pushed quite high and little attention is given to selectivity because this matter is taken care of automatically by the necessarily small antenna that is used. For an aerial, a pair of wires strung between the front and rear axles, under the car, has been found very effective. Where the shielding effect of the chassis is too great, a piece of copper screening may be tacked to the inside of the top of the car, or a wire run around the edges of the running boards.

Air Swallowers

ONE of the most common American complaints is the swallowing of air, sometimes called "aerophagy." At least 60 percent of people with disturbances of the gastro-intestinal tract swallow air and belch. In fact, the habit is not associated merely with modern man, since it is referred to in the writings of the ancient Greeks and Romans, including Martial and Petronius. Among the causes particularly for the swallowing of air and its return are rapid eating, gulping of food, and involuntary swallowing of air during breathing. With almost every swallow of food or saliva air enters the esophagus and is either eructated at once or goes into the stomach.

Dr. Asher Winkelstein has given special attention to this trouble, and mentions the fact that there is one group who voluntarily swallow air in large quantities and expel it at all times and in all places. These people are usually neurotic and perhaps indulge in this performance as a means of expressing themselves.

Another group has various forms of gall-bladder, intestinal, heart, or liver disease, with a constant sense of pressure in the abdomen. Having learned that belching will relieve their sense of pressure in the abdomen they swallow air, belch, and thus temporarily obtain a sense of relief. When air is swallowed, it is trapped in the stomach by a contraction of the end of the esophagus and by a spasm of the pylorus through which the stomach empties into the intestines. It requires some time or activity to cause the air to leave.

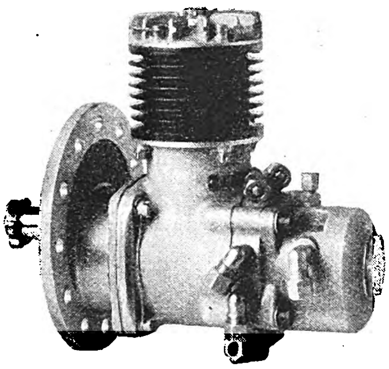


X ray shows the distended stomach and intestines of an air-swallower

In the control of the condition, Doctor Winkelstein recommends the training of habits so that air will not be swallowed, the use of mild sedative substances, and occasionally instrumental dilation of the end of the esophagus which has not only the instrumental effect but the possibility of powerful psychologic effect. It is, of course, necessary for the physician who examines such a patient to determine definitely that this symptom exists and not anything more serious as, for example, heart disease, intestinal obstruction, or fermentation.—*M. F.*

The Heywood Injection Starter

SWINGING the airplane propeller in order to start the engine will soon be entirely a thing of the past. The dangers and discomfort of swinging have been replaced by starters of various types—electric, inertia, hand, and pressure-injection types. The Heywood starter, of the latter type, built by the Sky Specialties Corporation, has been fitted successfully to many engines and in many planes.



Compressor of an injection starter

The Heywood starter consists of a small air compressor, a steel tank, a pressure regulation valve, a starting valve, inlet valves for each of the cylinders, tubing, pressure gage, and primer. The weight of the starter is about 30 pounds.

The small air compressor, shown at the top part of the accompanying photograph, is driven off the rear of the engine shaft, requires only one quarter of a horsepower, and can refill the starting tank in one minute.

The tank (not shown in the illustration) has a capacity of about one half of a cubic foot, and holds air at 400 pounds per square inch pressure.

When starting the engine, the pilot primes in the usual way, but the gasoline does not go directly to the cylinders or the manifolds of the engine, but into a small gas chamber on the starter where it is held until the starter trigger is pulled.

After the ignition is switched on, the starter trigger is pulled. The trigger allows the air to be released from the tank and to go to a chamber in the starter where it is routed by means of a rotating disk that is timed on its shaft with the engine. This rotating disk has one large and one small hole, and rotates close to a stationary disk that has as many holes as there are cylinders in the engine. The large hole in the rotating disk registers with the appropriate hole in the stationary disk and allows the compressed air to go through to the cylinder which is in position for a power stroke. This starts the engine in rotation.

Simultaneously, part of the air in front of the rotating disk goes to the gas chamber, and forces the gasoline through a small

Promote, Manufacture, Distribute and Finance

●

This advertisement is addressed to an inventor, manufacturer or patent holder, of an article having possibilities of a large potential market, but limited by lack of organization or financial backing.

●

One of the country's largest corporations, in expanding its activities, is looking for a new product to manufacture and sell.

Negotiations are invited (1) on the basis of outright purchase of a small business having a good product but lacking merchandising ability or capital, (2) or of a product still in the experimental stage, (3) or of a patented article, probably of a mechanical nature, that can be developed and put on the market.

A complete description, accompanied by blueprints, if possible, should accompany your reply, which we will forward to the company, where it will be seen by one man, a major executive, and held in extreme confidence.

For the right product this advertisement opens a way for future development which has seldom been duplicated in the annals of American business and manufacturing.

Address all correspondence to Howard L. Spohn, Vice President, Gardner Advertising Company, 1 Pershing Square, New York City.

Personal interviews
or telephone calls
cannot be considered.

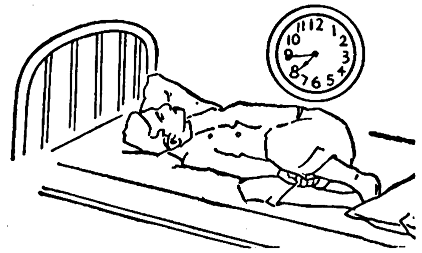
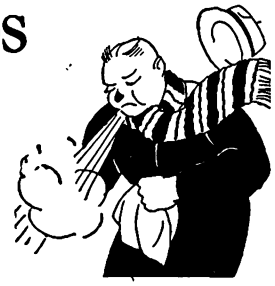
ACROBATICS while you SLEEP



Are you *sure* that you "slept like a log" last night? Or, would a moving picture machine reveal you rolled up like a ball, twisted like a rope or hanging over the side of the bed like a line of clothes? Drs. Johnson, Swan and Weigart took movies of 150 sleepers. The results were astonishing. They showed that a soundly sleeping, healthy man may struggle through forty or fifty different positions nightly, not one of which will be held more than an hour. A description of this extraordinary, scientific experiment, with pictures of 33 "sleeping beauty" postures appears in the September HYGEIA, the Health Magazine of the American Medical Association. It is a real contribution to an all important subject.

COLDS *and The Other Fellow*



You have heard that colds are contagious, and you would like to know just how they are spread so that you can allay unnecessary fears and sensibly avoid the cold-infection. The September HYGEIA contains a timely discussion, by Dr. Rachael Ash, especially directed to parents and teachers, explaining the way colds spread and how to keep yourselves and your children from catching the debilitating cold germ—a most helpful article with the cold season just around the corner.

Other Vital Features in HYGEIA

"How Much Should the Patient Know"—"The Tardy but Tempting Tomato"—"The Movies in Medicine"—"The Undernourished School Child"—"Questions and Answers"—these are only a few of the features of the September HYGEIA. Every article is written by an authority who proves theory with practice. The language of HYGEIA is non-technical, simple and even entertaining. Every issue is a gold mine of reliable health information. As you value your health you will value HYGEIA.

carbureter nozzle that projects into the center of the rotating disk and up to the small hole that also registers with a hole in the stationary disk, and allows gas to flow to the appropriate cylinder.

There is therefore simultaneous rotation of the engine and injection to the cylinders from a small gas supply of a richly carburetted mixture. The starter rotates the engine at 400 to 500 revolutions per minute.

It is claimed for the starter that it will function under almost any weather conditions, that it does away with the danger of back-firing, and that it is simple, dependable, and easy to operate.—*A. K.*

Explosions in the Laboratory

THE hazards of industry are seldom considered as concerning the research worker in the laboratory. Nevertheless, the chemist, the pathologist, the bacteriologist, and indeed even the physicist are constantly working with chemicals, germs, poisons, and electrical materials which can put them in jeopardy. Dr. John A. Marshall has reported an unusual incident in the laboratory in the University of California devoted to the staining of tissues.

In the incident reported, sections of bone and teeth were being stained by the silver nitrate method. The dishes containing a solution of ammoniacal silver oxide were left standing in the sun from Saturday noon until Tuesday morning. There were traces of alcohol in the silver solutions, carried there by the pieces of tissue which had been previously immersed in alcohol. The sunlight hastened the chemical change between the silver, the chemical, and the alcohol. As a result a highly explosive, sensitive, and unstable compound called silver fulminate developed. When the dish was taken up to be emptied and cleaned, it was warm from the sun and the mere movement of the liquid caused the fluid to explode.

As a result the warning is issued that one should never work in the direct sunlight with silver solutions or leave bottles or dishes containing them exposed. Every precaution must be exercised to keep out ethyl alcohol, and containers for silver solutions should be immersed promptly and carefully in cold water.—*M. F.*

Inventor of Ethyl Gasoline Scores Again With New Refrigerant

THE "big news" of the recent meeting of the American Chemical Society in Atlanta was the announcement of a new refrigerant, non-inflammable and non-toxic, by Thomas Midgley, Jr. Anything that Midgley announces is apt to be big news, for he has a way of striking out on entirely original lines and developing something that boosts General Motors stock. Midgley is the chemist who discovered the anti-knock properties of tetra-ethyl lead, and he was the first president of the Ethyl Gasoline Corporation. Now he has turned his genius to the perfecting of a refrigerating medium that his company can use in household electric refrigerators without the remotest risk of danger from leaky coils. His discovery of the suitability of dichlorodifluoromethane gives promise of the early use of refrigeration for air cooling in homes and theaters and other public gathering places where refrigerating engineers have hesitated to risk accidents with poisonous or explosive refrigerants.

Dichlorodifluoromethane is made from carbon tetrachloride (a common fire extinguisher) and antimony trifluoride. Human beings and animals can inhale vapors of dichlorodifluoromethane without the least ill effects. It is not only non-inflammable, but it is actually a good fire extinguisher. Of course, it is stable and possesses the necessary vapor-pressure characteristics for a good refrigerant. It boils at -30 degrees, centigrade, and freezes at -155 degrees, centigrade. It is non-corrosive with steel, aluminum, copper, tin, and monel metal.

Thus, while proponents of diverse standard refrigerants were arguing the question of which was the safest and best, Mr. Midgley settled the question in characteristic style by creating a new one which left no grounds for argument.—*A. E. B.*

The Future of the Aviation Industry

THE Curtis Publishing Company has recently issued a magnificent book summarizing a long and thorough survey of the aviation industry. The study is most comprehensive, covering planes, schools, markets, speed, comfort, air transport, financial, and many other aspects of the industry. The material presented is accurate but not new. What is valuable is the conclusions of careful and independent observers as to the "underlying trends." These conclusions appear in the very first chapter and are of interest to any one who is at all concerned with the future of American aviation. We quote from this chapter in part:

"We have confidence that the aviation industry will develop into a large and sound industry. This confidence is based on two facts. First, the idea of air travel is sound. Air travel is certainly the quickest, we believe it can be made the most comfortable, and ultimately we think probably the least expensive method of long distance travel."

"Enthusiastic service appears to be more true of aviation than any other form of transportation and also more true of aviation than of any other industry we have studied. . . ."

"It seems to us likely that ultimately all first-class mail will be carried by airplane wherever an airplane can speed delivery; that a majority of 'Pullman class' day travel for distances in excess of 100 miles will be by air; that air package transport may exceed first-class mail and passengers combined."

The report is equally enthusiastic about the possibility of privately owned planes having a large market. The findings are qualified, however: "If through the autogiro or some other principle, it comes about within the next five years, that planes when they lose speed will settle to the ground without damage, if they can be taken safely into and out of a four-acre lot, and if a person with average mechanical training can in a short time at small expense learn to fly a plane safely, and if, furthermore, planes are sold at prices comparable with automobile prices, within fifteen years, there should be 1,000,000 privately owned planes in operation with an annual market of 250,000." This view defines at least the problem before our constructors and they will certainly do their utmost to meet the challenge successfully.—*A. K.*

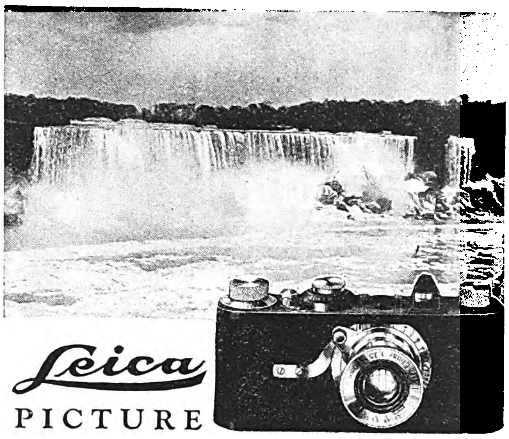
THE 92 ELEMENTS is a folder giving their numbers, names, symbols, atomic weights, melting points, and years of discovery. *P. C. Kullman & Co., 110-116 Nassau St., New York City.—Gratis.*

ACUTE RESPONSE OF GUINEA PIGS TO VAPORS OF SOME NEW ORGANIC COMPOUNDS. I. ETHYLENE DICHLORIDE (Reprint No. 1349 Public Health Reports, Public Health Service, U. S. Treasury Department) by R. R. Sayers, W. P. Yant, C. P. Waite and F. A. Patty. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*



PICTURE
ENLARGED
to 24 x 36 inches

Only an exceptional camera permits such pictures

When you snap a picture with the Leica camera, no important detail is too small to escape.

Thus the beauty and clarity of Leica enlargements—thus the amazing sharpness of screen reproduction from the positive film. The Leica picture shown here has been enlarged to 24 x 36 inches and every single detail is marvelously clear, sharp and distinct!

Even under adverse conditions of light, weather and temperature the Leica excells. Indoors or outdoors, on the ground or in the air, this compact camera gives unfailing service. The ideal camera for snapshots, portraits, sports and action pictures. The camera chosen by eleven members of the Byrd Antartic Expedition, travelers on the Graf Zeppelin's World Cruise, scientists, explorers, professional and amateur photographers everywhere.

Leica is the smallest roll film camera with a focal plane shutter, with lens speeds of 1/20 to 1/500 of a second. Fits vest pocket or purse and is ready for use on an instant's notice. A single roll of cinema film takes 36 pictures, double frame size. See this unusual camera at your photographic supply store or write for catalog 1174. E. Leitz, Inc., Dept. 9S.A., 60 East 10th Street, New York, N. Y.

Brown Indicating and Recording Remote Type Instruments (Catalogue No. 7501) deals with instruments for measuring pressures, liquid levels, and flows, and for indicating positions. *The Brown Instrument Company, Philadelphia, Pa.—Gratis.*

Serpents of the Eastern States (Bulletin No. 3, Vol. XXXII) by Dr. Raymond L. Ditmars, is a comprehensive study of the harmless and dangerous snakes in the region covered, which includeds New England, parts of New York, Pennsylvania, and New Jersey. *New York Zoological Park, New York City.—35 cents, not gratis as previously stated.*

Diamond Core Drill Fittings (Commercial Standard CS17-30, Bureau of Standards, U. S. Department of Commerce). *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

An Annotated List of the More Important North American Forest Insects (Miscellaneous Publication No. 74) by F. C. Craighead and William Middleton, gives a list of insects and the damage they do. There is an excellent bibliography. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Direct Bone Formation in the Antler Tines of Two of the American Cervidae, Virginia Deer and Wapiti (Zoologica, Vol. XI, No. 3) by Charles V. Noback, Ph.D., and Walter Modell, B. S. *New York Zoological Society, Bronx Park, New York City, N. Y.—65 cents, mailed.*

Timber Growing and Logging Practice in the Northwest (Technical Bulletin No. 166, U. S. Department of Agriculture) by Samuel T. Dana, with an introduction by William E. Greeley, treats of the measures necessary to keep forest land productive and how to produce full timber crops. *Superintendent of Documents, Washington, D. C.—40 cents (money order).*

Vitreosil deals with vitreous silica and forms a valuable treatise on fused pure quartz and fused pure silica. *The Thermal Syndicate Limited, Schenectady and Atlantic Avenues, Brooklyn, N. Y.—Gratis.*

Studies in the Electro-Deposition of Metals (University of Illinois Bulletin No. 206, Engineering Experiment Station, Urbana, Ill.) by Donald B. Keyes and Sherlock Swann, Jr. *University of Illinois, Urbana, Illinois.—10 Cents.*

Propagation of Aquatic Game (Farmer's Bulletin, No. 1612, U. S. Department of Agriculture) by W. L. McAtee. Full information regarding a small but growing industry, fully illustrated. *Superintendent of Public Documents, Washington, D. C.—10 cents (coin).*

Manufacture and Properties of a Cellulose Product (Maizolith) from Cornstalks and Corn Cobs (Miscellaneous Publication No. 108) by C. E. Hartford, describes the utilization of agricultural wastes. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

The Relation of Carbon Residue to Lubricating Performance. Lubrication, January, 1930. *The Texas Company, 117 Battery Place, New York City.—Gratis.*

Foundry Patterns of Wood (Commercial Standard CS19-30, Bureau of Standards, U. S. Department of Commerce) contains a fine plate giving standard pattern colors. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Laboratory Tests of Reinforced Concrete Arch Piles (Bulletin No. 202, Engineering Experiment Station, University of Illinois) by Wilbur M. Wilson. *University of Illinois, Urbana, Ill.—55 cents.*

Weather and Health (Bulletin No. 75 of the National Research Council) by Professor Ellsworth Huntington is a scientific effort to determine the relation between weather and health. *National Research Council, Washington, D. C.—$2.00.*

Warning Agents for Methyl Chloride in Refrigeration Systems is a contribution to the household refrigeration industry from the *Roessler & Hasslacher Chemical Co., 10 East 40th St., New York, N. Y.—Gratis.*

Slope Corrections for Echo Soundings (Special Publication No. 165, Coast and Geodetic Survey, U. S. Department of Commerce) by A. L. Shalowitz, deals with the "fathometer" invented by Dr. Reginald A. Fessenden and the proper corrections to be made. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Durability Tests of Spar Varnish (Bureau of Standards Reprints, No. R.P. 146). *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

A Young Man Looks at the Eastman Kodak Company gives a quick glance at a great industry and the opportunity that it offers to ambitious men. *Published by the Training Department of the Eastman Kodak Company, Rochester, N. Y.—Gratis.*

Sickness Among Industrial Employees (Reprint No. 1347, Public Health Reports,) by Dean K. Brundage. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

Triangulation in Colorado (1927 Datum) (Special publication No. 160, Coast and Geodetic Survey) by Oscar S. Adams. *Superintendent of Documents, Washington, D. C.—15 cents (coin or money order).*

Mining in the Fortymile District Alaska (Bulletin 813-C, Geological Survey, Department of the Interior) by J. B. Mertie, Jr. *Superintendent of Documents—Washington, D. C.—5 cents (coin).*

International Trade in Mica (Trade Promotion Series No. 95, U. S. Department of Commerce) gives valuable information about this type of mineral deposit. *Superintendent of Documents, Washington, D. C. 10 cents (coin or money order).*

Our Point of View

The International Bank

(*Continued from page* 175)

contention among world powers is a reasonable certainty to all acquainted with European history.

If this new bank cuts deeply into the profits of central banks of England, Germany, and France, its existence may be brief. Pretexts for its dissolution could quickly be produced. Its attitude during war, or even a period of strained relations between European powers, would be difficult if not impossible. Most of its optimistic founders calmly ignore the possibility of future European wars in forecasting its future, but war comes unbidden to most of his hosts.

We welcome the new bank and are proud that American bankers were its originators. Undoubtedly American membership on its staff will involve us still further in world affairs, but we are so thoroughly involved already that the new bank adds little to our commercial ties with Europe and nothing to our political responsibilities.

CIVIL AND MILITARY AUTHORITIES

THE time is near when our civil authorities will be obliged to pay more heed to their military and naval advisers than they have in the past, else the interests of the United States will suffer. The substance of the defense of the naval treaty by our delegation was that "it was the best we could get because both Japan and England had out-built us, and naturally we could not expect them to scrap ships already built or building." Yet in 1921, Mr. Hughes, ostentatiously refusing to consult with our naval officers, did scrap our battleships and battle cruisers. Americans should remember that, under the auspices of Mr. Hughes, we were willing to sacrifice naval superiority in 1921-22; and in 1930, Japan took advantage of her actual naval position to upset the naval ratio between the two countries. We will be under a handicap during the life of this treaty but we can overcome it easily in the period 1935-40 if we have really learned the obvious lesson.

OUR NEW MERCHANT MARINE

ONE of our few industries that is doing better in 1930 than in 1929 is shipbuilding, and for this we can thank the recent legislation by Congress, specifically designed to encourage the rebuilding of an American merchant marine. Four of our largest shipbuilding companies show an increase of 21 percent in the number of men employed. This increase is spread through all the skilled trades and crafts needed in the construction of a modern sea-going vessel. The support of Congress was extremely timely for under the severe competition of foreign companies that can build and operate vessels with cheaper labor, our shipyards were being abandoned and the many trained artisans necessary to that industry were being dispersed to other trades.

Efficient shipyards and skilled shipwrights are essential to our foreign trade in peace and to our fleet in war. Other nations give much care to their shipbuilding industry. Thus, at the London Conference, Japan insisted that she be allowed special permission to replace some of her submarine tonnage before it become obsolete in order to insure permanent employment to her trained shipbuilders. If with her present financial burdens, Japan can subsidize her shipyard workers, we can certainly afford to reassemble our workers before they are entirely absorbed into other trades.

FRENCH EVACUATION OF THE RHINELAND: INCREASE IN ITALY'S MILITARY FORCES

ALMOST simultaneously with the announcement of the evacuation of the Rhineland by the French forces in accordance with the provisions of the Dawes-Young plan for reparations, comes the news of further increases by Mussolini of Italy's land, sea, and air forces. At first glance these two occurrences may seem a mere coincidence, but it is well known in Europe that France does not wish to confront Italy with a large part of her army in Germany. With Italy scarcely concealing her conflicting ambitions, France naturally hastens to reduce her differences with Germany, re-group her armies, and strengthen her Italian frontier. Franco-Italian jealousy may prove a blessing to Germany.

To view further the already complicated European picture, in parts of Jugoslavia anti-Italian demonstrations have taken place. Americans can scarcely imagine the war-scourged Serbians considering another resort to arms so soon, but Mussolini regards the French-Jugoslavian menace sufficiently real to increase Italian taxes to add to his armed forces. As Mussolini has heretofore steadily reduced imposts on his heavily burdened people, the significance of this increase is apparent.

THE SEA FRONTIERS OF THREE NAVAL POWERS

THE London Conference called the world's attention to a wet triangle that can be somewhat loosely inclosed by lines drawn from the south point of Formosa to Guam, thence to Hong Kong, then returning to Formosa. This area of mixed land and water includes the sea frontiers of the three naval powers, Japan, Great Britain, and the United States. In a political sense, this wet triangle resembles the "buffer states" of a generation ago, the most famous being the Balkan States whose boundaries were fixed by various European conferences to reduce the risk of war between the three land empires, Russia, Austria and Turkey.

A glance at a world chart will reveal the importance of this area navally and commercially. It controlls the routes from the Far East to Europe and to Australasia, and the routes from the west coasts of the Americas to the Philippines, Southern Asia, and India. For this reason, Great Britain insisted upon the right to create an impregnable first-class naval base at Singapore, when at the Washington Conference Japan succeeded in restricting any further fortifications at Hong Kong or Manila. We did not appreciate the necessity of naval bases for our fleet and in consequence, our nearest naval base, Honolulu, is almost 5000 miles distant. It is hoped that our Delegation to the Naval Conference in 1935 will go with a mandate to redress the naval balance in this area.

TEN MILE EYES!
10 POWER
$21.75 Pre-paid
"Cheap at $50"
—*Says Navy Man*
Buy Direct—SAVE HALF

TEN MILE EYES! Think of the things you can see! Ten mile radius—a 20 mile circle—nearly 400 square miles. And you can easily have them. If you can see one mile, these super-power French 10x32mm. stereo-prism binoculars will extend your vision 10 TIMES. ENJOY YOURSELF 10 times more! Multiply pleasures of hobby and sport. Use a pair touring, observation, hunting, golfing, nature study, astronomy, etc. Superbly made for a lifetime of service. Case and straps free.

10 Lenses

4 Prisms

Did you know many ordinary field glasses have but four lenses and most of the better ones only six? But this binocular has 10 LENSES and 4 PRISMS. No wonder it gives an expansive field, brilliant illumination and fine definition.

Extra Power Without Extra Cost

Send $2.75 today for one on FREE TRIAL. Or $1 for one C. O. D., paying postman balance and few cents postage. Check and compare it in every way for five days with others selling for double or more. If you do not like it for any reason whatever your money will be promptly returned. Every glass tested. The U. S. Gov't and State Forestry Depts. buy from us. The same in 8x only $18.50. Surpasses others at $23.50 and more.

Books Selected by the Editors

Simplified Aerodynamics—*By Alexander Klemin, Prof. Aero. Eng., N. Y. Univ.*

IT is indeed an accomplishment when an author can take an abstruse subject like this one is and expound it in language the average intelligent person can understand. Prof. Klemin, however, has done it most admirably and has produced an indispensable reference that should be in the possession of every pilot, every mechanic, and every person seriously interested in aviation. Reduced to the very simplest mathematics, physics, and mechanics, little difficulty will be experienced in mastering the subject and applying the knowledge successfully. A much needed work splendidly handled. $3.65 postpaid.

Playing Airplane—*By J. F. McNamara*

IF you have a youngster who keeps continually asking you questions about airplanes, we suggest that you get this book and carry out the plan outlined therein. We will warrant, even if you are an experienced flyer, that not only will you get the proverbial "barrel of fun" but also you will learn some things about flying that you hadn't thought of. A most happy conception of fun and information by an R.C. Lieutenant whose children have been brought up near Roosevelt and Mitchell Fields. $2.65 postpaid.

My Automobile—*By H. F. Blanchard*

A SECOND edition completely revised and reset giving the step-by-step details for locating trouble and making minor repairs. The front wheel drive is given the final chapter and the whole is written for those who need information in the most clear and ready form. The author is technical editor of *Motor*. Fine format. 227 illustrations. $3.65 postpaid.

Parachute—*By C. J. V. Murphy*

TRUE tales taken from the journal of the Caterpillar Club, to tell the full story of the history and development of the parachute from the experience of individual performance. A well developed, chatty narrative. $2.65 postpaid.

Handbook of Formulas and Tables for Engineers—*Peirce-Carver-O'Rourke*

FOUR sections are devoted to mathematics, one each to Measurement, Physical and Chemical Properties, Mechanics, Columns, Beams, etc., Structural Data, Reinforced Concrete, Strength of Materials, Standard Gages, Steam Tables, and Mathematical Tables. A complete reference especially strong in civil engineering data, concise and handy. $2.65 postpaid.

How the Derrick Works—*By Wilfred Jones*

YOU will be surprised to learn how many people in these offices have borrowed the review copy of this book to read how the derrick is handled on the building which is going up across the street. The plentitude of illustrations are shade wood-cuts and fully bring out the details as well as the romance of construction.—$2.20 postpaid.

A Dictionary of Color—*By A. Maerz and M. Rea Paul*

UNDOUBTEDLY this is the most ambitious and certainly it is one of the most complete works of its kind that we have seen. A well rounded outline explains the field of text, references, frequency of use of names, polyglot table, and bibliography. Sixty-six color plates with corresponding skeleton plates naming the colors, cover every conceivable shade throughout the range and this is followed by a brief history of color standardization, an index of color names, and notes thereon. It would be difficult to see wherein this work could be enhanced and for anyone having to do with color in all of its applications, this is an invaluable reference. 9 x 11½. $12.50 postpaid.

German-English Technical and Scientific Dictionary—*By A. Webel*

THERE are several features of this most excellent work that will appeal at once to one familiar with the usual reference dictionary. English script is used and the word sought stands out to the eye for the reason that following explanatory text is indented sufficiently to give good white margin on the left—a point most inexplainably ignored in most dictionaries. No jumble of explanatory pronunciations, derivations and deviations follow the word, for infinite care has been taken to select the most authoritative translation—scarcely any individual text exceeds three lines. It is just such a work as scientists, students, writers, and translators need, for it grants some knowledge on the part of the seeker and does not burden him with nonessentials. Chemistry, mathematics, metallography, electrical engineering, physiology, medicine, fuels, woods, oils, brewing, dyeing, paper making, textiles, and so forth, are amply covered. A monumental work of 20 years compilation. $10.75 postpaid.

New International Year Book—*H. T. Wade, Editor*

PERSONALLY we find this reference one of the most useful in our library and one reason beyond the excellence of the material and its wide scope, as the name implies, is the simplicity of format and straightforward way of running throughout the book in alphabetical arrangement of subjects irrespective of grouping. Busy people wish to find their references in the easiest, simplest, and most natural way and we find this compendium of the world's progress for the year 1929 fulfills these requirements. Cloth. $7.00 postpaid.

Number, the Language of Science—*By Tobias Dantzig, Ph. D., Prof. Univ. of Md.*

HERE is a book of a "different" kind, one which will delight all those whose leanings are philosophical—thinkers, figurers, delvers, and others whose instinct drives them to burrow below the superficial appearances of things. It isn't a mere schoolbook on algebra, geometry, calculus, or any other horrible kind of formal mathematical torture—plenty, too many, of these have been written already—but it occupies a different corner of thought and science. For example, some of the typical subjects are: the origin of zero, the use of symbols, the notion of infinity, transcendentals, amicable numbers, perfect numbers, various theories of number. No school book contains the same stuff and if it did it would be deadly dull, while this book is lively bright. If a reader has had high school mathematics he will be able to grasp its contents, and whether he likes or dislikes mathematics proper, the pure philosophical interest of the book will hold his attention and cause him to exclaim at least once per page, "Well, I never thought of that before." The author also is Lecturer in Mathematical Physics at the U. S. Bureau of Standards. $3.70 postpaid.—*A.G.I.*

From Recent Publications

FIELD BOOK OF PONDS AND STREAMS—*By Ann Haven Morgan, Ph.D., Prof. Zoology, Mt. Holyoke*

THE finest book on pond and stream life—tiny animalcules, rotifers, leeches, aquatic insects, and larger animals—which has yet appeared, will be the verdict of all lovers of aquatic life, whether amateur or professional. Professor Morgan has anticipated the needs of all classes of students of water life and has produced a guide which is at once technical, readable, and comprehensive. The illustrations are excellent and are arranged in graphic form. This convenient pocket book (7 x 4½ x 1 inches, 448 pages) will be suitable to take on tramps and to camps. $3.65 postpaid.—*A.G.I.*

EXPLORING FOR PLANTS—*By David Fairchild*

AN intimate narrative of a scientist's adventures in little known lands, based on notes of the Allison V. Armour expeditions. Dr. Fairchild is a botanist of note with a remarkable record of doing things, the results of these expeditions being the introduction into this country of many useful new plants and trees. Ranking as a scientific book, its charm for the average reader lies in the ease of style and the joyous appreciation of life looked at from every angle. The story is so smooth one assimilates the botany with no effort whatsoever. Good science, good reading, good writing. We highly recommend it. Abundantly illustrated. $5.20 postpaid.

ROOSEVELT: THE STORY OF A FRIENDSHIP—*By Owen Wister*

AS might be expected this is a sympathetic, manly word portrait and incidentally quite a autobiography. With his charming style which still lists "The Virginian" among the best sellers, the author covers 40 years of interesting friendship, reaching through the years from college days to the end. It is also an interesting study of the Familiars (as they are denominated) whose lives intimately touched that of our great President. A book that cannot be overlooked. $4.20 postpaid.

ST. AUGUSTINE—*By Giovanni Papini*

THE same vivid, fervent style that made the "Life of Christ" one of the most popular works of its time in every country of the civilized world, is displayed in this story of the Roman scholar who became a saint and a Christian philosopher. Now on the 15th centenary of St. Augustine's death, we have this most sympathetic and understanding story of his life, which has become one of the greatest moral and intellectual forces that Christianity has produced. It should be made a "must read" on every list. $3.20 postpaid.

THE LAST PARADISE—*By Hickman Powell*

BALI, a small island in the Dutch East Indies, still retains much of the manners and customs of the days when it was subject to Hindu influence. The story depicts the writer's life with a native family in all its serene peacefullness and topsy-turvy excitements. $4.20 postpaid.

HER PRIVATES WE—*By Private 19022*

THIS is the story of an educated man, as the frequent Latin phases would indicate. As such, one will appreciate that the philosophical introspections and the search for underlying bases of emotion and thought are of a more penetrating and analytical kind than has appeared in any war book to date. It is again the story of a private of officer caliber, but the setting is the life, in and out of the trenches, of an English battalion. So faithfully does the author strive to record actual conversation, that one rather tires at the redundant use of three or four expletives. None the less it is a gripping story and quite different from all the others. $2.65 postpaid.

CHANCES—*By A. Hamilton Gibbs*

"SOUNDINGS" by the same author will be remembered as a very popular novel of 1925. Here again we find the same sureness of handling and dramatic quality. It is the story of two brothers of fortunate circumstance who love the same girl and carry through the war experience, meeting the crises of love and valor with undiminished attachments. A most readable story. $2.65 postpaid.

GREEN MAGIC—*By Julia Closson Kenly*

THIS is a Nature wonder book which relates in liveliest style how plants lead most busy and remarkable lives; their habits and ways. An ideal book for boys and girls who are enthralled by the romance of growing things. $2.65 postpaid.

THE TECHNICAL ARTS AND SCIENCES OF THE ANCIENTS—*By Alfred Neuburger*

WITH considerable enthusiasm we call attention to this book we have always longed for. To get in such condensed form things relative to arts and sciences that we have searched for in libraries for days, is a great satisfaction. The scope is very wide and each subject is adequately and evenly treated—a rare virtue. Our knowledge of metallurgy of the ancients is quite considerable and here we have each metal treated by itself; for instance, how interesting to trace the origin of the blast furnace! Here we plumb the secrets of the ancient jeweler and see his faint attempts at mass production, and can follow on trade after trade as well with equally good results. Some of the illustrations are classic but most seem unfamiliar. There are 676 illustrations and the half-tones are well printed on coated paper which makes a handsome though heavy book. This volume is indispensible as a reference for almost any library, even a small one, for it is a great treasure house of entertainment as well as cultural information. It is one of the most interesting we have seen in months. $10.25 postpaid.
A. A. H.

STANDARDS AND STANDARDIZATION—*By N. F. Harriman, Bur. of Standards*

TO promote economy through standardization by giving an outline of current standards and what they may accomplish, is the purpose of this concise account. Ample references provide for collateral reading. $3.20 postpaid.

We Can Furnish the Above, as Well as Any Other Books That Are in Print, at List Prices, Plus Postage

Facts and Notes of Interest to Inventors, Patentees, and Owners of Trademark Rights

Similar Food Trademarks Allowed

IN a recent decision, First Assistant Commissioner Kinnan held that the Lush'us Products Company, of Chicago, Illinois, is entitled to register as a trademark for canned peas, a composite mark consisting of the representation of a chef holding a dish of peas in one hand and lifting the cover of the dish with the other, together with the words "Lush'us Peas," which words are disclaimed, notwithstanding the prior adoption and use by the California Canneries Company of the term "Lusk's Luscious" as a trademark for canned fruits and vegetables.

The ground of the decision is that the two marks have nothing in common but the descriptive word "luscious" and since no one is entitled to the exclusive use of the word, there is no likelihood of confusion by reason of the use of the two marks.

After stating that the word "luscious" was obviously descriptive of the goods and it is a matter of common knowledge that it has long been applied to both fruits and vegetables, the First Assistant Commissioner said:

"No one is entitled to exclusive appropriation of the word. The opposer is only entitled to exclude others from using this word in the particular and distinctive way it has used the word on its goods; that is, in connection with the word 'Lusk's.' The applicant is likewise entitled to use this word, misspelled as it is shown, in connection with the other distinctive features which constitute the entire mark. This descriptive word, which is open to everyone to use in connection with the goods of this character, being the only feature of similarity between the two marks, it is believed the opposer cannot prevail."

Concrete Mixer May Be Beautiful

THE Court of Customs and Patent Appeals has held that a specific design for a concrete mixer truck body and frame constitutes proper subject matter for a design patent, and has overruled the decision of the Patent Office refusing an applicant a design patent, according to *The United States Daily.*

The beauty and ornamentation requisite in design patents is not confined to such designs as may be found in the "esthetic or fine arts," the majority opinion states. Tools and mechanisms which are patentable because of their utilitarian qualities, it was further ruled, also may be properly the subject matter of design patents if they possess qualities which the law requires.

Articles of manufacture, the ornamentation of which, owing to their nature, are of no concern to anybody, are not proper subject matter for design patents, the majority opinion states, but held that the particular article did not come within this class.

While the concrete mixer has movable parts, there is nothing connected with the mechanism, or with the machine as a whole, which produces such a multiplicity of designs, the opinion states, as to require the refusal of a design patent.

In the dissenting opinion, it is contended that the design disclosed and claimed does not represent patentable subject matter. "It has escaped our observation," the two members of the court state in their dissenting opinion, "if the pulchritude of articles like concrete mixers has ever excited any great public consideration."

Bottle Cap Not Mark for Milk

RECENTLY First Assistant Commissioner Kinnan held that the Walker-Gordon Laboratory Company, of Plainsboro, New Jersey, is not entitled to register, under the Act of 1905, as a trademark for milk, a mark defined as consisting of a "substantially silver colored cap for milk bottles."

The ground of the decision is that the alleged trademark is a mere color of the container of the goods or a substantial part thereof.

In his decision, after noting the grounds above stated, on which the examiner refused registration, and applicant's argument that, by reason of its long use of such colored bottle caps, that color constituted a trademark, the First Assistant Commissioner said:

"It is well settled that mere color aside from some particular symbol or design, such, for example, as a circle, square, triangle, cross, or star, cannot constitute a valid trademark. (Decisions cited.) There is no contention here that it is new to employ a metal cap upon a milk bottle which is attached to the bottle by being bent down over the top much in the way the applicant uses the cap. This being true the applicant is merely seeking a trademark for the color of the cap of the bottle which contains the goods."

The First Assistant Commissioner further noted patent No. 531,796, disclosing and claiming a "tin-foil cap for milk bottles," and said:

"Since tin-foil is either what the applicant here employs or is substantially the same and has a substantially silver color, the registration sought by the applicant would, if granted, be in effect a perpetual patent upon a tin-foil milk bottle cap. The Hall patent expired 18 years ago. If registration were granted the applicant neither Hall nor the public could use the device of that patent without infringing the applicant company's trademark. It is obvious enough under these conditions registration must be refused."

Fly Sprays to be Correctly Labeled

FLY sprays for animals are not "100 percent effective," or "safe," or "non-poisonous," or "harmless," and neither do they "prevent infectious diseases," nor do they "increase milk production" above normal, and if they are claimed to be effective for longer than 8 hours they are open to question, says Dr. C. C. McDonnell, in charge of insecticide control, Food, Drug, and Insecticide Administration, the organization of the U. S. Department of Agriculture which enforces the Federal Food and Drugs Act, the Federal Insecticide Act, and other Federal regulatory laws.

"There is a marked difference in the action of sprays on various species of flies, and broad claims to the effect that a product is effective for all flies are unwarranted," says Doctor McDonnell. "In defining the action of fly sprays, a distinction should be made between preparations that actually kill flies and those that only repel them."

Not only must the label on fly sprays be free from false or misleading statements, but if the product contains any inert ingredients the label must state the name and percentage of each inert ingredient, or the name and percentage of each active ingredient and the total percentage of inert ingredients.

Name for Glass Must Not Mislead

USE of the word "Jena" either independently or in conjunction with the word "Glass" will be discontinued by a corporation in the sale of medicinal supplies and syringes designed for use by the medical profession.

According to a stipulation agreement between this corporation and the Federal Trade Commission, the company will not use the word "Jena" in any way as descriptive of its product so as to mislead the public into the belief that its product is Jena glass, which is understood by the scientific and professional world to be that glass manufactured by a competitor of the respondent company.

(Names of individuals or firms signing stipulation agreements are not mentioned in the commission's press releases or publications, but the facts in each proceeding are presented to show methods of competition condemned by the commission as unfair, for the guidance of industry and protection of the public.)

Refrigerator Trademarks Clash

IT has been held by Assistant Commissioner Moore that the McKee Refrigerator Company is not entitled to register, as a trademark for refrigerators, the term "Iced-Aire," both because it is confusingly similar to the term "Frigidaire" previously used by the Frigidaire Corporation, of Dayton, Ohio on the same goods and because it is descriptive of applicant's goods.

In his decision, after noting the holding of the examiner of interferences that the notation Frigidaire is descriptive and therefore not owned by the opposer, and the use of that notation would not therefore support a claim to damage, the Assistant Commissioner said:

"That it is not necessary, in order to sustain an opposition, that the opposer shall own the trademark, registered or not, before he can oppose the registration of the mark to another person, has been held in many decisions, both by this office and by the Court of Appeals of the District of Columbia. . . . A comparison of the two marks shows that they both have the same ending and the same suggestive meaning, namely, that the air as in a cold state. While the word Iced and the word Frigid do not look alike, yet it is believed that, since they convey the same meaning, their concurrent use on refrigerators would be likely to cause confusion or mistake in the mind of the public as to the origin or ownership of the refrigerators to which the marks are appropriated."

With reference to the character of the marks, after stating that the examiner of interferences did not exceed his authority in holding the word descriptive, he said:

"The mark Iced-Aire, when applied to refrigerators, would convey no other meaning than that the air is rendered cold by the application of ice, and, if the applicant's refrigerator does not operate on this principle, then the mark is deceptive and, in either case, should not be registered."

"Special" Price Must be Special

MISREPRESENTATION of the regular price of a course of instruction as a "Special" price, will be discontinued by an individual engaged in the sale and distribution of certain formulae and courses of instruction in resilvering and replating metal goods, the respondent having signed a stipulation agreement to this effect with the Federal Trade Commission.

Specifically, he agrees to cease and desist from the use of such a statement as "I will send all for only 5 dollars, the regular price being 10 dollars, but for a limited time only the price has been reduced to 5 dollars" when such is not the fact.

He agreed also to stop using the word "Special" to designate the price of his products when in fact such price is not special but is the regular and customary price asked in the usual course of business.

The respondent further agreed to desist from the statement "I am the sole owner of 14 patents, grants, and copyrights" so as to imply and mislead the public into believing that he actually owns the specified number of patents, grants, and copyrights, all of which relate to the art of plating or the process of mirror silvering, when in truth such is not the fact.

Legend Not Allowed As Trademark

IN a recent decision, First Assistant Commissioner Kinnan held that Chevy Chase Dairy, of Washington, D. C., is not entitled to register, under the Act of 1920, the notation "Safe Milk for Babies" as a trademark for milk, cream, buttermilk, cheese, and eggs.

The ground of the decision is that this legend or notation does not constitute a trademark as it does not indicate origin or ownership of the goods.

In his decision, after stating that applicant had already registered a composite trademark which included the legend in question, and now seeks to register the legend alone, he said:

"It is believed entirely obvious this legend does not function as a trademark but constitutes a mere laudatory statement as to the character of milk sold by the petitioner. When used upon milk the purchasing public would merely understand this legend to mean that the milk was safe as a food for infants. When used upon the other goods specified, the cheese, butter, eggs, et cetera, the legend would not be interpreted by purchasers to refer to the goods at all but to constitute a mere laudatory advertisement or statement that the petitioner also sold milk of this character."

Description of Function Not Registrable

IT has been held by First Assistant Commissioner Kinnan that the National Licorice Company of Brooklyn, New York is not entitled to register, under the act of 1905, the notation "Helps," as a trademark for licorice cough drops, since this notation is merely descriptive of the goods.

In his decision, after noting the argument that the mark was suggestive rather than descriptive, and pointing out why certain decisions cited in support of that contention were not conclusive of the question, and noting that registration had been refused of certain marks which were descriptive of a quality of the goods such as "Getwell" for a medicine, "Health Food" for a food product, "No-D-Ka" for a tooth paste, he said:

"In view of the foregoing, it seems clear enough the notation here sought to be registered is descriptive of the function or effect of the use of the goods and is, therefore, merely descriptive."

Duplication of Words Voids Trademark

THE mark "White Cap" with or without a representation of ocean waves having white surfaces, is deceptively similar to the mark consisting of the words "White Cap" above a representation of a rounded cap such as is frequently worn by chefs.

Because of this similarity and the further holding that baking powder and self-rising flour are goods of the same descriptive properties, the Court of Customs and Patent Appeals has held that "White Cap" is not registrable for use on "plain and self-

Classified Advertising

Advertisements in this section listed under proper classifications, rate 25c per word each insertion; minimum number of words per insertion 24, maximum 60. Payment must accompany each insertion.

Anyone desiring the address of a patentee listed in this section may obtain it by addressing Munn & Co.; those desiring official copies of patents herein listed, may secure them by remitting 15 cents for each one (state patent number to insure receipt of desired copy) to Munn & Co., 24 West 40th Street, New York City.

Pertaining to Aeronautics

Amphibian Airplane—Having provision for alighting upon water, ice fields, level or otherwise, or desert sands, a stabilizing apparatus functioning in such manner as to retard the descent, in the event of an emergency. Patent 1765214. Frederico G. Diago.

Parachute and Aerial Life Buoy—Whereby a bouyant body is provided using gas, and a smaller spread to the parachute presenting a floating structure when landing on water, and whereby a comparatively slow descent is secured. Patent 1765075. Edward G. Johnson.

Pertaining to Apparel

Waterproof Overalls—Which may be open at the front while sitting, but having a shield and drain so that water caught by the opening will pass off at a point exteriorly of the garment. Patent 1765096. Meyer Reingold.

Rubber Heel—Having an outer face formed of a plurality of ribs, and grooves spacing the ribs from each other with passages extending lengthwise through the ribs, the body being provided with sockets for securing the heel. Patent 1765155. Harry Heady.

Garment—Which may be readily placed upon an infant, secured in place, and conform to the body to allow free movement without binding, and which obviates the need of the ordinary rubber pants, which bind the legs. Patent 1765105. Bertha B. Skinner.

Chemical Processes

Process for Purifying Pearl Essence—Which consists in bringing the pearl essence to a state of aqueous paste incorporating amyl acetate collodion containing from 8 to 14% nitrocellulose, liberating the water, and washing the product with clean ammoniacal water. Patent 1760771. Jean Paisseau.

Fertilizing Solution for Seed Treatment—By treating the seeds with chemical agents so that the chemical action may in due time promote the growth of the plants or increase the quality or the quantity of product therefrom. Patent 1762294. William F. Gericke.

Designs

Design for an Ensemble Suit—The inventor has been granted two patents, numbers 81394 and 81395. Dorothy Long.

Design for a Mirror Stand—Patent 81345. Frank N. Mariani.

Electrical Devices

Electromagnetic Ignition Device — Adapted to light gas-nozzles, burners, stoves, or fuel mixed flames in general, is very compact comprising but three elements, namely a fixed core, a vibratory blade, a substantially fixed blade, and the usual magnatizing coil. Patent 1763443. Ruggero Righetto.

Electric Tea Urn or Perculator—Comprising a water vessel, electrically heated, on top of which is a steam-tight vessel, having at its bottom a tea receptacle, and a pipe extending into the lower vessel, allowing steam to be passed through the tea. Patent 1762303. John A. McBride.

Generator Circuit Protector—Which will automatically shut the current from a generator to a resistance when the current is not being used for charging a battery, or when faulty connections exist between the generator and the battery. Patent 1762297. Elton R. Hopkins.

Shade Holder for Electric Lamps—A semicircular wire strand, for attaching a glass hood rising flour," in view of the prior registration of the similar mark for baking powder.

While there is no evidence that the two products have ever been manufactured by the same producer, the opinion states, still their relation to the art of cooking and their use in the production of bread and other food products is such that confusion is likely were similar marks for both registered.

"Suntan" Not a Trademark

THE notation "Suntan" for use on various articles of wearing apparel, including bathing suits, dresses, hosiery, caps, and so on, is not registrable as a trademark in the Patent Office, because descriptive of the goods, the Assistant Commissioner of Patents has ruled.

By extension of the meaning of the term the opinion states, "it now designates not only a color simulating that produced by the sun, but also the characteristic of wearing apparel which permits the direct action of the sun's rays upon portions of the body in order to produce a tanning effect."

Fictitious Names in Business

AN individual doing business under his own name and initials, followed by the word "company," is not required to comply with the provisions of the so-called fictitious name statute, since the name is not fictitious, the Supreme court of California has just ruled.

The statute, the opinion explains, provides that every person transacting business in this state under a fictitious name and every partnership transacting business in this state under a fictitious name or a designation not showing the names of the persons interested as partners in such business "must file with the clerk of the county a certificate stating the name and place of residence of the person or persons interested in the business."

Prior Disclaimer Nullifies Usage

THE disclaimer of any rights to the words "Liquid Solder" in an application for a trademark previously registered precludes a subsequent application to register these words as a trademark, where they have since the disclaimer been registered to another, even though their use by the applicant as a trademark was prior to their registration by the other party, the Court of Customs and Patent Appeals has ruled.

The court overruled a decision of the Patent Office which had ruled that a disclaimer in a trademark proceeding may not be urged, by subsequent users of the mark disclaimed, as an estoppel.

Foreign News Reels Allowed in Italy

THE Italian government ban on the reproduction of foreign dialogue in sound pictures has recently been lifted to the extent of permitting the exhibition of news reels containing foreign dialogue, according to a report received in the Department of Commerce from Trade Commissioner Geroge R. Canty, Paris.

The following is a translation of the communique: "While the existing regulations forbidding the public showing of foreign dialogue pictures are still in force, the ministry of the interior has deemed opportune to concede the permission to show films containing talking sequences and dialogue in foreign languages when such films are taken from real life and reproduce: 'Actualities, ceremonies, sporting tournaments, military exercises, characteristic scenes or events, and so forth.' "

of the sectional type commonly employed for enclosing a portion or all of an electric bulb, adapting the same for use as a colored decorative light. Patent 1765212. Jay J. Decker.

Of Interest to Farmers

CHICKEN ROOST—Which may be suspended from the roof or placed just above the floor, will be proof against lice or other insects, due to the fact that receptacles containing insect-exterminating liquid or powder, are suspended under the roosts. Patent 1760748. Henry Fintel.

AGRICULTURAL MACHINE—Of the disc gang harrow type, whereby the disc blades of each gang may be set to a desired working position so that the soil broken by the leading gang will be further broken by the trailing blades. Patent 1760569. James S. Stewart.

COTTON HARVESTER—In the form of a vehicle adapted to be drawn over the rows of cotton plants with means incorporated for removing the cotton and discharging it into a body mounted on the vehicle frame. Patent 1762045. Arthur V. Benson.

COTTON HARVESTER—Adapted to be moved between rows of cotton plants, and having mechanism for removing cotton directly from the bolls of the plants and placing them in a predetermined manner in a container, ready for bailing. Patent 1763607. Julian E. Watkins

COTTON HARVESTER—Whereby the bolls and open cotton may be stripped from the stalks and the cotton which is left, together with the loose cotton, driven off and carried up by strong currents of air from the machine. Patent 1767979. Bedford Hestand.

RAKE CONSTRUCTION—Which not only facilitates the collection of matter by the rake, but functions effectively to clear its teeth or tines of matter adhering to or impaled thereon providing economy in labor. Patent 1768101. Erwin L. Bell.

Of General Interest

CIGAR LIGHTER—Having a simple and efficient means for throwing sparks from a block of pyrophoric alloy, to ignite a wick, will not readily get out of order, and may be easily assembled, adjusted or repaired. Patent 1762079. Charles Rubsamen.

LOUD SPEAKER—A central cylindrical internally threaded casing, in which a single diaphragm mounted within the casing is adapted to propagate sound waves from a plurality of tone chambers. Patent 1762050. Charles G. Cook.

SPRINKLER HEAD—Which operates with a minimum quantity and pressure of water and in a manner to produce a maximum of slow and even distribution over a given area, particularly adapted for sprinkling lawns and gardens. Patent 1760903. Frederick Henkel.

ROTARY GATE VALVE—In which gates or shoes are mounted on a rotatable element so as to form a tight seal when the valve is closed, but when open a fluid may flow there through without obstruction or the formation of eddies. Patent 1760951. Richard G. Manifold.

COMB AND GLOVE THEREFOR—A form-fitting cover of soft flexible material to be drawn over the teeth of the comb for dressing the hair, the attachment may be readily washed, kept free from dandruff and in a sanitary condition. Patent 1760928. Samuel W. Whitney.

PHOTOMETER AND EXPOSURE CONTROL—The inventor has been granted two patents for the measurement of light to determine the proper length of exposure and manipulation of the camera shutter, in the art of photography. The one is an independent apparatus, the other is attached to the lens for automatically adjusting the diaphragm, and also includes means for finding the proper exposure time. Patents 1762047 and 1762048.

Truth in Sales Schemes

AN individual engaged in selling to retailers such services as sales promotion schemes, advertising data, and specialty merchandise, signed a stipulation with the Federal Trade Commission agreeing to discontinue a number of unfair trade practices.

To retailers he sold merchandise and plans of merchandising involving operation of a lottery. A retailer would buy from him a padlock, a large number of keys, and one of three pieces of merchandise; namely, a radio receiving set, a boy's auto, or a child's scooter, with which he received a supply of advertising hand bills, and window cards. The retailer would then give a key to each customer purchasing merchandise to a fixed minimum amount. When the keys were all distributed, the radio, auto, or scooter would be given as a prize to the customer holding the key that would unlock the padlock.

In selling his products he declared that he manufactured radios, when in truth the respondent did not represent a syndicate or association of advertisers and did not own, control or operate a mill wherein the merchandise he sold was manufactured.

He advertised that certain of his products were offered for sale at factory cost when in fact all of his products were sold at a profit.

He shipped to merchants the instrumentalities and means of conducting a game of chance or lottery, with appropriate literature offering the gift or prize, and encouraged and enabled retail merchants by means of advertising literature to represent that they were selling merchandise at factory cost, when in fact it was sold at a profit.

Motor Bus Accidents Decrease

ONE motor bus passenger in every 1,250,000 passengers carried on buses in Ohio was killed during the last year, it was stated by the chairman of the public utilities commission, Frank W. Geiger, in noting marked improvement in the manner of operating buses since the commission issued a safety order some months ago.

During the year, the chairman said, motor buses carried 32,375,531 passengers, and of these 26 lost their lives in accidents. In this time, he stated, 1032 cars traveled a total of 56,224,254 miles.

Color in Rope Trademarks

THE Assistant Commissioner of Patents has ruled that a trademark for wire rope, consisting of a silver strand which is incorporated in the rope during its manufacture, is registrable in the Patent Office, even though the opposer has a registered trademark for a similar rope consisting of the use of a red strand in the rope.

The Assistant Commissioner found that there would be no confusing similarity between the products as marked by the two different colored strands.

Flat Asbestos-Cement Roof and Wall Sheet—Constructed to be applied directly to a vertical supporting frame member of a building without sheeting or horizontal supports and without overlapping, is not too flexible or brittle, and will form good insulation against heat and cold. Patent 1763469. Louis Lane.

Dispensing Container—For holding sugar, salt, pepper or the like, is sealed against the entrance of moisture, dust or insects, by the mere act of being placed upon a support, the upper end being completely closed. Patent 1763449. Henry T. Trautvetter.

Folding Chair—Having a canopy readily foldable with the chair, the construction is such that it may be readily set up for use, and easily folded to occupy little space for storage. Patent 1763455. Emil de Bruijn.

Pipe Insulation—Which may be mechanically constructed in sections, at little cost, and applied to refrigerating pipes and the like, has novel means for sealing the various sections, making the connections both weather and air-tight. Patent 1762276. George J. Schreier.

Attachment for Collapsible Tubes—In the form of a discharge nozzle which may be bent with the fingers without closing the passage to provide a terminal at an angle to a tube, to be used as an eye dropper or the like. Patent 1765114. George S. Turner.

Box—Which may be cut from a single pasteboard blank and shaped to be readily folded into a rectangular box structure having a retaining locking extension and an ornamental upstanding projection on top for receiving decorations. Patent 1765084. Edwin A. Locke, Jr.

Pin Hinge—For an ornament, wherein the hinge is molded on the ornament body as the molten metal cools, the mold parts being readily separable for the removal of the ornament. Patent 1765131. Israel W. Cooper.

Acoustic Device—More particularly a sound generator for radio loud speakers, comprising a diaphragm made in the form of a frustrum of a hollow cone, the sound reproducing apparatus being connected to the smaller aperture of the cone. Patent 1765124. Max P. Bonnat.

Cover Holder—For retaining the lid of a cooking vessel, kettle or like receptacle, in position and for preventing unintentional displacement while canting the vessel for the purpose of drawing off liquid. Patent 1765135. Eben G. Doland.

Steam-Pressure Cooker—Which is made of aluminum, with handles formed on opposite sides, with arms and spaced ears extending upwardly, which resiliently clamp the edge of the lid to withstand the steam-pressure. Patent 1765072. Takichi Hashimoto.

Container Head—Constructed of composition material covered with a layer of sheet metal, or fiber, which will provide an effective substitute for a solid wood or all-metal head, and comprises a complete unit. Patent 1764389 Herbert L. and James N. Carpenter.

Balanced Three-Way Valve—A self-closing valve wherein the outlet ports are so formed as to present a maximum opening, while preventing any parts being interfered with, may be used for many purposes where short admission of fluid pressure is desired. Patent 1765090. George G. Morin.

Closure for Toothpaste Tubes—Formed with a rotating closure plate capable of being moved to an open position by the thumb, and moved to a closed position by spring pressure, the structure coacting with a resilient lock. Patent 1765128. Claude A. Conover.

Tally Card—Especially designed for use in connection with card games, such as bridge-whist, in which the players are arranged at a number of tables for progressive play, the tally simultanously indicating the games played. Patent 1768020. Joseph J. Arnold.

Conical Grater—Having a removable grating chamber which is provided with a plurality of radially extending barriers adapted to retain the material to be grated against the grating surface. Patent 1768076. John W. and Arthur E. Klensch.

Clip—Known in the trade as a "money clip" for clamping bills of different denominations and which will permit the ready removal of a single bill from the stack without disturbing the other bills. Patent 1767973. Stanley L. Gedney.

Binder—Which is strong and durable and adapted to support a book or books or other objects for pivotal mounting in connection with a bookstand, and having means for locking the parts in operative position. Patent 1767978. Walter E. Haskin.

Envelope Sealer—Wherein means are presented for easily receiving and guiding the envelope and its flap so that the flaps will first be moistened and then pressed to a sealed position; the device may be applied to a wall or support. Patent 1767908. Benjamin Zuckerman.

Atomizer—In the form of a doll having one or more movable appendages, such as the arms or legs constituting parts of the doll, which may be manipulated to cause atomization of the perfume or other liquid used. Patent 1767911. Benjamin Berko and Joseph Brewer.

Pipe—A tobacco pipe, which may be constructed from a wide range of materials, and so formed that the various parts may be readily aired, cleaned, and kept in a sweet condition. Patent 1767997. Robert W. Nicholls.

Combined Seat and Carrier—A combined portable carrying case and seat, which is of simple construction and particularly adapted for outings or picnics for transporting luncheons and various articles for use on the trip. Patent 1767925. Thomas Hargreaves.

Envelope—A remailing envelope of the single pocket type formed of two sheets of paper with flaps disposed in opposite directions, the envelope being adapted to be folded upon itself when remailed as first class matter. Patent 1768164. Nathan Sternheimer.

Container—Having a hinged closure, and a resiliently raised article holder, which when opened will dispose articles such as cigarettes and matches, etc., to a position where they may be readily grasped. Patent 1768064. George O. Holben.

Attachment for Pencils—Which may be used for scraping, cutting or clipping bills of lading from packages and the like, the device may constitute a part of the main chamber or be used merely as an attachment for mechanical pencils. Patent 1767948. John C. Taylor.

Oarlock—Constructed of a minimum number of parts, so that on the pull stroke, roller bearings will engage one side, and on a push stroke the other side, the oar lock may be converted for sculling a boat. Patent 1768006. Arin G. and Harold M. Seberg.

Atomizer—By which the heavier hydrocarbons can be reduced to such a fine degree of atomization as to produce substantially perfect combustion, greatly facilitating the cracking in distillation of petroleum. Patent 1764107. Oscar Kay.

Bullet Mold—For casting hollow-point or solid point bullets as desired, the hollow point is automatically withdrawn when the mold is opened, the bullet readily dropping from the mold after casting. Patent 1763977. Marion G. McNeely.

Panel Construction—In the form of a removable panel construction, comprising a plurality of frames having panel receiving recesses for tile, marble, plate glass mirrors, which will eliminate waste of labor in assembling and installation. Patent 1763966. Louis Hoffman.

Gift-Dispensing Apparatus — Comprising a board in representation of a rainbow having chutes thereon for dispensing gifts to children, in a manner to carry out the mythical belief that at the end of the rainbow is a pot of gold. Patent 1763733. Alice C. Westgate.

Angle Trisector—Having a semi-circular shaped member, a radially-extending arm projecting therefrom, and a curved arm having its ends secured to the semi-circular member, for giving the proper point location for an angle between zero and 180 degrees. Patent 1764581. Sojiro F. Shibuya.

Display Rack and Stand—Having novel means for supporting a plurality of racks or casings so that they may be moved in a circuitous path with respect to their supporting member and with respect to each other. Patent 1767980. Raymond S. Hintzee.

Hardware and Tools

Saw Table—A movable frame for supporting a circular saw in substantially a horizontal plane, manual means being employed for moving the frame and saw, and its operating means, longitudinally of the table. Patent 1763478. Clarence E. Palmeter.

Window Fastener—Comprising a corrugated fastening strip secured to the frame and a hinged fastener with tension spring, for locking the window in any position against upward movement but allowing a downward movement at will. Patent 1762280. Arthur J. Slingerland.

Dado Cutter—A device of simple construction for cutting grooves, whereby a plurality of grooves may be formed of various dimensions through adjustable means for controlling the position of the cutters. Patent 1763463. John Garthe.

Combination Cleaver, Knife and Saw—Comprising a blade, the major portion of which forms a knife, the remainder being thickened to form a clever-like structure, the construction being such that the back of the blade will support a saw. Patent 1763452. Bert Williamson.

Ice Pick—A pick or awl-like member which may be safely disposed within the handle, when not in use, but may be readily projected and held in active position for breaking ice. Patent 1768035. William E. Domaratius.

Sharpening Device for Curved-Edged Tools—A manually operable sharpening tool for traversing and conforming to the swing of the curved cutting edge, making it possible to sweep the cutting edge at one stroke and at the proper angle. Patent 1767941. Norris T. Pindar.

Heating and Lighting

Revolving Broiler—Wherein different kinds of food to be cooked are carried by suitable supports, and caused to rotate while exposed to view, but remain unmolested until completely cooked, yet may be basted from time to time. Patent 1762035. George Soylian.

Apparatus for Utilizing Solar Heat—Which includes a chamber adapted to be exposed to the sun rays' and in which the sun's heat is concentrated, a steam generator into which heated gas is introduced under pressure for utilization. Patent 1765136. Charles H. Drane.

Cold-Water Tube and Cleaner for Domestic Boilers and Heaters—Wherein a clean-cut tube is provided which may be used by workmen for cleaning out a boiler or heater or may be used as a combined cleaner and cold water supply pipe. The inventor has been granted two patents of a similar nature. Patents 1767919 and 1768039. William Eiermann.

Machines and Mechanical Devices

Lubricant-Distributing Apparatus—By which the various movable parts of an engine or other mechanism, can be automatically lubricated, the feeding being increased or decreased according to the speed of the engine and excess lubrication prevented. Patent 1760902. David Grattan.

Beater—Which utilizes an electric motor and a form of planetary gearing whereby the beaters or stirring members may be grouped so that certain members will move in a circle and others will rotate in situ. Patent 1762081. George Schleicher.

Apparatus for Liquefying Solidified Honey—Whereby the liquefaction of solidified honey in cans, may be effected in order that the honey may be removed, without discoloration, thus maintaining its original market value. Patent 1761479. Aleck G. Kuykendall.

Load-Ejecting Apparatus for Conveyers—Such as dredgers, excavators, loaders and trenchers, having buckets or scoops in which loads of material are adapted to be transported and the material completely and automatically ejected therefrom with the utmost ease. Patent 1760964. Harold M. Ruth.

Speed-Changing Mechanism—Whereby a speed changing device is provided which gives four direct running speeds with three pairs of gears only, the transmission gears serving not only as idlers but themselves contributing to speed reduction. Patent 1762080. Charles Schaefer.

Hydraulic Actuating Mechanism—Whereby positive control of the valves is maintained, and the position of the valves, is totally independent of the particular construction of the engine, as the usual valve working rods, levers, and cams are completely dispensed with. Patent 1762068. Heinrich M. M. Mattern, Jr.

Fishing Tool—For removing from wells broken or lost parts of rotary bits; or other tools used in rotary drilling, in such manner that by removal of the drill pipe the obstructing object may be recovered. Patent 1761463. Govenor K. Beckett.

Well-Casing Shoe—For use in the sinking of outer or inner casings or screens, to afford means for introducing water under pressure to the lower edge of the shoe for eroding the formation through which the casing is being sunk. Patent 1762012. Elmer D. Every.

Combined Drying, Drumming, Cleaning, Caging and Finishing Fur Machine—Capable of effectively performing all the necessary steps to condition fur-skins or pelts for commercial purposes, incidentally accomplishing these results with comparative economy as to time, labor, and expense. Patent 1763462. Herman Gabbe.

Plaited Hat Lining and Method and Apparatus for Making the Same—A sewing machine with an attachment for plaiting hat linings in which a stiffening filler piece is employed to connect the side, crown and tip of the lining to give a highly tailored effect. Patent 1763468. Alfred Kurtz.

Road-Working Apparatus—Preferably in the form of a power operated vehicle having electromagnetic means adjustably mounted thereon, and to be transported along a road for picking up all ferrous materials or substances injurious to pneumatic tires. Patent 1763457. Charles R. Churchill and Joseph R. Haynen.

Fortilla-Forming Machine—A cake forming machine embodying a pair of coacting dough pressing rollers having means for detaching the dough from one roller and subsequently detaching the cut or stamped cakes from the other roller. Patent 1763445. Luis Romero.

Drawing-in-Filling Preventer—For preventing the catching of the remaining filling on a bobbin between the shuttle and box plate of the loom, and the breaking off at a moment of transfer of a new bobbin from the magazine. Patent 1763456. Theophile Caux.

Spray Gun—Which has novel means for actuating the air valve and paint valve simultaneously, whereby there will be no frictional contact, and means whereby the spray may be changed from a round to a flat. Patent 1762282. Emil H. Stephan.

Automatic Sash Machine—For use in the manufacture of window stiles, wherein means are provided for feeding the stiles to the machine, boring, grooving, molding the stock on two edges, and dressing to a desired thickness, in a series of operations. Patent 1762273. David B. Mackenzie.

Power Steam-Feed Lever—For operating the steam feed valve in a saw mill by mechanical power, which will eliminate fatigue on the part of the operator in using the hand-operated devices usually employed. Patent 1765069. Edwin J. Gibson.

Pump—Primarily designed for oil wells in which one or more controlling pistons are positively manipulated from above the surface of the ground, either hydraulically, mechanically, electrically, or by air or gas pressure. Patent 1765085. Harley H. Markey.

Semiautomatic Dipper Trip and Monkey-Line Winder—A re-winding mechansim for monkey lines, wherein the line may be maintained taut, taken in and allowed to slacken as desired, for maintaining a clam shell bucket in a swinging or desired position. Patent 1765089 George G. Morin.

Ship-Unloading Device—Whereby means are provided for quickly conveying merchandise from the hold to the deck, and by a chute directly from the deck to the quay or lighters, without encumbering either the hold or the deck. Patent 1765118. Mario Abriani.

Dispensing Device—Which is adapted to dispose in bottles predetermined amounts of liquid with means for varying the amount disposed, the operation continuing until the entire amount of liquid in the machine has been disposed of. Patent 1763971. James Kantor and Charles H. Miller.

Submarine - Salvaging Apparatus — A suitable number of floats carried by a submarine are released by the sunken boat, whereby a salvaging crew, with the aid of a mother ship, may raise the submarine without requiring divers to be sent down. Patent 1765101. John Schierenbeck.

Lawn Mower—Particularly adapted for cutting grass located adjacent to the trunks of trees or close to fences, walks, bushes or other parts adjacent to a lawn which have been inaccessible by the conventional type of mower. Patent 1762287. John H. Blair.

Vending Machine—Adapted more particularly for vending flat articles, such as newspapers, periodicals, etc., a slidable drawer permitting the delivery of the article after a required number of coins have been deposited. Patent 1765216. Major Duncan.

Boiler Flue and Pipe Cutter—In which a circular knife is moved into contact with a revolving pipe to be cut, a motor causing operation of rotating means, revolving means being manually actuated for causing the cutter to engage the pipe. Patent 1765208. James I. Cunningham.

Sheet-Cutting Machine—A rotatable work support and conveyer for moving rubber sheet material in a longitudinal direction for cutting sheets at predetermined points as the rubber is fed from the calendar. Patent 1765184. Elno H. Trump.

Bottle Washing Machine—In which the bottles are inverted and successively fed over jets of fluid containing solid objects such as rubber spheres, which are projected for removing foreign matter both from the interior and exterior of the bottle. Patent 1761492. Frank B. Reily.

Bit-Forming Machine—With which uniform shaped bits of comparatively superior construction may be produced expeditiously and for sharpening used bits of uniform shape, may be adjusted to different sizes. Patent 1767881. Jeremiah V. Gustin.

Pump—A rotary high speed submerged verticle type; the blades of the water wheel being constructed to obtain a greater lift in proportion to the horse power required, especially useful for irrigation purposes. Patent 1768130. Robert L. Meaux.

Lock—Designed to be gravitationally locked and electrically released although intended to broadly cover mechanical releasing means, particularly adapted for sliding closures, such as cages in banks, is simple and highly efficient. Patent 1768021. William E. Bauerband.

Multiple-Speed Transmission Mechanism—Which includes a shiftable carrier composed of sections which are sleeved on the drive and driven shafts, whereby various combinations of gearing and different speeds will be effected. Patent 1767909. Herbert G. Altvater.

Watch-Crystal-Fitting Device—Whereby the pattern and size of crystal may be readily and accurately traced on a crystal blank directly from the inside edge of the bezel of the watch case to which the finished crystal is to be applied. Patent 1767935. James B. McDaniel.

Cutting and Grinding Mill—For feed, silage, etc., having a stationary cutting knife at the entrance of the machine in connection with the rotary cutters, whereby the material will be cut into pieces before grinding so that no choking of the machine will occur. Patent 1767921. Steve R. Gately.

Machine for Cleaning Cotton and the Like—Which continuously utilizes the same current of air, so that the moisture content may be relied upon as being substantially uniform, and the change of air at short intervals obviated. Patent 1767957. John S. Bachman.

Floor Polisher—A unitary structure which may be readily applied to the floor and easily operated with means for adjusting the horizontal position of the brushes. Patent 1767983. William H. Hughes.

Closure-Operating Mechanism—By which doors, particularly garage doors, are adapted to be automatically opened or closed according to the vehicle approaching or leaving the garage, thus obviating annoyance in inclement weather. Patent 1764150. George G. Candee.

Apparatus for Automatically Determining and Recording the Specific Gravities of Fluids—For use in measuring gases, natural or artificial, flowing through pipes, where due to the mixture of different densities, it is desired to have a record of the specific gravity at all times. Patent 1764103. Harry A. Hurley and Herbert J. Tones.

Street-Marking Apparatus—Having one or more brushes, each rotatable about a vertical axis, in a manner to produce a painting motion for marking highways with lines for defining pedestrian and vehicular traffic zones. Patent 1764546. William B. Burnley.

Medical and Surgical Devices

Womb Medical Applicator—Comprising a ring of semi-flexible material, and a receiving bag associated therewith, with inwardly extending loops adapted to receive and apply a medicament to the cervix and associated portions of the female anatomy. Patent 1760751. Jose L. M. Guenard.

Test-Tube Rack—Composed of several parts which can be nested and conveniently carried from place to place in a satchel and set up for supporting the tubes during the heating and cooling action, and the draining and drying. Patent 1763461. Charles Fowler.

Musical Devices

Music-Teaching Device—Having a staff board and a number of lights representing notes on the scale, the lights being controllable by the teacher, whereby the students will quickly learn to sing at sight from the illuminated notes. Patent 1763444. Michael B. Rock.

Musical Instrument—Especially designed for use in children's bands, as a foundation for other instrumental work, it being constructed to start the coordination of the tongue, lipping and fingers, as used in wood wind instruments. Patent 1767998. William B. Parkinson.

Plumbing and Fittings

Plumbing Fixture—A pressure trap, having in combination therewith a pivoted buoyant valve member adapted to control the flow of fluid therethrough in a predetermined direction, the whole forming a simply assembled and disassembled fixture. Patent 1763466. Albert M. Khun.

Plumbing Fixture—A back pressure trap with leverage means for controlling the movement of an associated valve whereby the flow of fluid is confined to a predetermined direction and back pressure is prevented. Patent 1765078. Albert M. Khun.

Prime Movers and Their Accessories

Valve Mechanism for Internal-Combustion Engines—A valve in the form of a vertically positioned sleeve mounted to turn in a circular groove in the head of the engine, and held in place by a top plate, annular gear teeth imparting the turning movement. Patent 1763460. Jesse F. Fisk.

Reversing Gear for Reciprocating Engines with Hydraulically-Operated Valves—Whereby reversing is effected by altering the admission and discharge of the fluid to and from the pistons, by means of cocks or other control devices in the corresponding pipes for the liquid. Patent 1763474. H. M. Meier Mattern.

Valve Lifter—Adapted to be operated in conjunction with spring-actuated poppet valve members of an internal combustion engine, affording a positive vertical lift, simplicity in operation, extreme power, and insuring a positive lock at any height of lift. Patent 1765138. Willard J. Dunston.

Valve—Having novel means for directing the exhaust gas away from the valve head in an internal combustion engine, preventing the warping and leaking of the valve and keeping the valve head cool. Patent 1763951. Carl F. Burgmann.

Engine—Of the two-cycle principle, in which the customary piston is inverted and the explosion of the gas takes place within the interior of the piston, a novel water jacket cooling the inside and outside. Patent 1763959. Fred F. Finch.

Valve-Spring-Lifting Tool—For compressing the coil spring around the stem of a poppet valve of internal combustion engine to release the tension upon its supporting pin so that the pin may be withdrawn and the valve removed. Patent 1764519. Arthur L. Mettler.

Railways and Their Accessories

Rail Fastening—Including a fastener plate formed substantially H-shaped and having overhanging shoulders with the parts formed to be secured to ties by spikes, welding, rivets or other securing means. Patent 1760723. John G. and Arthur N. Snyder.

Dirigible Headlight—For locomotives, or the like, having a support responsive to gravity to cause the light to automatically illuminate the track in advance of the locomotive, whether the latter is traversing a curved or straight stretch. Patent 1761484. George G. McNee.

Flange Oiler—For oiling locomotive wheels whereby the lubricant may be directed against the flange of the wheel which is brought into direct contact with the sides of the treads of the rails. Patent 1765202. James C. Burford.

Air-Actuated Mechanism for Locking Throttle Levers—Wherein the air employed for positively locking the throttle lever may be passed to a bell-actuating mechanism for notifying persons upon the train or there around that the train is to be set in motion. Patent 1763954. William M. Cross.

Combined Tie Plate and Rail Anchor—Which will rigidly hold the rail against lateral or longitudinal displacement, obviates the need of the ordinary tie plate and protects the tie, and acts as a brace for the rail. Patent 1767937. William A. McFarland.

Signal Recorder—A recording mechanism for each actuation of a signal, which embodies a horological instrument and a pressure actuated time stamping mechanism operable incident to the action of the signal, or the actuation of a whistle on the locomotive. Patent 1768154. Harry O. Sampson.

Pertaining to Recreation

Toy Palpitating Heart—A toy of novel construction which may be used to simulate the action of a palpitating heart, for the purpose of surprising and amusing onlookers. Patent 1763467. Herman H. D. Klinker.

Swimming Device—By means of which persons not experienced in the art of swimming are able to keep afloat on the surface, to increase the efficiency of the stroke, and thereby reduce the muscular force exerted in swimming. Patent 1765116. Linwood R. Williams.

Game Board—Of the type in which objects moving about the surface of the board are controlled by a player, the board having a resilient mounting, may be readily tilted to various angles and inclinations. Patent 1768016. Arthur L. Walker.

Ski Sled—Which may be used as a sled and the runners thereof being in the form of skiis, may be readily detached for use in the usual manner for sliding over freshly fallen snow. Patent 1768046. Christian Fredrickson.

Pertaining to Vehicles

Vehicle—A pedal-operated device whereby smooth operation will be insured during all the various stages, and having means whereby the vehicle may turn a corner at a high rate of speed, with a minimum risk of overturning. Patent 1758957. Robert G. McKay.

Parking Device for Motor Vehicles—A simple attachment which may be used with a standard automobile, whereby the front wheels may be lifted and the rear end wheels swung about as a pivot, until a curbing, or the like is paralleled. Patent 1758964. John Myers.

Rumble-Seat Top—Which is incorporated in the car body during manufacture and completely housed in the seat structure when not in use, but readily capable of extension to completely house the occupants when required. Patent 1760334. Otto Altenbach.

Motor-Vehicle Seat—Particularly adapted for use in connection with the driver's seat, whereby the seat is so constructed that it may be adjusted to alter the vertical height to that most comfortable for the driver's personal use. Patent 1762046. Albert B. Blumenberg.

Lining-Gun Nozzle—Comprising a tapered tubular intake stem and a form of hair-brush or pencil, designed to be drawn along a moulding or the plain surface of a motor car, a drip container catching any surplus liquid. Patent 1762058. Herbert H. Harris and William T. Whittingslowe.

Steering Gear—In which the engine or motor is utilized to shift the angular disposition of the wheel, it being only necessary for the operator to initiate the movement. Particularly adapted for heavy vehicles requiring great strength. Patent 1763470. George E. Lemon.

Signal Mechanism for Automobiles—For automatically lighting the lamps at the front and rear to indicate turns, the mechanism being manually actuated, and independently functioning for lighting the lamps in different sequence, to indicate the turning motion. Patent 1763465. William F. Hild.

Device for Supporting Articles on Tires or the Like—For supporting, for instance, a mirror, on the spare tire, commonly carried on the running board, of an automobile, in such position that it may be conveniently observed by the driver, but secured against theft. Patent 1765099. Abraham W. Rosen.

Motor-Vehicle Brake—Wherein the brake band has one end fixed and its other end movable so that upon application of operating pressure the entire band will be circumferentially expanded against the brake drum. Patent 1768176. Gus Walker.

Recording Device for Automobiles—Which may be secured to the instrument board of a car, and swung from behind the latter into position for quickly recording various data relating to gasoline filling, oil, etc. Patent 1767924. Nelson L. Greene.

Signal Device for Motor Vehicles—An arm type of signal, for extension outwardly from the side of the vehicle to indicate to the drivers of other vehicles the stopping, slowing, or direction of turn, the device is manually controlled. Patent 1768034. John Deblieux.

Card Holder—Whereby a certificate or owner's registration card or the like, may be securely fastened in a conspicuous place on a part of the automobile, and means for preventing substitution of another card. Patent 1767993. Adolph G. Lorenz.

Theft-proof Tire-Valve Cap—A simple device which will be under control of an authorized person to make possible the application or removal of the valve stem cap, but impossible for unauthorized persons to remove the cap. Patent 1767884. Harison Heinrich.

Air-Pressure Gauge—A gauge for use in connection with an attachment employed for inflating tires, the device is of simple construction and arranged to permit the gagging and indicating of various pressures. Patent 1768275 William C. Urton.

Mechanical Engineering

Learn at Home

Mechanical Engineering embraces the design, construction and operation of machines and machine tools. It is a profession which offers almost unlimited opportunities to men who combine natural mechanical ability with technical training.

For this is The Age of Machinery. Almost every convenience, luxury or necessity which we enjoy depends on machinery for its production or adaptability to our needs. Every new invention multiplies the opportunities for competent designers, builders, erecting engineers, etc.

One of the best ways to train yourself to secure a position as a Mechanical Engineer is through the home-study courses of the International Correspondence Schools.

These courses are complete and up-to-date, and they are especially arranged to meet the needs of the student who studies at home.

They are particularly helpful because they are written by well-known mechanical engineers who have had years of practical experience in this field and who know the quickest, best way to solve every problem.

Just mark and mail the coupon and we'll gladly send you Free Booklets describing the I. C. S. courses in Mechanical Engineering or any other course in which you are interested.

S. A. Mitchell

FOR the determination of the distances of 1000 stars, Professor S. A. Mitchell, Director of the Leander McCormick Observatory at the University of Virginia, recently has been honored by other astronomers—as Professor Russell explains on page 280 of the present number. The stars whose distances were determined are within the galaxy—that is, within our own "island universe." They range from six to 600 light years. The work involved no simple, easy "mass production" method of ascertaining these distances, but each individual star required much painstaking labor and application. Dr. Mitchell's prominence in astronomy, however, is based not alone on this kind of research; he is a leading authority on solar eclipses, his large book, "Eclipses of the Sun," being the standard work on every aspect of the subject. Professor Mitchell also has done research at Yerkes Observatory, also at Columbia. He is a Canadian.

A group of members of the American Association of Variable Star Observers visiting Georgetown Observatory during a Washington meeting. About half are "professional" and half "amateur" astronomers, but in astronomy such a distinction seldom is made, because the amateur has done so much professional work in the past

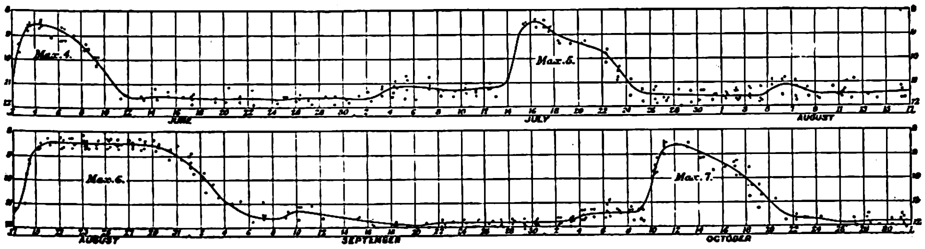
One Touch of Nature

By DAVID B. PICKERING

The American Association of Variable Star Observers

OF the tens of thousands of millions of stars which photographs taken through the world's great telescopes will show us, all but a few thousand, a mere handful, are staid, well balanced citizens of space. All, of course, are suns, larger and brighter on the average than our glowing orb of day, but so vastly distant that they appear but as points of light even through our most powerful instruments. In human affairs our concern is with those who disobey the laws of society and ignore its conventions. Even so, in the world of stars we are drawn to those nonconformists whose vagaries, in many cases, seem to be beyond the pale of the law. Unlike their more regular brethern, they dare to change their brilliancy—throwing into space at times vast quantities of light; while at other times, so prodigal of this commodity have they been, that they shine with but a fraction of their former brightness.

The basic laws that underlie these changes in brilliancy are, in many cases, still a mystery to man, but his urge to know the truth impells him, nevertheless, to study them with sometimes passionate intensity. These lawless ones are known as variable stars. In the catalogues of the heavens they are designated by certain Roman capital letters, and the name of the constellations in which they appear. Thus we have SS *Cygni* —the variable star SS in the constellation of Cygnus, the Swan. To an observer with a small telescope, this star remains in comparative obscurity for an indefinite period, and then with startling rapidity grows in brilliancy to nearly 100 times its former state. It is one of the most mysterious and and therefore most famous of all variables—a veritable François Villon of the skies, whose next daring move his closest observers may not even guess.



From the *Journal of the British Astronomical Association*

Light curve of the variable star SS *Cygni*, 1927, from observations by the Variable Star Section of the British Astronomical Association (another amateur and professional body—in fact, this point of view is world wide)

LET us recite an emotional experience from the life of any variable star observer:

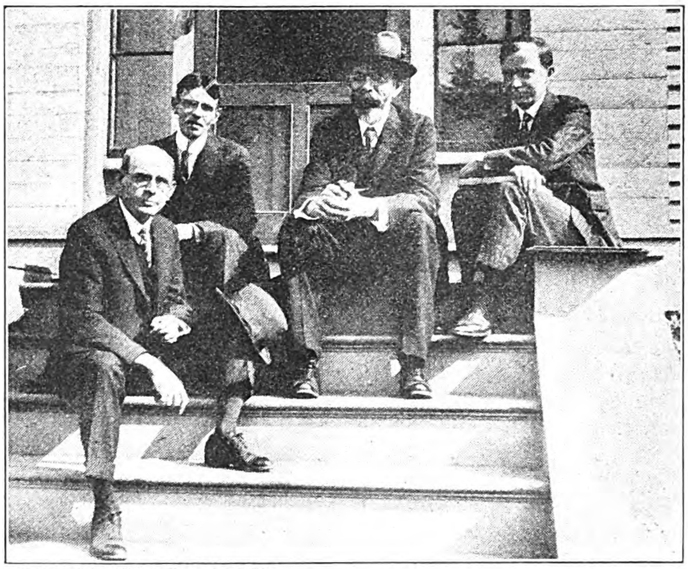
"Watchman, what of the night?" Many times throughout the day this phrase had trailed dimly through his mind as he sat in his stuffy office in the city, immersed in the details of accounts. Many times he had glanced quizzically through the window at the occasional clouds that sailed above the sea of brick and stone without. Later, from the window of the train that bore him to his suburban home, he noted with a thrill that the October sun decended through a cloudless sky.

As the evening meal progressed, as the dusk deepened and the lamps were lighted, wife and daughter wondered at his almost furtive manner. The faraway look in his eyes, the air of

"A.A.V.S.O's" hobnobbing. Left to right: Yalden, Godfrey, Miss Cannon, Miss Potter, Dean Potter, Professor E. W. Brown, Olcott

suppressed nervousness, led them to think that perhaps the daily office grind was proving too great a strain. With a guilty smile he excused himself before the meal was finished, and a moment later, as he passed through the dining room bearing the long yellow tube of his telescope, he was abashed by his wife's expression of quiet resignation. But, once the kitchen door had closed behind him, his spirit, imprisoned during the day, rose to meet the stars that kept their tryst with him—there in his own back yard.

He clamped the tube of his three-inch telescope into the cradle of the mounting atop the post that stood between the rose bushes, and adjusted the screen that shielded his eyes from nearby lights and kept the vagrant breezes from disturbing his charts on the little table at his side.



Photograph by William Henry, A.A.V.S.O.

Group at an A.A.V.S.O. meeting. Left to right: Pickering (the author), Olcott the founder, Yalden, Professor Harlow Shapley (Director, Harvard Observatory)

NOW his eyes rested for a moment on the stars overhead, then dropped westward to the great Cross of the North that glowed in that group called Cygnus — the Swan. There on its side it lay, submerged in the depths of the Milky Way. He lighted his dim lamp and let its red rays fall upon his star atlas. How still everything seemed, here in this secluded little garden. He swung his telescope until it was directed toward the slanting cross; then, while glancing at the sky along the edge of the tube, raised it until it rested some distance above the sparkling star Deneb.

He places eye to the eyepiece and cautiously moves the tube, slowly sweeping it back and forth, up and down. In the round, star-filled field of the eyepiece, the bright asterisms assume many and various forms, but with suppressed excitement he seeks one familiar form in particular. It is an "L" shaped group of stars, resembling a carpenter's square, opposite which is a group of fainter stars which, because of its dome-like shape, is known as the "bee-hive." Between these lies a triangle of stars, in which is located that elusive, mysterious variable, known to astronomers as SS *Cygni*.

On every clear night, for weeks past, he has sought this part of the sky—found and noted the familiar asterisms of this particular field—but on each night, though he knew the exact spot where it should appear, the object of his quest has eluded him. Last night again, it was beyond the power of his glass. Once more tonight, with the patience of a sleuth, he seeks the outlaw. Ah! here at last is the carpenter's square—and there the little bee-hive.

But—what is this! For an instant his heart seems to have stopped beating—then it begins to pound again—he is breathing faster. Something must have happened. Something *has* happened. SS *Cygni* is the brightest star in the field. Sometime within the last 24 hours, this giant sun has burst the bonds of mediocrity and is now radiating with one hundred fold the force of yesterday's energy. No wonder his emotions run riot. Seated here in the silent darkness among his roses, he is the lone observer of this tremendous cosmic event—the witness of a mystery which no man has fathomed.

The kitchen door swings wide. A stream of light from within flows across the lawn to the telescope. A girlish treble calls: "Hey, Dad, you goin' to the movies?"

Tomorrow's paper will tell of the gowns worn at the Vandercliff wedding—but there will be no mention of this magnificent gesture on the part of the Creator.

OBSERVING variable stars is the job of a trained amateur astronomer. The word "amateur" means one who does a thing because of his love for it. It is often wrongly applied to a fumbler. I have never known an astronomer—man or woman—who was not an amateur. If it so happened that astronomy was also his vocation, his professionalism was quite a secondary matter. What more natural than to find a brotherhood of interest among astronomers, such as exists perhaps in no other branch of science. Quite likely it was this fraternal instinct that, 20 years ago, brought together the late Edward C. Pickering, Director of the Harvard College Observatory, and William Tyler Olcott, an amateur telescopist of Norwich, Connecticut. Pickering, the professional, had a job for amateurs. Olcott, the amateur, was looking for a chance to aid science. Pickering became the "Big Brother" of all variable star lovers. Olcott became the founder of the "American Association of Variable Star Observers."

In was in 1911 that this Connecticut attorney began to enlist the services of other amateurs in the great game of estimating the brightness of the long period variable stars. In that year, seven men formed an Association, and began work. At the end of three years there were about 20 members. Today the Association numbers about 300 men and women in 23 countries of the world.

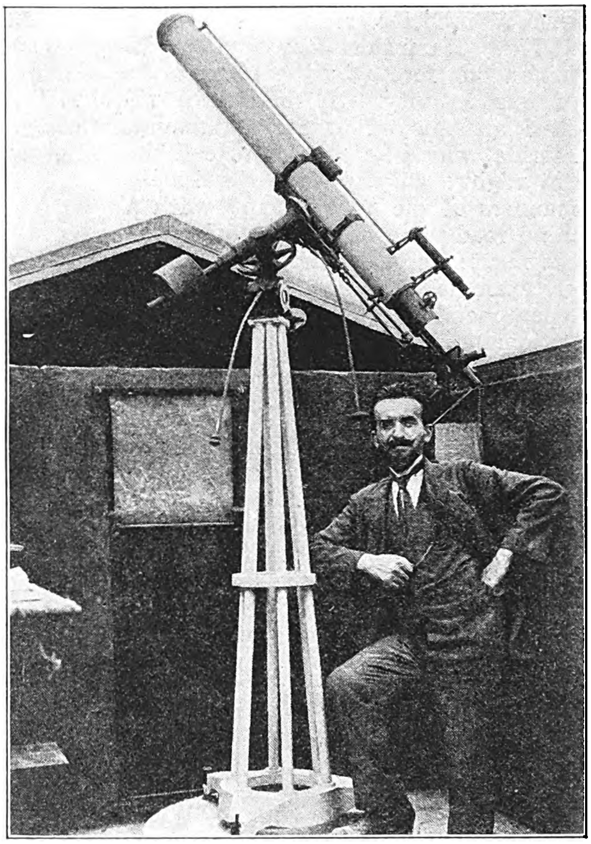
The fact that some of the stars are not constant, is the "touch of nature" that has "made kin" of hundreds of people all over the world—people whose vocations are almost as varied in character as are the stars themselves. Among the great amateurs of the country who make astronomy a profession, and who form the solid background and support of the Association, are several famous men, who, though listed as Honorary Members, are active in the extreme. Upon the shoulders of Dr. Harlow Shapley, Director of the Harvard College Observatory—"the man who remeasured the universe"—fell the cloak of that "Big Brother" who was our original inspiration. Professor S. A. Mitchell, the genial Director of the Leander McCormick Observatory—"the man who made a thousand parallaxes"—is devoting himself to the great task of revising our charts; redetermining our fainter magnitudes by the aid of his 26-inch telescope, in Virginia. Professor Ernest W. Brown, of the Yale Observatory, found that the earth and moon were out of step, and set certain members of our Association "marking time" for this pair. Largely through the efforts of this group, he has recently determined that the earth is the culprit—being out of rating to the extent of one second in a hundred years. This friend and companion of ours never misses a meeting of the "A.A.V.S.O."

BUT most of the variable star observers make of astronomy an avocation. There is Leslie Peltier, for example, whose home on the farm lands near Delphos, Ohio, is many miles from a railway. As a boy he would take his little two-inch glass out into the fields, then make his reports of the brighter variables regularly to the Harvard Observatory. Long since he graduated to a six-inch instrument, and for years was the outstanding "ace" among "A.A.V.S.O." observers. Incidentally, Peltier is the discoverer of two comets, one of which is Comet 1930a, the first to be found this year.

Speaking of comets, the second discovery of the year—1930b—was made also by another member of the "A.A.V.S.O.," Max Beyer of Hamburg, Germany. Though a true amateur, and a major contributor to the Association's reports, he is the publisher of the well known Beyer-Graff Star Atlas which so many of us use.

In the little town of Faenza, Italy, the town whose distinctive pottery gave to the world the name "faience"—lived the postal clerk, G. B. Lacchini. With what ardor he loved the stars and with what great facility he observed the changes in the variables, his long record of faithful service, preserved at the Harvard Observatory, will attest. The authorities at Rome, recognizing his rare ability, have recently taken him from the postal service and made him a member of the staff of the Royal Observatory of Catania, thus granting his heart's desire to devote his life wholly to the stars. His little family moved from their home in the north, to far away Sicily. From the shadow of Mount Etna, his charming daughter, Bianca Rosa, sends me occasional verses in excellent English. Today Lacchini contributes more observations to the "A.A.V.S.O." than any other member.

Lacchini and I had corresponded for a dozen years or more. Then one memorable day in 1926, we met—in Faenza. It was the first time that Lacchini had ever seen a member of the organization which he had served so faithfully, and for so many years. It was a day to be marked with a white stone. On that occasion, too, I met those fine protégés of Lacchini—Benini and Ancarani—who have remained in Faenza to carry on the work he began. Together with one Gallanti, they have organized the "Osservatorio Urania Lamonia," where, with an eight-inch reflector, the property of the "A.A.V.S.O.," they are doing faithful work for the Association.



The topnotch observer of the "American" Association of Variable Star Observers is an Italian, Lacchini, who lives near Mount Etna

Variable star observers commune at Faenza. Left to right: Benini, Pickering, Lacchini, and Ancarini. The organization is international

In the city of Seattle, Washington, lives another man of Italian birth, D. F. Brocchi, an engineer and draftsman for the Northern Pacific Railroad. He too employs his talents making master charts for variable star observation. Later he checks these with the sky by the use of 10- and 12-inch telescopes of his own making. Lacchini and Brocchi and I have for years been responsible for the chart work of the "A.A.V.S.O." Lacchini and Brocchi have never met. Brocchi and I have never met. We are separated from each other by thousands of miles—yet what chums we have become, and what fun we are having, through this common interest.

For many years the head of the "Baron de Hirsch Trade School" in New York City was J. Ernest G. Yalden—the sage of Leonia, New Jersey, whom his friends have affectionately dubbed the "Baron." This tall, bearded genius, with the heart of a boy and the brain of a philosopher, resigned his post some time ago to devote himself entirely to the study of time and the stars. His versatility is astounding—yachtsman, navigator, mathematician, architect, astronomer, and outstanding authority on the ancient art of sun-dialing. He is chief advisor to the Association on observatory construction, and is Chairman of the Committee on Lunar Occultations, another of our important activities.

The Rev. Mr. Tilton C. H. Bouton was a minister of the Gospel in a New Hampshire town when he joined our forces in the early years of our activity. He has since retired and moved to St. Petersburg, Florida, which he chooses to call the "Starlight" City. With the kindly manners of the "old school," with a mind ready and able to grapple with the mysteries of Nature, he has been an example of dependability to his fellow members. He varies his observational and lens-making activities by collecting china and building bows and arrows of rare excellence.

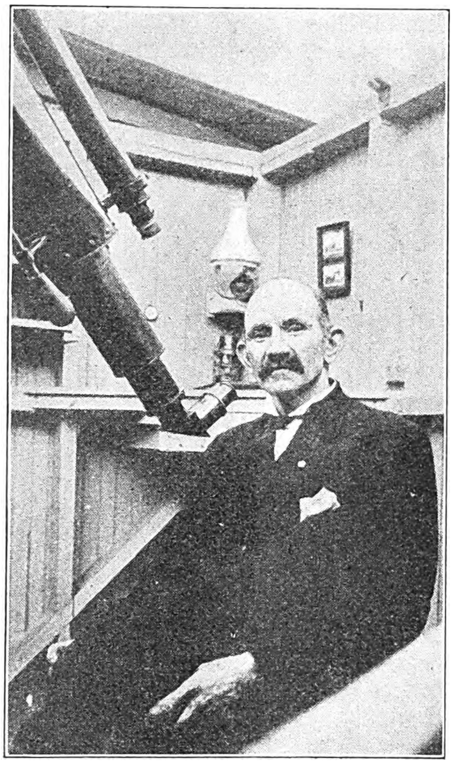
IN 1927 the Association sustained a great loss in the death of its President, Dr. Charles A. Godfrey, a leading physician of Bridgeport, Connecticut. What volumes could be written about his career. He had no means to buy a telescope when as a country boy the stars beckoned to him, so he made his own mirrors and mounted them too.

Another whose memory shall ever be green in the minds and hearts of his fellow members, was Charles Y. McAteer, of Pittsburgh, one of the seven original members of our Association. During his busy, happy life, he spent many hours out of every 24 at the throttle of a Pennsylvania Railroad locomotive. A rack in the side of his cab held a Bible and a star atlas—the only guides he knew or required. Finishing his trip when the night was half spent, he would hurry with his telescope out under the stars, there to observe variables until dawn and sleep broke his vigil. "Mac" was a rough diamond—but of the first water. The great in science were proud to call him friend.

Today, there are Arthur Butler of the New York Stock Exchange; George Waldo of the press; Ernest Jones of the insurance world; Charles Elmer, the court reporter—but space precludes an extended category.

Strange to say, among the 30-odd women who grace the membership of our Association, by far the greater number have chosen astronomy for their vocation. Among the latter who play a prominent part in its affairs, is Professor Anne S. Young, Director of the Mount Holyoke College Observatory, one of our past presidents, and now the editor of our publications.

The president of the Association, at this time, is Dr. Alice H. Farnsworth, also of the Mount Holyoke Observatory, while our vice-president is Professor Harriet W. Bigelow of the Smith College Observatory. Mrs. Margaret Mayall, and Miss Helen B. Sawyer, both of the Harvard staff, are curators of our charts. Dr. Caroline E. Furness, Director of the Vassar College Observatory and author of that splendid treatise, "An Introduction to the Study of Variable Stars," and her assistant Miss Alberta Hawes, are both ardent supporters of the Association and active in its affairs. Equally so, is Dr. Leah Allen, Director of the Hood College Observatory of Frederick, Maryland, and Miss Margaret Harwood, Director of the Maria Mitchell Observatory, on Nantucket Island.



Charles Y. McAteer, one of the seven original members, was a locomotive engineman—"a rough diamond, first water," was "Mac"

Outstanding among the non-professional members is Miss Helen M. Swartz, of South Norwalk, Connecticut, whose devotion to the Association is unquestioned. In Haverford, Pennsylvania, lives Mrs. Otto Haas. Despite the care and responsibilities of rearing her family and attending to her domestic duties, she contributes regularly to our observational records. Still another housewife who devotes her available time faithfully to "A.A.V.S.O." affairs, is Mrs. Mary E. Morris, of Nantucket, Massachusetts.

To our meetings in the spring and fall, come these men and women. Overlords and underlings of big business, professors and students, housewives and teachers, all forgetful for the time being of their daily occupations, they meet on common ground to consider subjects of common interest—to revel in the exchange of thought with kindred spirits. It is at these meetings that Leon Campbell, member of the Harvard staff, and dean of the variable star fraternity, discusses the results of our work. As recording secretary of the "A.A.V.S.O.," it is he who prepares our observations for monthly publication in *Popular Astronomy.*

The dinners with which these meetings invariably close are occasions to be remembered. Thereat we descend from heights of pure research to frolic and fellowship. Woe be to him who tries to hide his pet foible under a bushel of dignity; some one will find him out and exploit his weakness either in verse or song. After every such affair, we return to our familiar stars with a better appreciation of the value of team work.

WHAT a satisfaction it is to know that, because of the far-flung membership of the "A.A.V.S.O.," we are enabled to "spell" one another around the world. Perhaps Peltier of Ohio may be watching for a suspected change in the light of some puzzling star; as daylight ends his vigil, and the shadow retreats westward, he knows that there is a long night ahead in faraway Japan where Sigeru Kanda of Tokyo, or Teiju Kanamori of Naganoken, may mount guard over the same field of stars. When the hours of their stewardship have passed, Chandra of Jessore, India, brings his glass to play upon the sky. Later still the charge may fall to Ehric Liner of Konstanz, Germany, or to A. N. Brown of London. Thus when night again falls upon America, we may feel assured that the sun has not thwarted us.

But, despite this pretty system and these widely separated stations, the Association needs more workers. There are hosts of long period variables and never enough observers to follow all their caprices. We will gladly lead the amateur telescopist into the pleasant and profitable pastures of the variable stars. Through personal contact, by correspondence, or by the aid of literature and charts, we will instruct him in our methods and impress upon him the great assistance which his subsequent service will afford to science. Then, when he has acquired the knack of finding the star fields and estimating the brightness of the stars, and has assured us of his intention actively to co-operate with us, we will welcome him to membership in this happy fraternity of ours.

The very hope of adding one jot to the sum total of accumulated knowledge, seems sufficient reason for anyone to devote time and energy in the pursuit of truth. Perhaps another urge may lie, however, in the response of an eminent man of science when asked why he had given his life to research:—"Because it's so much fun."

OUR POINT OF VIEW

Glenn Hammond Curtiss

THE news of the untimely death of Glenn H. Curtiss at the age of 52, on July 23, came as a shock not only to the aviation world, of which he was one of the few outstanding pioneers, but to the world in general. Inventor, pilot, and manufacturer, he was in turn a bicycle racer and repairer, a motorcycle manufacturer, the first man to make scheduled airplane flights, and finally, an airplane manufacturer. He contributed more to the development of heavier-than-air flight than any other man, and much of America's success in building planes during the war was due to his genius.

After winning many trophies in bicycle racing, Mr. Curtiss made a 10-mile motorcycle record that stood for 16 years. Next he built a motor for an airship, the flight of which was so successful that the government ordered a dirigible. When this was built in 1905, it passed all tests and became Army Dirigible 1. Together with Alexander Graham Bell, he formed, in 1907, the Aerial Experiment Association and built the *Red Wing* which cracked up on its first flight of nearly 319 feet, the first public airplane flight in America. On May 22, 1908, Curtiss flew his second plane, *White Wing,* a distance of 1017 feet and landed safely.

The first previously announced flight in America was made by Curtiss when, on July 4, 1908, he won the first leg of the SCIENTIFIC AMERICAN Trophy by a flight of one kilometer in the now famous *June Bug.* His attempt to take off from the water in the *June Bug,* refitted with pontoons, was unsuccessful but the attempt led to the development of the flying boat which he perfected in 1912.

The second leg of the SCIENTIFIC AMERICAN Trophy was won by Curtiss in the first exhibition flight in America at Hempstead Plains, Long Island. This flight covered 24.7 miles. Then on May 29, 1910, came his greatest triumph: a successful flight down the Hudson River from Albany to New York City by which he won the *World* prize and the third leg of the SCIENTIFIC AMERICAN Trophy, the latter then becoming his permanent possession.

As a builder of planes, Curtiss designed and produced many machines of distinctive design and developed many types of aeronautical motors. In recent years, however, he had relinquished all active interest in the aviation companies that bear his name.

It will be impossible ever to calculate the debt which the world owes to Glenn H. Curtiss but it is an assured fact that aviation will place him forever on the pedestal beside the Wright brothers and Langley. While the world pays tribute to the energy and versatility of the man, SCIENTIFIC AMERICAN, because of its close touch with him during the early skeptical days of aviation, feels that it has suffered a distinct, almost personal loss.

Helping the Deaf

THE almost overwhelming noises of our great cities and of our industrial plants are said to be causing a large increase in the number of the cases of deafness. And it is now understood that deafness frequently tends to cause a mental slowing up and, in some cases, does cause a positive dullness.

The importance, therefore, of the efforts of the Chicago League for the Hard of Hearing to encourage installation of hearing aids on certain seats of churches, theaters, and other large auditoriums so that deafened people may hear and enjoy sermons, music, entertainment, or whatever program is being given, can readily be realized. There are in this country, the Hearing Aids Committee of the above-mentioned organization says, 10,000,000 deafened people, 300,000 of whom are in Chicago. Most of these people have ceased to attend church, cannot enjoy the drama or educational talks, and, since the advent of talking movies, are denied even the pleasure formerly afforded by silent movies. The Committee is backed, in this work, by prominent Chicago organizations.

We wish the League a full measure of success. Theirs is a splendid undertaking and we hope it will be followed in other cities. The world of the person who is hard of hearing is narrow and dreary indeed, and we who have our hearing should extend to him, as much as possible, the means of enjoying the entertainment and cultural programs which so often satiate us.

Before the Accident

DESPITE the disastrous nature of the World War, *The Travelers Standard* voices the opinion that it served a great purpose. It showed how exceedingly horrible a modern war can be and turned men's minds more definitely toward the prevention of future wars. Similarly, the sinking of the *Titanic,* with the loss of 1500 lives, was, it is pointed out, a beneficent disaster because it brought the realization that additional marine safeguards and an ice patrol of the North Atlantic were needed.

In industry, the thousands of safety inventions and devices—mechanical guards over moving machine parts, goggles and masks for workmen, safety valves, protective clothing, and so on—were all born of human agony and sorrow. Someone had to suffer before foremen, plant superintendents, and executives could realize the hazards of old methods.

It is a puzzling and unfortunate fact that foresight, in the matter of industrial safety, has been and is lacking as a rule. The workman has had inculcated in him the spirit of efficiency so that he takes an interest in his work, but he has not yet fully felt the need of accident prevention measures and devices. Working on machinery that is well-protected, he often removes safety devices in the belief, apparently, that he can do his work faster or with less effort.

Some plants are making great advances in safety. In these, workmen are taught the meaning of accident prevention measures and are encouraged to look ahead and devise safer methods of doing the things they do every day. But the toll in fatalities and injuries is still far too great. If the human equation is to blame, then change it by an intelligent educational campaign. The result will be safety before, not after, the accident.

International Affairs

THE THREE POWER NAVAL PACT

PRESIDENT HOOVER won a decisive victory in the prompt and almost unanimous ratification of the naval pact by the Senate. We believe the Senate reflected the public opinion of the country in their action; nevertheless the outcome is a personal triumph for the President, and coming at the close of a Congressional session where his leadership had been several times repudiated, it must have been gratifying. We believe the President deserves all the prestige he has gained by his patient and tactful handling of this difficult problem.

At the same time we entirely understand and sympathize with the patriotic motives that inspired the small group of Senators, ably led by Hale and Johnson, who unsuccessfully opposed the ratification. There is no gainsaying the facts they brought out

The "bathosphere" emerging from a quarter of a mile dive. Note the cannon-like eyes

A 1400-foot Dive

By OTIS BARTON

THE 13th expedition of the Department of Tropical Research of the New York Zoological Society under the direction of Dr. William Beebe has had a very successful season in Bermuda and our knowledge of undersea life has been greatly enlarged by the use of the "bathosphere," designed by the writer and Mr. J. H. J. Butler. This spherical steel diving chamber or tank is a single steel casting fabricated by a firm specializing in hydraulic machinery. The first casting weighed five tons, and proved too heavy for Dr. Beebe's winch. This casting was therefore junked and another "bathosphere" weighing 5000 pounds was substituted. It is four feet nine inches in diameter and its walls are more than an inch and a half in thickness to resist the enormous pressure that is found at great ocean depths.

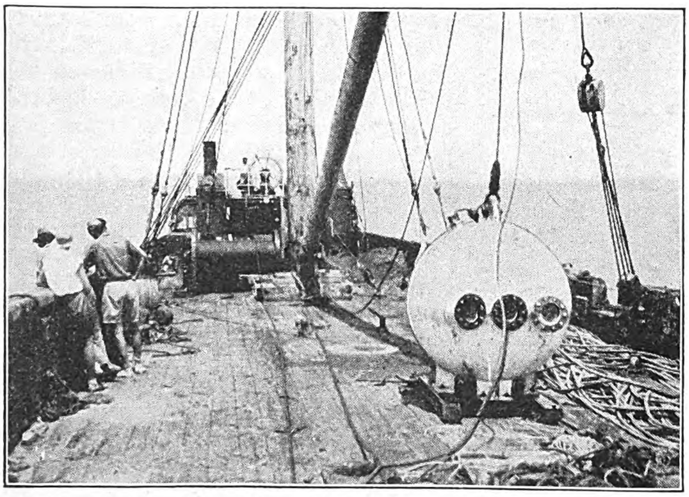
Access to the sphere is gained by a 400-pound door in the rear. It is secured with ten large bolts. In the center of the door is a wing-bolt plug which can be quickly screwed in or out. The door has a circular metal gasket which fits into a shallow groove. This joint, when packed with a little white lead, was entirely waterproof at a test submersion of 2400 feet.

THE windows in front are cylinders of fused quartz eight inches in diameter and three inches thick. They are a special product of the General Electric Company and are fitted into cannon-like projections in the front of the sphere. The joint is secured by a paper gasket and with white lead, and a light steel frame is bolted over the front of each window. In all we had five quartz windows. The first was chipped in an attempt to grind it into its seat. The second gave way under an internal pressure test of 1250 pounds to the square inch. It seems probable that the frame in front was bent and that the resulting shearing strains broke the glass. The third was broken when the frame bolts were tightened unevenly. The remaining two, however, have never leaked a drop, have withstood the pressure under test at 2400 feet, and will no doubt stand much more. We were obliged to seal the third projection with a steel plug.

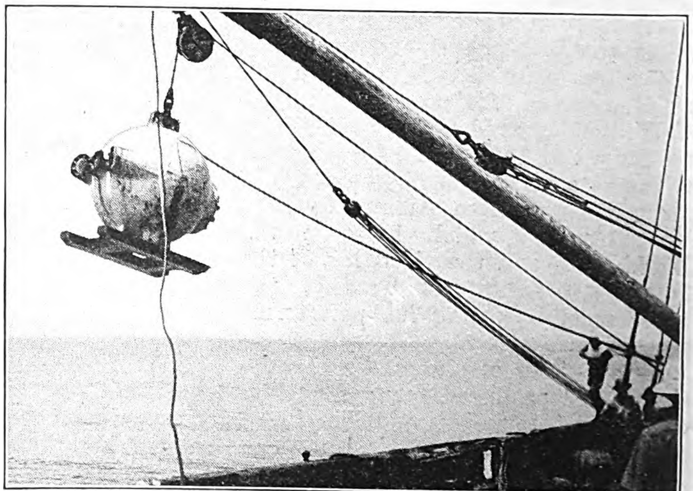
The electric cable was specially made. It is one and one tenth inches in diameter and has heavy rubber insulation. Inside are two conductors for the lights and two for the telephone. The cable passes through a stuffing box in the top of the tank and is squeezed up by two glands, one on the outside of, and the other within, the sphere. The glands proved entirely waterproof under all pressures we encountered, but the higher ocean pressures caused the electric cable to slip in through the stuffing box. It was this which turned us back at 1426 feet. Eventually we succeeded in jamming the cable with friction tape.

The two largest conductors passed to a 150-watt spot light in the right forward projection. At depths of over 700 feet the beam of light could be seen passing through the water. When more illumination was desired, it was simply necessary for the divers to direct the deck crew, by telephone, to speed up the generator. The light was turned out by the divers when they wished to observe the effects of the natural submarine illumination. To facilitate these observations the entire interior of the sphere was painted black. All observations taken in the depths were recorded by the deck crew.

THE breathing apparatus employed was designed by Dr. Alvan Barach of New York. Clamped to the wall of the sphere were two oxygen tanks, either of which would take Dr. Barach's special valve. We set this valve to allow two quarts of oxygen per minute to escape for the two divers. At this rate, one tank lasted



The "bathosphere" on the deck showing the "eyes." The winch and the steam boilers are at the left and Dr. Beebe (hatless) may be seen looking over the rail



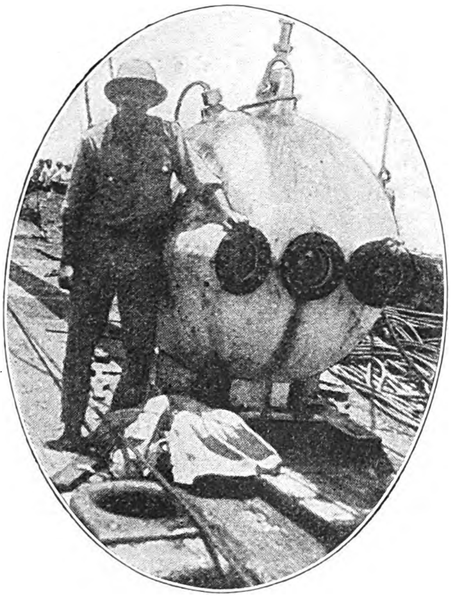
The "bathosphere" is swinging outboard for the dive. Note the skids and the electric cable which carries all the wires for the telephone and electric lights about three hours. Above each tank was a wire mesh tray. One contained soda lime, which took up the carbon dioxide. The other held calcium chloride which absorbed the moisture in the air. Palm leaf fans kept air in circulation. During our deepest dive of 1426 feet we were comfortable and cool, although we were inside more than an hour and a half. The physiological balance was excellent, although after a long dive there was a slight excess of pressure. This we noticed on our ears when the central plug was unscrewed upon reaching the surface.

We always entered the sphere head first, wriggling our way through the narrow manhole. There were no cushions on the floor, for these might hide some of our small implements or obscure leaking drops of water. Our bodies, however, fitted comfortably against the rounded steel walls. The door was put in place with a small hoist. The pounding down of the ten bolts and central ring bolt plug created a fearful racket in the interior. The jarring, however, never seemed to affect the quartz windows.

THE "take-off" always felt smooth, like that of a dirigible. In the air the "bathosphere" swung like a hammock. At times we almost began to feel seasick. Once in the water, however, all was well. We were steady and cool and only knew when we were being lowered by the jerking of the steel cable.

For lowering the ball, we used Dr. Beebe's five-ton winch and special large reel. To operate these, we installed two boilers on the after part of the long deck of our 130-foot lighter, which had once been H. M. S. *Ready*. The lighter was in turn towed by the tug *Gladisfen*, of the New York Zoological Society. This equipment was used on the Arcturus expedition, as were also the three six-ton sheaves. One of these was bolted to the deck about 60 feet in front of the reel, which was amidships. From this the cable returned to the second block close to the mainmast and then passed to the third at the end of the heavy boom.

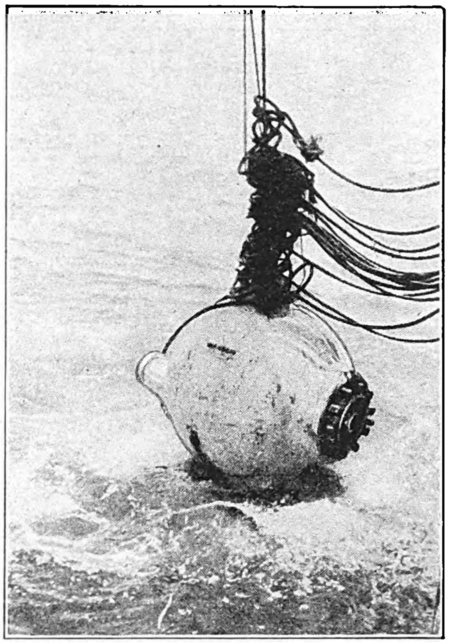
The cable was a special seven-eights-inch steel-center non-spinning type, 3500 feet long, capable of sustaining 29 tons. The amount of cable paid out was tallied by a special meter wheel from the *Arcturus*, as well as by a system of ribbons tied around the cable.



Two of the three windows are closed by heavy three-inch quartz plates

The comparatively light electric cable was let out by hand, and attached at intervals of not more than 200 feet to the steel one. This was done at first with brass clamps, but later it was found better to tie the cables together with lengths of rope about a yard in length, since these took up much of the twisting. The winch was stopped while the tie was made.

Several problems were naturally encountered in these operations. Perhaps the greatest trouble was caused by the twisting of the rubber hose about the steel cable. When twisting was bad we would tie up loops every 200 feet in a loose coil, through the center of which the steel cable continued to operate. Finally, however, we succeeded in getting out as much as 2000 feet without twisting.

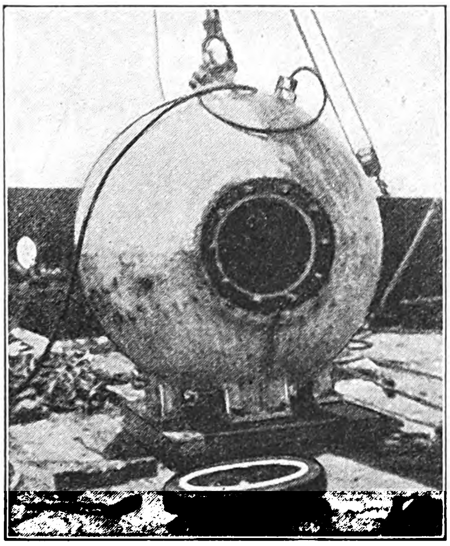


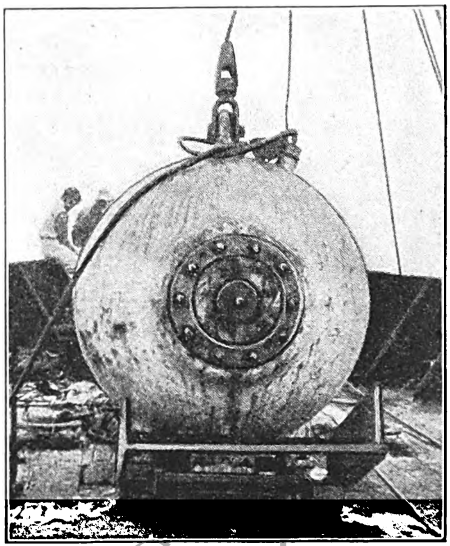
Tangle of steel and electric cables on the first test dive of 2000 feet

Besides taking observations at great depths in the open ocean, we tried towing the tank along under the vessel, endeavoring to keep the bottom in sight and not to run into any ledges, which rise up quite suddenly in these waters. In this work we nailed a wooden rudder on the rear end of each skid, by which the windows were kept always to the front in the direction of motion. A brace of fish hooks was also attached on a frame outside the window. These proved very sensitive indicators of the currents.

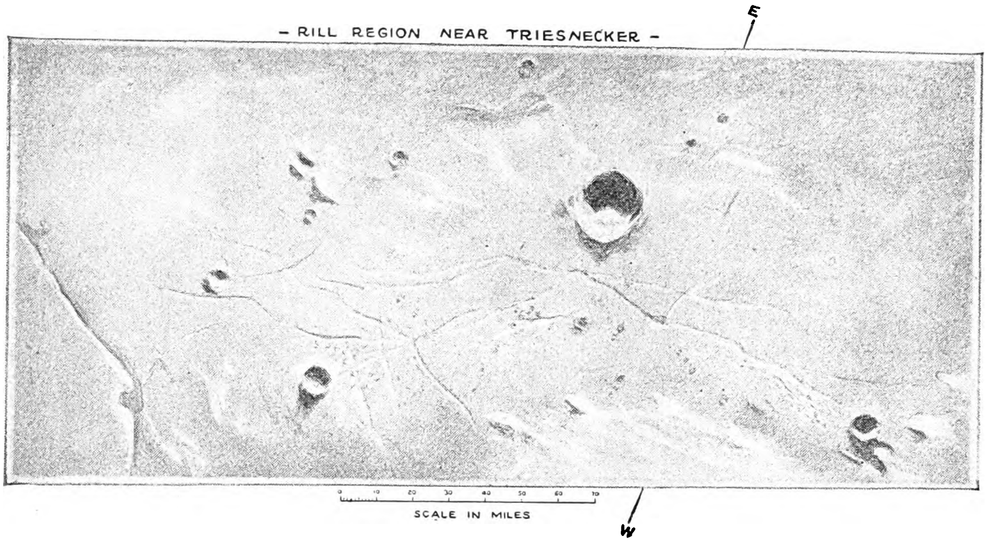
It is with this outfit that we hope next season to study the contours of the bottom down to 500 feet and also to make dives in the open ocean of 2000 feet. The margin of safety seems entirely satisfactory.

Besides the use of the "bathosphere," intensive trawling with meter nets was done, as well as some bottom dredging with the aid of the five-ton *Arcturus* winch. One of the chief objects of the expedition is to determine the continuity of fish life which connects the mid-water zone of one hundred fathoms with that of the ocean's floor two miles down. The expedition has been rendered possible by the generosity of two members of the Society's board, Mr. Harrison Williams and Mr. Mortimer L. Schiff.





After the divers enter the sphere and the four-hundred-pound door is fastened with ten bolts, they are ready to start for "Davy Jones's Locker"



Rill region near the lunar crater called Triesnecker. The drawing extends across about one eighth of the moon's diameter. Lunar "rills" are deep, narrow, crooked depressions, resembling valleys

Moonscapes

A Letter from RUSSELL W. PORTER

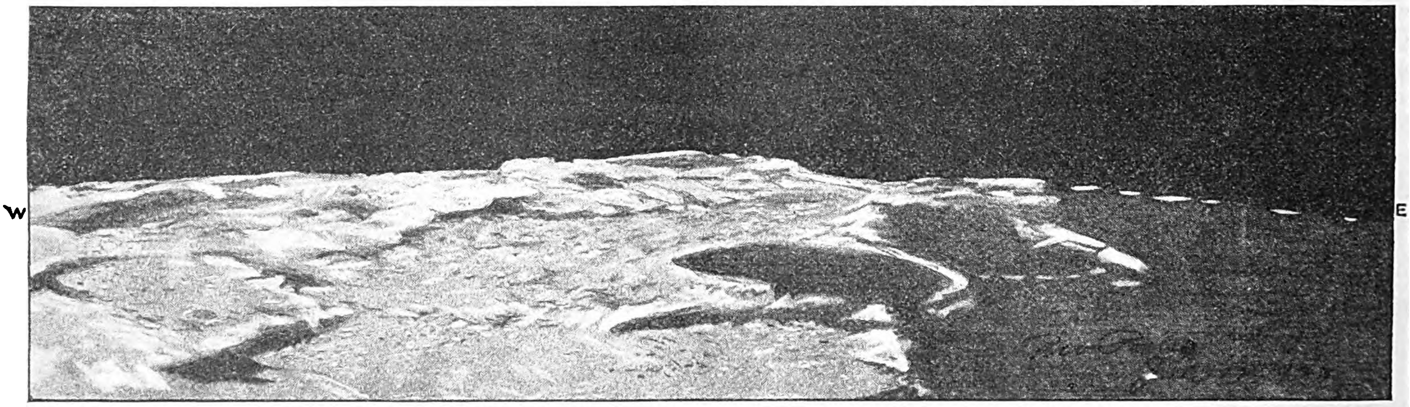
Optical Associate, Jones and Lamson Machine Company; Associate in Optics and Instrument Design, California Institute of Technology; Contributing Editor

ONE of my red letter days came at Mount Wilson when it was suggested by the astronomers that I try my hand at drawing details of the moon's surface—details which are too small to be recorded on photographs. Previous work of this kind, done some years before, together with a facility in using a pencil, made it seem likely that, provided the seeing was good, I would be able to transfer to paper certain lunar objects or markings which would be of value and serve as a kind of standard of seeing.

Unfortunately, the nights allocated to me turned out to be accompanied by relatively poor seeing—from 1 to 3 on the familiar Harvard scale of 10. Therefore these three moonscapes have no particular scientific value, but fall into the category of interesting sketches. Nevertheless, the thrill I got at the eyepiece of the 60-inch telescope during the few hours available will live with me for many a day.

The instrument itself, which I first sketched by daylight [see page 248—*Ed.*], is one of the largest of reflectors, and is greatly beloved by the astronomers. To me, as I sketched the monster taking his afternoon nap, bathed in the dim light that filtered through the shutters of the observatory dome, it seemed to possess a certain sort of personified austerity. If the term "noble" can be ascribed to an inanimate object, I would clothe the wholesome design of the 60-inch reflector with the attribute of nobility.

The moon's image was formed at the Cassegrainian focus near the lower end of the telescope tube, and that night was viewed through a low-powered eyepiece. With the help of the mechanician, Mr. Jones, and the night assistant, Mr. Krisler, my drawing board was fastened with clamps and brackets to the right of and near to the eyepiece, and after many trials was adjusted in such a position that it gave the maximum of comfort and convenience for drawing with my right hand while constantly shifting the eye from the eyepiece to the drawing. A

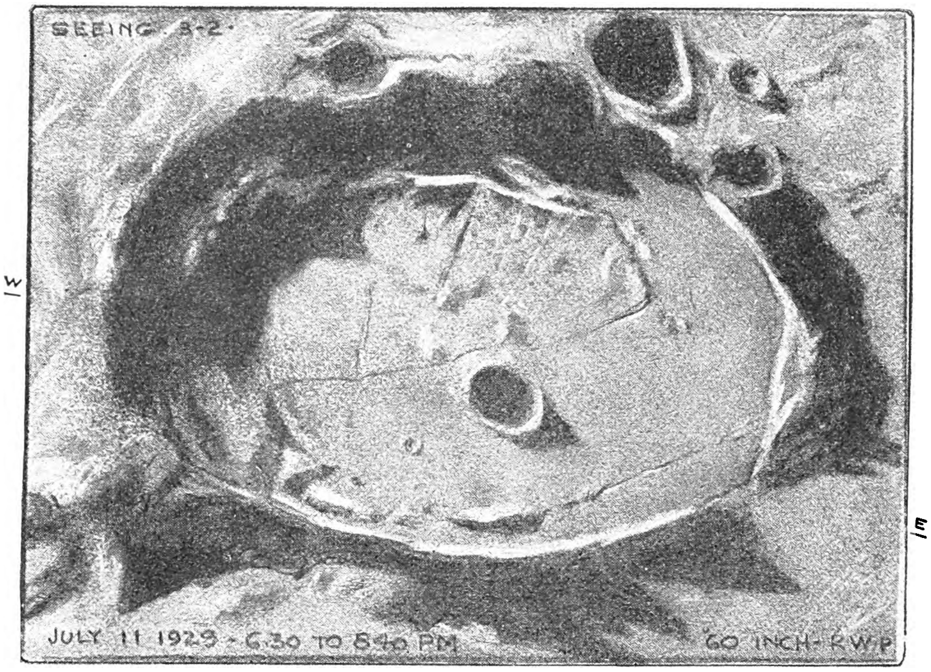


Region around the moon's north pole, showing the craters of Meton and Euctemon. All of the moon's craters are named and thousands of astronomers, professional and amateur, carry the moon's map as vividly in mind as the map of their own city or state. For many years these "selenographers" have concentrated regularly on systematic programs of observation of certain craters and some, notably Professor W. H. Pickering of Jamaica, believe there are small regular changes due not alone to the gradual shifting of lights and shadows. If these changes are objective their cause and nature are unknown.

The moon's temperature range recently has been worked out experimentally by the astronomers Pettit and Nicholson of Mount Wilson Observatory. They state that "the temperature rises from that of liquid air at sunrise to the boiling point of water at noon; returns as the sun becomes lower in the lunar sky, and hovers near that of liquid air during the next fortnight"—that is, during the long lunar night. Even in the lunar day the temperature of the craters shown above is only about 60 below the Fahrenheit zero, because these craters lie where the sun's rays barely graze them; that is, near the moon's limb

lamp bulb clamped to the board, and shielded from the eye, illuminated the paper in such a way as to approximate in intensity the brightness of the image of the moon itself. The drawing paper used was prepared beforehand by rubbing upon it the powdered dust of a soft pencil lead, until an even gray tone covered its surface. Areas darker than this medium tone were then filled in at the eyepiece, while the brighter areas were picked out with an eraser.

The first attempt was made when the moon was in the last quarter. The telescope was in use by others until 2 A.M. and the drawing was actually commenced about 3 o'clock. After exploring the moon's surface along the terminator, where the shadows model the lunar features to best advantage, I picked out an area near the crater Triesnecker, traversed by a network of cracks known as "rills."



The crater of Posidonius. Several smaller craters appear near the crater's rim and a system of cracks covers the floor. Note shadow of peak, near center

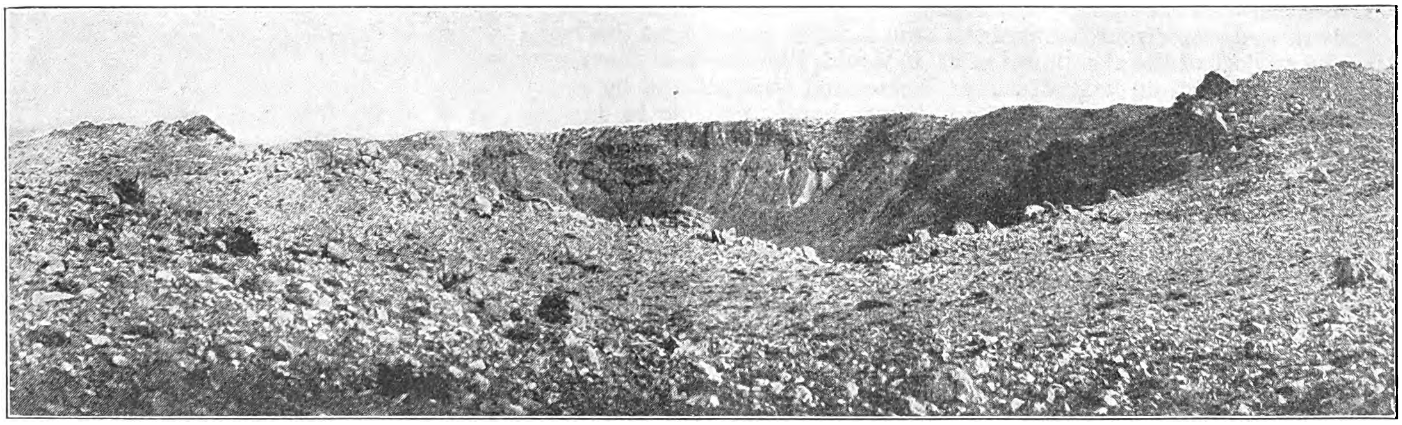
MY time was all too short, for daylight put a stop to the sketching at 5 o'clock. But in moments of better seeing there came fugitive glimpses of minute detail almost too elusive to catch and record. Thousands of tiny craterlets appeared, quite generally distributed over the plains, down the crater slopes and filling the bottoms of the rills. They could not have been far from the order of a few hundred feet in magnitude. These craterlets seem to be typical of the moon's surface.

The other two drawings were made when the moon was in the first quarter. The seeing conditions here were no better than before, although intervals of steady air revealed the great wealth of fine detail so rarely to be caught. Some time I hope to have the privilege of pursuing them further under better conditions, and finally capturing them.

I have been fortunate—or unfortunate—enough to have spent several years in the north polar regions, within a few hundred miles of the pole. These recent nights with the moon vividly recalled the trackless wastes of arctic snow and ice, because of the similarity of the desolate and dead moonscape to our arctic regions.

Through the eyepiece of the 60-inch telescope the moon seems very near, somewhat as though looking down upon it from an airplane. Recently I have seen the moving pictures of the south polar regions, brought back by Admiral Byrd's Antarctic Expedition, and here again the likeness to parts of the moon's surface was recalled. I refer more particularly to those lunar features called "seas," immense undulating plains, slightly crumpled, with here and there apparent cracks running at random—all under dazzling sunlight.

Not long after my final night with the moon I drove through the monotonous deserts of Arizona. A feature lying some seven miles off the trail to the south caught my eye and the car was brought to an abrupt stop. There, for all the world, was a "moon crater," transported to our own earth. Within an hour we were on its rim, looking down into that hole nearly a mile wide and some 500 feet deep. It was the famed Meteor Crater, its origin attributed by astronomers to impact from some celestial wanderer. While I do not advocate the impact theory of lunar craters, a startling likeness to them became apparent when I first saw the profile of Meteor Crater looming out of the desert haze.



Meteor Crater, Arizona, which resembles some of the lunar craters. Professor Henry Norris Russell says: "The evidence appears very strong that this crater has been produced within modern times, geologically speaking, by the impact of a great mass of meteoric material . . ." (Russell, Dugan and Stewart's Astronomy). This also is the point of view of virtually all men of science. On the other hand the majority of astronomers lean, tentatively, toward the volcanic theory of the lunar craters, while a minority hold the meteoric bombardment theory. There is much to be said on both sides. The argument is summarized by Professor Charles P. Olivier in his work entitled "Meteors." He points out that the strongest argument for the meteoric hypothesis of lunar craters is the great difficulties which confront the volcanic hypothesis. The fact that many of the craters overlap, strongly suggests their meteoric origin. On the other hand, the distribution of the craters ought to be fairly uniform if they are of meteoric origin, and it is not uniform. Acres of ink have been spilled in astronomical journals but the question still may be considered wide open. A committee of astronomers and geologists is studing it

same, but, knowing that the seniors have at one time been juniors, I very much doubt whether the seniors are deceived. But it just has to be done. After the inspection is over, the dirt is put back where it belongs and if you look closely, you will find it. It can not be thrown overboard and on an inspection morning the incinerator just can not burn it all.

It seems that I have had the job of keeping a ship clean for a long time; even before that I had some part of it to look after. I have had battleships for over four years and I know the job fairly well—just fairly well at that.

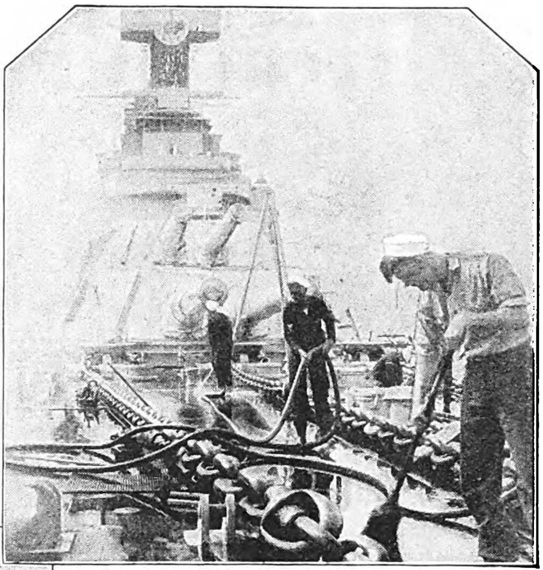
A few months ago a woman from the middle west came up to me and asked how a ship could be kept so clean. I felt inclined to talk to her and tell her something about it. Usually I duck out of this if I can, but she explained that she was from an inland state where such a thing as a ship had never been and wanted me to tell her how it was done. After I had talked with her for awhile, she became enthused; she thought I should write it up for others to read. It seems a very dull thing to write about—especially after having just published an article about battleships and not one word about dirt.

BATTLESHIPS do get dirty! They have to be gone over most thoroughly each week from stem to stern and from keel to truck. Beside this, many men are engaged in cleaning up very nearly all the time. In a way a ship reminds me of a baby. You clean and polish him up most thoroughly and you dress him up in spotless linens and then you put him down on the floor. If it so happens that you burn coal and have a scuttle full in the house anywhere, that is where you will find him all smudged up with coal. When you get your ship all dolled up, if you happen to be a coal burner, you will then coal ship. If you happen to burn oil it may be lots worse; you may get a cloud of oil half way up the boat deck when a line carries away.

When coming in from a long sea trip, the gangways are cleaned before going over the side

Then we always have the recruit. You watch him. As he walks along the deck he exudes dirt. First he surreptitiously drops a cigarette butt on deck against a stanchion; 10 feet farther on he drops a candy wrapper; after a few moments he shakes out his pockets. After this he starts in to collect more odds and ends which he tries to distribute about the decks with impartiality. He doesn't mean any harm.

One man is chipping a bit of rusty paint-work when one of the aviators turns on the engine of a 200 horsepower motor—the "prop" does the rest. The rust goes far and wide while the ever-moving feet of hundreds of men pick it up and mix it with grease from half a hundred different places while the finely ground dust from the hardwood decks swirls about and collects on the paint work, mixed with the sulfur-soot that comes out from the stacks in clouds when the tubes in the great oil-burning boilers are blown.



The anchor, coming up from Davy Jones' locker, brings up mud from the bottom. The anchor and its chain must be scrubbed clean

The human element is comparable with the mechanical. One of the greatest causes of troublesome dirt is the endless preparation and serving of food. Again the recruit, of whom a large percent of the crew is composed, drops his food far and wide. After a meal, the decks look as if they had never been cleaned up. But as the sailor makes the dirt, he also has to clean it up, so for an hour after meals you see him cleaning up. The dirt he picks up is dumped in the slop box if at anchor, or overboard through the slop chute if under weigh.

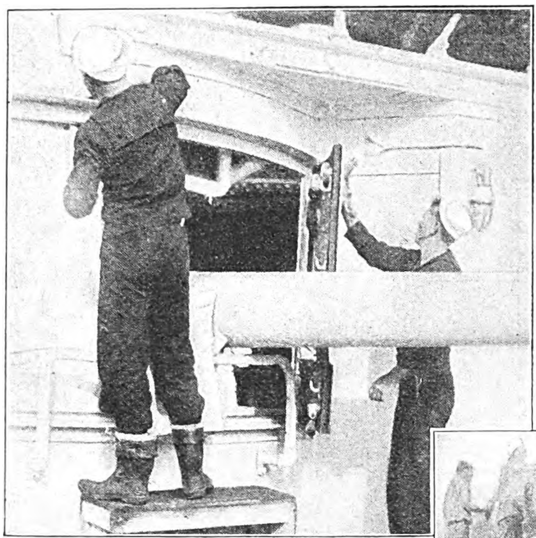
It is a curious thing, but the slop box has a name all out of keeping with its real contents. It is called the "honey box"! It holds around 1600 pounds and is filled, much more than filled, each day. It is no small matter to get rid of the refuse in the honey box of a large ship. A great many times it has to be loaded on one of the work-boats and carried out to sea and dumped, otherwise bathing beaches might suffer if located in the near vicinity, not to mention the breaking of harbor regulations that prohibit throwing refuse overboard.

It is an art to keep the vicinity of the honey box clean; I never have for any length of time. Five minutes after everything has been cleaned up, along comes more slop, and there you are.

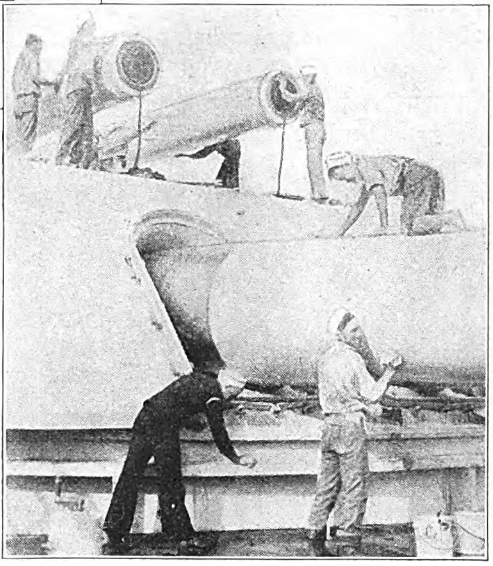
A BATTLESHIP—any ship—uses much food. Each month we take on about 100 tons on a certain day that is set aside for that purpose. A list of these stores reads like an inventory of a wholesale grocer's combined with a meat packing plant. Each and every box, crate, bag, or frozen piece of meat that comes on board brings its full quota of dirt.

We usually finish taking on stores by noon; then, if my friend from that inland state could see us, she would hastily depart and her report to the folk back home would do us very little good. However, we do not take visitors on board during that time, except in rare and urgent cases.

When the ship is got under weigh, the huge links of the chain leave the bottom where they are deeply imbedded in mud and bring some of it up with them, as do the great 10-ton anchors. The chain is washed off with fire hose under pressure, but, mud gets in just the same. I handle the anchors and when I leave the fo'c'sle, it is usually a messy, muddy place: mud, dirty water, and torn up paint work. The boys then go to work and clean it all up again. We average around a



Target practice with the big guns means another cleaning job—and a big one at that. Here sailors are seen scrubbing muzzles, barrels, and turrets of guns after firing



hundred of these evolutions each year.

We go out on the target range and after much practice, the actual firing takes place. After firing half a dozen salvos from a battery of eight 16-inch rifles, the ship is all dirty again—and this time she *is* dirty. Not only that, but everything breakable is broken from the concussion, which now brings us around to the seemingly everlasting task of cleaning up once more.

It is said that there is never a time when someone is not painting something on board a battleship. I think this is so on any ship. It is painted and very soon it is scrubbed off—and then painted again. Thus the battle against dirt goes on day after day.

Someone is always busy painting somewhere aboard a battleship

The ship is so large that one man, even in a supervisory capacity, could do very little with it, so the ship is divided into many parts and even these parts are again sub-divided among the men who belong to that part of the ship. Each man then has a very definite part to play in the morning watch when the decks are wet down and the scrubbing begins. Some are detailed to scrub the decks, some scrub paintwork, while still others scrub canvas and look after boats and the endless pieces of gear that go to make a big ship comfortable as well as efficient. Someone is detailed to look after everything.

The amount of soap, soap powder, scrubbers, polish, and other equipment that I serve out on a certain day each week looks like the beginning of hostilities on cleaning gear. I have a weekly issue of cleaning gear, a monthly issue, and also a quarterly issue. One can easily see that soap would be issued weekly; scrubbers and such, monthly; while some items like scrubber handles and scrapers would last for the quarter. However, there is an endless demand for all sorts of gear, no matter how much is served out. It is very little trouble to keep the ship looking pretty and nice if you can get enough cleaning gear and paint.

One issue of cleaning gear is made on Thursday. This is for general cleaning and is made on that day because the following day is Friday which with us is "Field Day"; that means that insofar as possible the day is given over to cleaning and tidying up the ship for captain's inspection, which comes on Saturday forenoon.

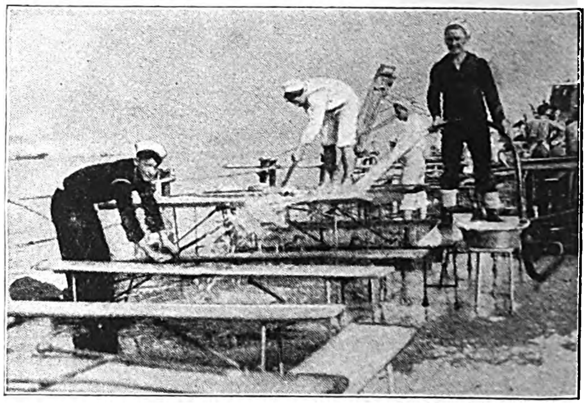
On that day the boys are given 450 pounds of soap; 144 boxes of soap powder; 100 cans of metal polish; 200 sheets of emery cloth; 100 pounds of rags, and a like amount of cotton waste; 50 pounds of air-slaked lime; and one ton of sand! At six o'clock the next morning the boys turn to and spend the entire morning and part of the afternoon in the rather pleasant task of cleaning ship. We still use the holystone on the decks, but I do not believe the boys like that any too well.

There are a good many things about cleaning a ship and keeping it clean without ruining other things as you go along. For example, if you scrub canvas or expensive fire hose while there is sand on the deck, the fabric will very soon be cut to pieces, yet it requires constant supervision to prevent this. One man will be painting aloft; almost invariably if not cautioned, he will spill much of it on the decks below. All of this has to be painfully scraped off. Every spot on the deck—and in the course of a week there are thousands—has to be removed. Lime is used to paint grease spots with good effect, but to complete the job the deck has to be gone over with sand and a holystone.

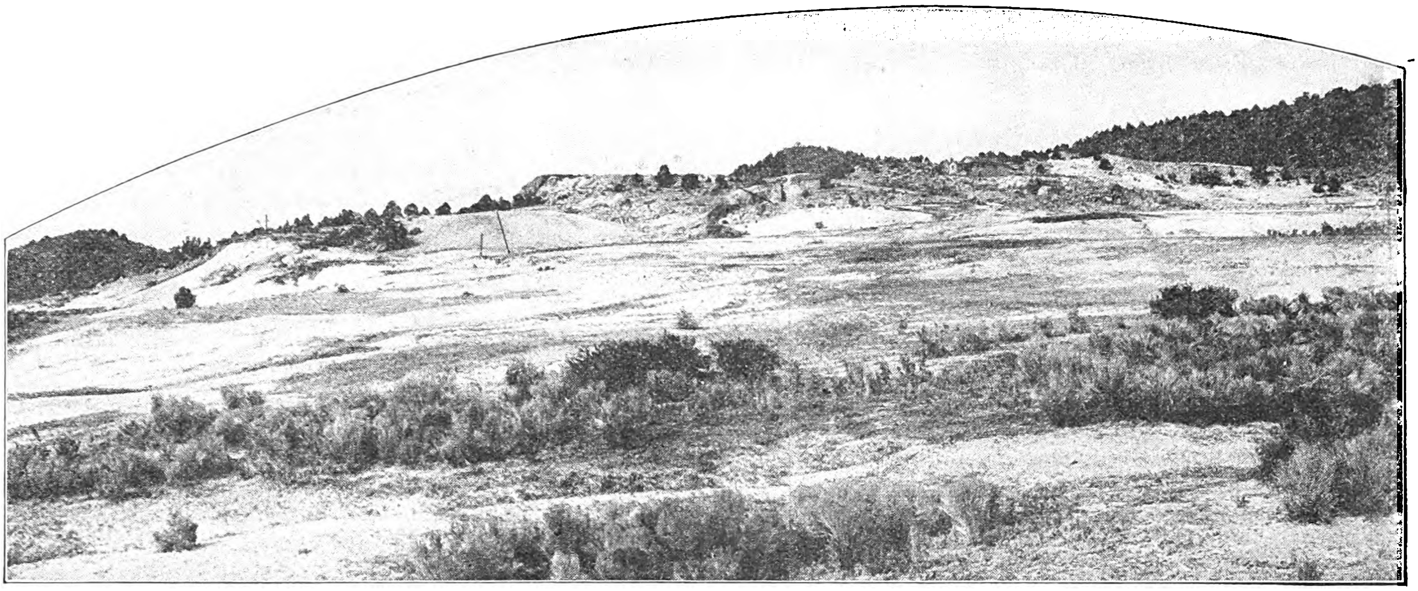
The modern appliances are great inventions, yet each one adds just so much dirt to a ship. The airplane, for example, one would say, surely could bring no dirt! But such is not the case. It is one of the worst offenders. It spatters oil and grease far and wide. Then, due to the fact that to operate the catapults all the stanchions have to come down, much paint work is torn up. This brings not only paint chippings but rust as well.

The ships' boats looking so trim and neat that you see running between the ship and the shore: surely they can bring no dirt. Once again you are wrong, for when I hoist them in—and that is another job I have—they just drip crude oil. After they are hoisted in, kerosene is used by the bucketful to wipe off the sides. Later, the small barnacles are scraped off and some of this is tracked to all parts of the ship.

ON Saturday morning after inspection, usually the ship is open to visitors and they come by the score from every state in the union. The ship is found to be so clean that one is led to believe that it just came that way—probably out of a band-box. Now when I go home—but I guess I'd better not tell anything about that.



Mess benches and tables are brought upon deck, scrubbed, and rinsed with salt water



A great hill of travertine formed by the flow of hot mineral water

Stone From Hot Mineral Springs

ONE of the oldest building stones with which we are acquainted is travertine. The name is derived from Tivoli, near Rome, where much of Rome's building stone was obtained. Many of the well-known buildings of antiquity were built of travertine faced with marble. Its employment largely depended upon its softness and excellent wearing qualities. Travertine is found as a deposit of calcium carbonate from hot springs, although there is also a silicous type. The cavities which add so much to the beauty of the stone are partly due to the decay of mosses and other vegetable matter.

In 1854 miners prospecting for gold in Mono County, California, found a deposit of stone they called "moss agate" and later it was called marble. It was afterward found to be travertine and the earthquake and fire in San Francisco in 1906 demonstrated the sterling qualities of this building material. The deposit in Mono County is being developed by the California Red Travertine Company of Los Angeles. Modern methods of quarrying are used. The stone when first taken out saws freely and takes a high polish. Some of the stone varies from clear white to gray, cream, and pale yellow. In other sections where the ascending waters have passed through a deposit of metallic oxides, the stone is handsomely banded with other colors. The red travertine is especially beautiful. The designs are largely dependent on the lichens which have grown up along the borders of spring pools and which have been replaced by stone in the course of time.

Waters of the hot mineral springs still bubble through crevices. The color of travertine varies from white to very dark red

Can We Signal to the Planets?

By JOHN THOMSON, M.A., B.Sc., Ph.D.
Lecturer in Physics in the University of Reading, England

FROM time to time during the last 50 years suggestions have been made for sending a message to a neighboring planet. In general these suggestions have been scientifically worthless, but for all that the possibility merits consideration. At the lowest estimate a general airing of the question seems to be required, while an accurate statement of the problem and its difficulties is the first step towards any attack which may be made upon it.

The question divides itself naturally into three parts. First, can we send a signal through space so that it may be detected on a companion world? Second, in the event of our being able to do so, is there any possibility of the signal being received and understood? Third, having regard to our answers to the previous questions, what signal would we send?

Mars as seen from its outer satellite Deimos. A painting by the astronomical artist Howard Russell Butler. Based on composite evidence.

TO illustrate the difficulties involved, let us consider the possibility of utilizing some form of televisor. In the May "Discovery," (London) mention was made of this means of signaling, and the conclusion rightly reached was that "the prospects of finding planetary neighbors equipped with the necessary apparatus are remote." The complete televisor consists of a transmitter and receiver. The signal propagated through space is, of course, an electro-magnetic disturbance, but this disturbance is obtained at the transmitter from light signals by a series of ingenious energy transformations. Similarly, the receiver, working on the same wavelength, must be able to transform back the electro-magnetic impulse into light signals. Such a process is very complicated and presupposes a vast amount of technical apparatus. But, as will be shown later, in communicating with another planet it is not permissable to assume the existence of any equipment similar to that which we use. The best we can hope for is that our planetary neighbors are aware of the existence of the electro-magnetic spectrum and possess some means of detecting electro-magnetic impulses.

There is another objection to visual signaling, of an even more fundamental nature. It is probable that the possible inhabitants of another planet react in some way to light signals; this appears to be a necessity for intelligent life. To suppose, however, that this reaction corresponds to our own visual sensations is pure speculation. Assuming that a television receiver existed on the planet under consideration, the picture formed on the screen would in all probability convey nothing to the inhabitants. Hence a scientific approach to the problem demands a form of signal much simpler and more fundamental.

Since we are attempting to communicate from the earth to another planet, and between them no material medium exists, it is at once evident that we must utilize as our signal some form of radiation which is transmitted by a vacuum. This is practically equivalent to saying that we must use some part of the electro-magnetic spectrum. But even a casual examination of the problem is sufficient to indicate that our choice of such radiation is extremely limited.

The mere fact that the solid earth is surrounded by an atmosphere capable of absorbing all radiation to a greater or lesser degree makes our choice a difficult one, while the problem of producing radiation of intensity sufficient to be detected some millions of miles away so far adds to this difficulty that we shall be fortunate to find any type of signal suitable for our purpose. Atmospheric absorption immediately rules out of consideration radiation of short wavelength, since X rays and ultra-violet rays are strongly absorbed by gases. Light and heat radiation do not suffer in this way, but these, as we shall see, are useless for a very different reason. Hertzian waves have been carefully studied in recent years so far as their propagation around the earth is concerned, and it is to such radiation that we must look most hopefully.

FIGURE 1 indicates the relative positions of the earth, Venus, Mars, and the sun when conditions would apparently be most favorable for communication between the three planets. The figure corresponds to what is known as an "opposition" of Mars and an "inferior conjunction" of Venus. It is at such an epoch that these two planets are nearest to the earth. Mars is then on the meridian approximately at midnight, while Venus is (along with the sun) on the meridian at midday. It is instructive to notice that under these conditions the appearance of Venus from the earth is similar to the appearance of the earth from Mars, while the appearance of Mars from the earth is similar to the appearance of the earth from Venus. It is useful to realize the point of view of the possible recipients of our signal.

Now we can not hope in signaling to compete with the sun. If the sun is sending out radiation similar to the one we might choose, then our signal will go undetected. A consideration of Figure 1 will make this perfectly clear. But the sun is continually radiating light and heat, and therefore these signals, as has been stated, may be left out of consideration.

It is obvious then that our attention must be limited to a consideration of Hertzian waves, the type of radiation propagated from a broadcasting station. At the very outset, however, we meet with a serious difficulty. Various writers on wireless communication have described it as "signaling through space," and so far as space is interplanetary, this is just what a broadcasting station does not do. One of the chief reasons why Hertzian waves have become an important means of communication over long distances is that the transmitted signals are confined to a comparatively narrow layer of space in the immediate vicinity of the earth. The signals broadcast do not spread out in all directions; they travel around the earth, practically never rising beyond the limits of the atmosphere.

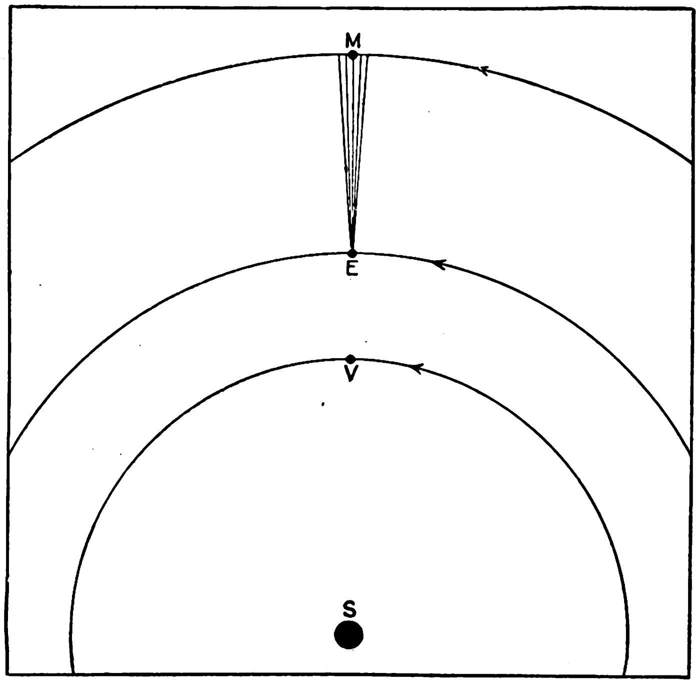

Figure 1: **Optimum conditions for interplanetary signaling between Mars (M), the earth (E), and Venus (V), when all three approach nearest together**

FIGURE 2 gives a rough representation of the path of a "wireless" ray from a radio transmitter T. The ray may move upward toward a layer of ionized gas known as the "Heaviside layer," but there it is bent downward again toward the earth. A straight beam from the transmitter parallel to the horizon is indicated by the dotted line. It will be seen that the latter could not possibly be detected at any distance from the station, as it would be lost in the upper atmosphere.

This bending of Hertzian waves due to refraction (or possibly in some cases to reflection) is of inestimable value in wireless signaling, and accounts for the remarkably long distances traversed by waves over the surface of the earth, but from the point of view of interplanetary communication the Heaviside layer is an unmitigated nuisance, cutting us off, as it does, from outer space. All Hertzian waves are not, however, equally affected in this way, the bending of the ray varying considerably with its wavelength, and hence it may be possible to find some band of waves which may escape to outer space. Recent experiments appear to suggest that short waves are less bent than long waves, and this is in agreement with the most important theory of the effect. It is probably impossible to produce Hertzian radiation which will traverse the atmosphere in an even approximately straight line, but if the wavelength is sufficiently short, there is a reasonable expectation that the deviation of the ray will be comparatively unimportant. Such radiation has a wavelength of less than ten meters.

Attacking the problem from another point of view, an alternative solution is indicated. Theoretically the use of waves of length greater than 10,000 meters should also obviate absorption and refraction in a layer of ionized gas.

Two possible bands of radiation would therefore appear to be suitable for the penetration of the earth's atmosphere, and we have now to determine which band is more suitable for our purpose in other ways. The question of the intensity of the signal decides, as we shall see, in favor of the short waves. Incidentally, it is useful to note, before we leave this part of the subject, that any radiation which can penetrate our atmosphere will be suitable to penetrate the atmosphere of the receiving planet.

We have said that it is preferable to use a radiation of short wavelength. This arises from the fact that in any attempt to signal over a distance of millions of miles some form of beam is necessary, since, if the radiation were distributed uniformly in all directions a negligible fraction would reach the planet. Now the concentration of Hertzian waves in the form of a beam necessitates the use of a reasonably short wavelength in order that the focusing may be efficient. Hence this is sufficient to decide between the rival claims put forward above.

Having decided on the type of radiation to be used, all that remains is to ask whether a signal of intensity sufficient to be detected can be sent. The answer to this question must necessarily be speculative, for, in the first place, we are not acquainted with any receiving apparatus which the other planet may possess. The signal emitted by our transmitter will suffer attenuation because of two factors. First, the spreading of the beam will decrease its energy per unit area. Secondly, the atmosphere of the earth and the other planet will be the cause of a certain amount of absorption. The spreading of the beam is an unfortunate necessity. By modern methods the pencil of rays could be made very fine indeed, and spreading (except that due to dispersion) could be avoided. But our aim at the planet can not but be very rough, and hence a very fine beam would be almost sure to be lost in space. In Figure 1 a pencil of rays is drawn from the earth to Mars. The pencil shown diverges much more than would be necessary, but in any case its cross-sectional area on arriving at the orbit of the outer planet would require to be at least 1,000,000,000 square miles, in order that there should be a reasonable probability of the planet coming within it.

THE sending of a very powerful short-wave signal is not, however, a very serious matter. Even assuming that the requisite intensity could not be obtained at our present stage of development, the problem is merely one of technique. The wireless engineers are quite capable of producing as intense a beam as we may require when the need for it should arise. The directing of the beam, making allowance for refraction in the upper atmosphere, would be much more difficult.

Assuming then that we are able to send a signal, what can be said of the probability of its being received? Many writers have discussed the possibility of there being intelligent life on other planets, but it must be borne in mind that the whole subject is purely speculative. It does not follow, however, that our speculations are irrational or idle. The modern physicist deals largely and with great success in probabilities.

From a philosophic standpoint it appears improbable that the earth is the only planet in the solar system which is the abode of intelligent life. Apart from all biological considerations, this makes an appeal to our philosophic instincts; anything else would savour of (Ptolemaic) egoism. Moreover, it is utterly impossible to argue that the other planets are unsuited for intelligent life, as has been done so often. Such an argument is founded on the assumption that protoplasm is an ultimate essential of life, while there is nothing to show that it is not the essential of life modified by terrestrial conditions. Even assuming that Martian or Venusian protoplasm would be identical with the terrestrial substance, there is still no sufficient evidence to state that life is impossible on these planets, and, where life is possible, intelligent life is probable.

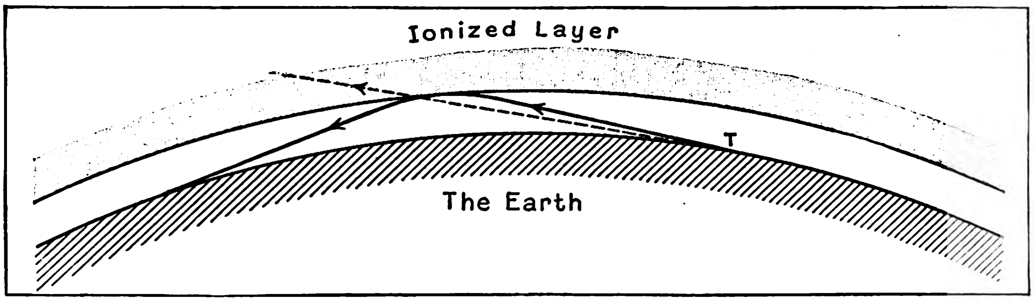

***Figure 2:* The solid line indicates the path of a reflected radio wave from a transmitter located at T. A beam parallel to the horizon is shown by the dotted line**

A more important and less speculative question is whether the intelligent life on another planet would be able to detect and understand the significance of a Hertzian wave signal. We must not transfer our own form of intelligence to Mars or Venus, and assume that natural science has been "studied" by intelligences there. We must remember that intelligent beings existed on the earth for some considerable time before any violent interest was taken by them in the phenomena of nature. However, if we assume on the part of these other beings a speculative and experimental interest in the material universe, then we may legitimately hope for some means of detection of short Hertzian waves.

After all, the mechanism of the universe is not terrestrial, and whatever we may think of our conception of Hertzian waves, the waves themselves are common to all space. The reactions of intelligent life on Venus or Mars to material things must necessarily be different from ours, but the reactions must exist, and they will be reactions to phenomena similar to those we experience.

Obviously, of course, the Martian observer will not "listen-in" by means of the mechanism which we employ, and equally obviously the connotation he may give to the signal is beyond our comprehension. At the very best the evolution of an intelligent life on Mars will have followed quite different lines from our own. The accidents of environment will have produced mental processes of which we can know nothing. Indeed, our very terminology with regard to possible inhabitants of another planet will have a wider meaning than the one which we usually assign to it. How far are we justified, for example, in speaking of the "mental processes" of such beings? Yet it must again be urged that the Martian reactions will be reactions towards phenomena similar to those which we experience.

Finally, we must consider what signal we are to send. Here we encounter difficulties quite different from those already discussed. Speaking generally, our message must abstract from human thought and endeavor something which we consider might be recognized as a message from terrestrial intelligence. It would be useless, for example, sending a message in the English language to a French savant, no matter how intelligent he might be, if he did not understand our tongue.

The only ray of hope is our belief that abstract scientific conceptions have a universal foundation in nature. The earth is the third planet in the solar system. No matter how the non-terrestrial intelligence acts, a sequence of three impulses must convey some notion of the number three. Therefore it might be suggested that a beginning should be made in our communication by sending a systematic series of three distinct impulses. We can form no conception of how the Martian inhabitant thinks "three," but it appears probable that our signal would be of a sufficiently fundamental type to cause the requisite mental reaction. If on any occasion it was discovered that signals on the same wavelength were being received consisting of four impulses, we might have some reason to believe that an answer to our signal was being transmitted from Mars. We might, under these circumstances, describe "three" and "four" as the interplanetary call signs.

It may be objected that the suggested message is too simple, and that surely another, conveying more intelligence, could be devised. An eminent astronomer, discussing the possibility of life on the moon, once suggested a signal to our satellite, taking the form of a drawing on the surface of the earth of the requisite dimensions of a right-angled triangle. He argued that this triangle, being of fundamental importance in geometry, would indicate to the possible inhabitants of the moon the existence of intelligent life on the earth. Leaving out of account the fact that Euclidean geometry is but a first approximation to the geometry of real space, did the astronomer not credit the Lunar intelligence with too terrestrial an origin? To imagine that the right-angled triangle, itself a mathematical abstraction, is common to all space, is surely like blaming an Englishman for not speaking Chinese! No! So far as interplanetary communication is concerned, we are strictly limited in our messages to signals of universal nature.

Now that we have considered the various aspects of the problem, we ought to be in a position to say whether the possibility of communicating with our neighboring planets comes into the realm of practical experiment. With regard to our means of sending a message, we have seen that we can hardly be sure that we possess the necessary equipment for making the attempt. On the other hand, researches at present in progress on the electrical structure of the upper atmosphere ought to provide the knowledge of refraction and absorption of short Hertzian waves which we require.

Assuming that we can send the signal, whether it will be received or not is a matter of speculation, but we can at least be certain that there is no *a priori* reason why it should not. In any case, the only messages which we can send with a reasonable expectation of their conveying the impression of being signals from the earth are of a very simple and uninteresting nature. Yet the possibility can not be dismissed as a scientific fancy. It lies on that borderline of the practicable which so many of our most important inventions and discoveries have but recently crossed.

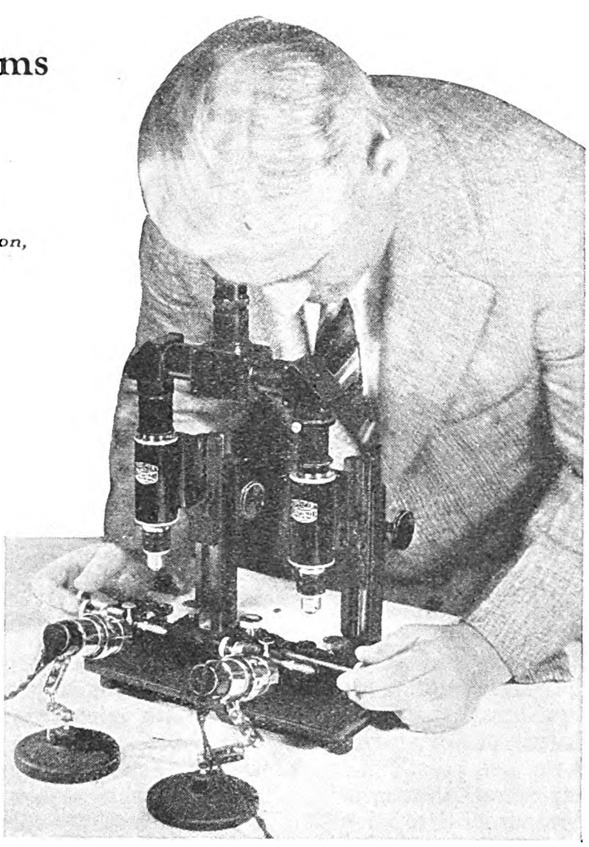
¶ *An interesting Hertzian wave phenomenon was reported in 1928 by the Norwegian physicist Stormer. The radio echo around the earth is a commonplace and requires one seventh of a second, but new echoes, delayed 3 to 15 full seconds, were heard. Possible explanations were: the retardation of velocity either in the Heaviside layer or in the earth; or the reflection of the waves from the moon, from the region of the zodiacal light, or from another and a more distant "Heaviside layer."*—The Editor.

Scientific Criminology

How Bullets and Firearms Are Matched for Identification

By STANLEY F. GORMAN

Lecturer on Bullet and Firearm Identification, Police College, City of New York



The author at work with the comparison microscope examining bullets in the holders

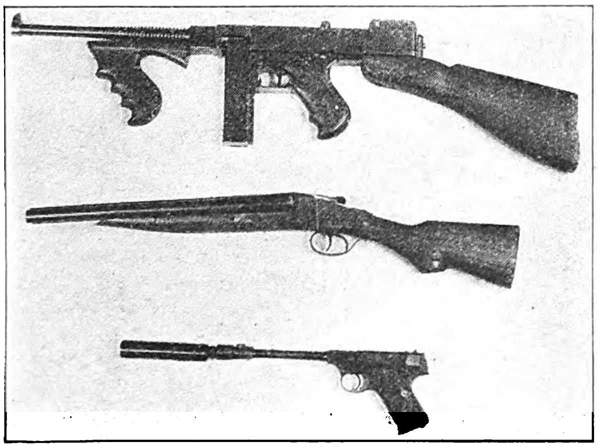
THE most important types of cases a detective has to deal with are homicides, suspicious suicides by means of firearms, suspicious accidental shootings, and assaults by means of firearms during the commission of a crime.

We are all familiar with the fact that, since the war and prohibition, there have been more homicides committed throughout the country by means of firearms than ever before, and it is usual that attempts are made to mislead the detective, either by the perpetrator or witnesses or both, as to the truth regarding the occurrence. It is his duty, however, to obtain facts, present them properly and intelligently, and also to be able to furnish proof of guilt or innocence.

Since the establishment of the New York City Police College by Ex-Police Commissioner Grover A. Whalen, Deputy Chief Inspector John J. O'Connell, the Dean of the Institution, has included a course of instruction in the scientific identification of firearms, shells, and bullets, which, today, is as important as the study of fingerprints. The results of this method of identification are definite and conclusive.

At the scene of a homicide, a suspicious suicide, or an accident where a firearm has been used, the detective is interested in the perpetrator, the witnesses, the surrounding circumstances, finger prints, the fatal bullet, the suspected weapon, and the discharged shell or shells found at the scene of the crime.

It is obvious, of course, that unless a suspected firearm is found, no comparison can be conducted except as pertains to the ammunition. However, with the suspected arm located and the fatal bullet recovered, a comparison microscopic examination and test can be conducted. The results obtained will prove whether or not the fatal bullet issued from the suspected weapon. It must be realized, however, that no identification is possible if the bullet, while passing through the body, comes in contact with bones that cause cuts, grooves, furrows, and so forth, on it, distorting it so completely as to destroy minute important characteristic marks. On the other hand, even if considerable distortion is so caused, but a small side area remains unmutilated, identification can be made. This same condition applies to a bullet which has passed through the victim and has come in contact thereafter with some surface hard enough to mushroom it completely, leaving no portion of the side available for study. If the bullet simply ricochets, however, and only a portion of its surface is flattened or distorted, there will remain sufficient area by which a comparison may be made.



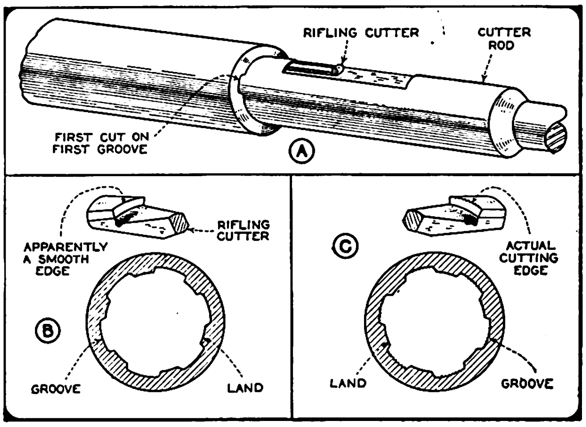
Guns of gangland. ***Top:*** **A Thompson sub-machine gun.** ***Center:*** **A sawed-off shotgun.** ***Bottom:*** **An automatic pistol equipped with a highly effective silencer**

In order to make clear the fundamental principles by which the expert in firearm identification is guided, it will be necessary first to explain in brief the process of gun-barrel manufacture. Here are born the tell-tale marks that are subsequently imprinted on the bullet when it passes through the gun barrel at the time of discharge. These minute marks give to each gun barrel a personality all its own.

In the manufacture of revolver, pistol, and rifle barrels, the first process is stamping out, by the drop-forge system, the gun-barrel "blank," cut off at the desired length. This "blank" is then bored lengthwise with a drill and finished to the proper size with a series of cutters and reamers. The resulting surface is known as the bore.

THE next manufacturing step is to create what is known as the rifling. This is a series of spiral grooves cut in the surface of the bore from end to end of the barrel. These grooves cause the bullet to spin around its longitudinal axis when fired from the gun. This rotating moment serves to make the bullet stable, so that while in flight it will travel nose first. The grooves grip the bullet at the instant of discharge and spin it as the cord spins a top. Just as the top is rendered stable by its spinning action, so is the bullet. In the latter case, however, a forward movement is imparted simultaneously with the start of the spin.

After these grooves have been cut, those sections of the original bore surface that remain between them are known as the lands. The manufacturers, because of their own patterns for this work, will be found to produce arms which differ in widths of lands and grooves. Some have narrow lands and wide grooves, some the opposite, and some have them equal. It will therefore be found that, in guns of a given make, the patterns of land and groove marks made on bullets fired through them will always be the same, and the same marks or patterns will not occur on a bullet fired from a weapon of any other make. In this way we are able to determine, by examination of a fired bullet, the make and type of arm from which it issued. It should be noted here that the lands or high parts of the bore, cut grooves or low marks on the bullet as it passes through. Thus, on a fired bullet, the low marks are made by the lands, while the high marks or rifling pattern are left by the grooves.



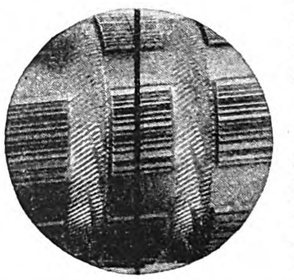
***A:* A rifling cutter starting on the second groove. *B:* How the rifling cutter and rifling should look. *C:* How they are in actuality. All these drawings are exaggerated for clarity**

Every manufacturer or ballistic engineer has his own pattern and formula for the depth and width of the rifling, as well as for the rate or degree of pitch. Different manufacturers use different numbers of grooves; some five and others six. The Colt company uses six, while Smith and Wesson use five grooves in all their arms except their .22 caliber, the automatic, and the .45-1917 model revolver, where they use six. The direction of the rifling in the Smith and Wesson arms runs from left to right and the lands and grooves are of nearly equal width. In the Colt guns the rifling is from right to left; the lands are narrow and the grooves wide. All other domestic manufacturers use five grooves and generally run to the right. In foreign guns will be found a mixture of from four to seven grooves running in either direction, frequently in arms of one make.

WHEN considering in detail the rifling or spiral grooves on the inner surface of the barrel, it must be remembered that the physical structure of any piece of metal is not the same throughout. The consistency of the metal varies at intervals; therefore it will be found that in no two gun barrels will the physical structure be identical throughout the bore. This fact has considerable effect on the tool which cuts the grooves, known as the "rifling cutter." These implements are made of the hardest of tool steel, in two styles. One is made in the form of a hook and is known as a "hook cutter." The other is made in a drawn out S shape and is known as a "scrape cutter."

The cutting edge of one of these tools, when it starts its first groove, is as sharp as a razor. To continue with this analogy: It is well known that after having shaved one side of the face with a razor, it frequently is necessary to strop the blade before shaving the other side. The blade has become dull, due to the action on the fine edge of the hair on the face. This action has in reality changed the shape of the edge. The microscope discloses the fact that a razor edge has teeth similar to that of a saw, although they are invisible to the naked eye. Stropping lines up these "teeth," while use forces them out of alignment: a dull blade results.

The action on a rifling cutter edge is similar. One can appreciate, then, as the rifling cutter is drawn through the barrel, while the barrel is rotated to give a spiral path to the groove, with the cutter so regulated as to cut $^1/_3$ of $^1/_{1000}$ of an inch from the interior of the bore surface on the first draw, that, considering the hard fine steel edge cutting away a hard steel surface, there is considerable wearing of the cutter edge in one stroke, during which it cannot be "stropped." So the rifling cutter edge is continuously changing its shape and, therefore, the pattern of scratches it leaves behind. The minute teeth on the fine edge are wearing down, chipping off in places, and the edge is scratching its ever changing pattern on the inner surface of the steel barrel.

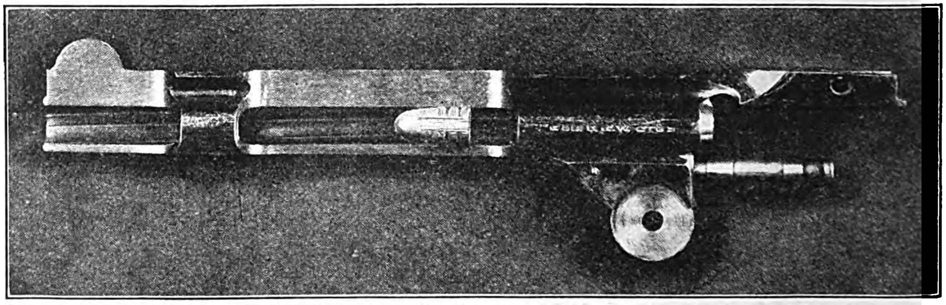


How two bullets look when viewed through the comparison microscope. The markings on the fatal and test bullets correspond

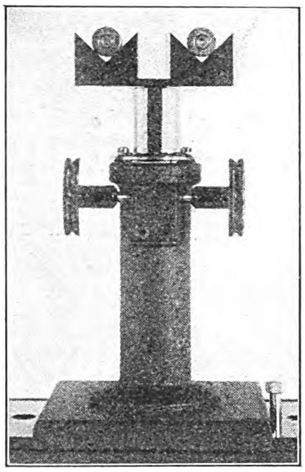
Another source of tell-tale bore markings is to be found in the slivers of steel that have been removed by the cutter and are constantly twirling around ahead of the cutter within the barrel. They not only create their scratch marks, but they also leave behind marks of "fractures" at the point where the steel sliver breaks from the interior barrel surface. Here another analogy may be drawn. When planing a piece of wood, a thin sliver is removed by the blade of the plane. This sliver eventually breaks from the wood body and leaves a plainly visible scar or "fracture" mark. A similar action takes place within the gun barrel. Considering all these facts, it can readily be appreciated how accurate it is to say that no two gun barrels are alike; and furthermore, that no two groove marks are identically the same in any one gun barrel.

TO the naked eye the interior surface of a gun barrel appears smooth, but by examination with the microscope it is possible to detect, examine, and compare these minute tell-tale marks which have been passed on to the surface of the bullet as it is being forced through the barrel under a pressure of from 8000 to 16,000 pounds to the square inch. This tremendous pressure behind the bullet expands it, pressing it against the inner barrel surface, so that it takes on every minute scratch mark of that surface. Some of these scratch marks, seen under the microscope, are more pronounced than others; one line may be faint at one end and come up stronger at the other; the more the gun is used the more pronounced the scratches become.

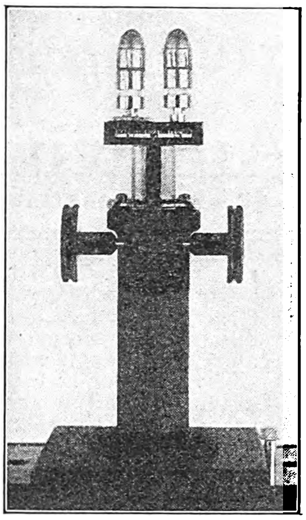
If any particular minute defect exists in the barrel or any rust marks are present, the gun's individuality becomes more pronounced and the marks of identification on the



Cut-away view of a revolver barrel, showing rifling. In the barrel has been placed a bullet, on which are seen the "finger prints" made by the bore



A new instrument designed by the author for holding and manipulating bullets and shells while being photographed. The views show the two different stages that are used



bullet become more positive. It will be noted that those marks imprinted on the bullet as it enters the barrel at the breech end are changed as the bullet progresses through, and it is the marks that are imprinted on the bullet by the last few millimeters of the barrel that serve as the identification card of the gun.

In the case of shell-head identification, the marks made by the firing pin and breech face are the "finger-prints" which must be followed. In the manufacture of the component parts of guns, the same change in the conditions of tools mentioned above gives a starting point for an identification method. If a series of seemingly identical parts, delivered consecutively from the same machine, are examined under the microscope, it will be found that each one differs in some respect from all of the others. The constantly changing tool marks or scratches on the firing pin and breech face are imprinted on the primer as it rebounds at discharge. It is possible to make identification of shell-heads in shot-gun cases in this manner, but because of the smooth bore of the barrel, nothing can be done with the pellets of shot discharged from this type of gun.

IN cases where automatic pistols are used, comparisons can be made of extractor hook marks and ejector rod marks, as well as the breech face marks on shell heads. This same method is used in determining what type of gun discharged a .45 caliber automatic cartridge, which could have been used in a 1917 model Smith and Wesson revolver, a Colt automatic pistol, or a Thompson sub-machine gun.

The method of identification consists of comparing the minute characteristic markings on the questioned or fatal bullet or shell with the markings on a test bullet or shell fired through or by the suspected gun. The bullet fired through a suspected weapon is caught in cotton waste so as not to distort it or cause any foreign marks to be imprinted on it other than those caused by the condition of the interior of the gun barrel.

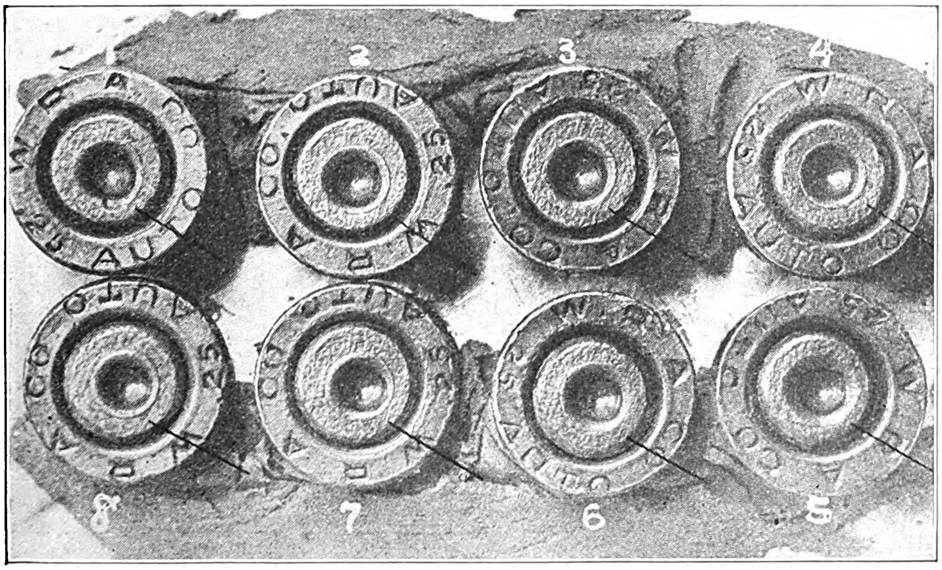
There are today a few experts who make identification in a logical and precise manner but there are also many so-called experts who recognize no limitations, no standards, and no equipment as essential in this field.

In the examination and comparison of fatal bullets and shells fired from suspected weapons, the most important instrument, which is today generally recognized as essential for satisfactory work in this field, is the "comparison microscope" which may be described as a specially designed compound microscope fitted with a comparison eyepiece, in which two bullets or shells can be examined at the same time. With such a microscope the fatal bullet and a test bullet fired from the suspected barrel are placed under the lens systems as shown in the photograph. Their images are fused into one by the arrangement of prisms in the comparison eyepiece. The result is a composite image, one half of which is contributed by the fatal bullet and one half by the test bullet. When the bullets are set in the microscope, they can be rotated independently or simultaneously by means of the mechanical stage.

One bullet is now held stationary, while the other is rotated so as to make various areas of its surface join against the area of the bullet which remains fixed in view. If both bullets are from arms of the same caliber and make, each land and groove mark on the rotating bullet, as it passes a land or groove mark on the non-rotating bullet, will fuse with it as to width and angle of pitch. If the bullets be from the same arm, not only will land and groove edges fuse, and angles be identical, but certain finer scratches from the lands and grooves, mentioned above, will, in some one given position, fuse also. Having located this position, the two bullets are revolved together, whereupon fusion of these fine lines, as well as of groove edges, will take place all around the circumference. Shell-heads are examined in the same way for tool scratch marks left by the breech block as above mentioned.

THE bullets having been examined microscopically and found to match, pictures are taken of both test and fatal specimens. These pictures are so arranged as to enable court and jury clearly to comprehend the result.

There are three pictures taken of the fatal bullet and two of the test bullet. These are arranged side by side in folder form, pasted together on the reverse side, in the following manner. From left to right, number one and two are pictures of fatal and test bullets, respectively; number three and four are pictures of the fatal bullet. The other picture of the test bullet is cut through the short diameter. The lower half is superimposed over the lower half of picture number three, of the fatal bullet, and the upper half over the upper half of picture number four, also of the fatal bullet. The fine lines or striations will match and prove identification.



A row of fatal shells and a row of test shells placed side by side in an accurately bored steel block for purposes of comparison and photography

My Experience in Amateur Telescope Making

By CLYDE W. TOMBAUGH

CLYDE W. TOMBAUGH, author of the accompanying account and the immediate discoverer of Pluto the new planet, "graduated" into professional astronomical work from amateur telescope making, as have several others up to the present time. Until he won a position at Lowell Observatory, Tombaugh was an obscure amateur, one of the 6500 of our readers who have gone in for this fascinating scientific hobby. For some reason he previously had not sent to this magazine a description of the failures and successes in his telescope building, and therefore was wholly unknown to the editors. Acting on a "hunch," when the newspapers stated that Tombaugh "had made telescopes," we found his name in the 1926 records as a purchaser of the SCIENTIFIC AMERICAN instruction book, "Amateur Telescope Making," and invited him to describe his efforts for publication.

Tombaugh's success is a refutation of the assertion, sometimes made, that the layman's worthy work stands little chance of notice by professional men of science. Here we have a plain young man, a farmer, without scientific connection. He makes several telescopes, studies, and wins a position at a noted astronomical institution—all without the least "pull" or preferment. Within three months his name is on every press wire, every cable. If that isn't romance, what is?

IN February, 1926, I began work on my first telescope, an eight-inch reflector, as that was the only way for one of very limited means to possess an instrument of moderate power. The work was new and unfamiliar and mistakes were made; for example, cementing a disk of wood of equal size to the back of the speculum. Another mistake was the flimsy equatorial mounting constructed, which teetered violently with the least wind. The tube was a square box seven feet long, made of four boards nailed together. The telescope was kept out-of-doors and these boards warped sadly in spite of their previous treatment with hot linseed oil and paint. Figuring the mirror was unsuccessful, also the silvering. The return of farm work forbade any further work on the mirror that season.

ABOUT this time, April, 1926, I learned that the SCIENTIFIC AMERICAN had published the book "Amateur Telescope Making," and immediately sent for a copy with the intention of "trying it again" the next winter. The eight-inch telescope was used occasionally during the summer and autumn, though its performance was disappointing. It would stand only the magnification of a two-inch eyepiece, 42 diameters.

A concrete cave (outside cellar) was built on the farm in the late autumn and this was seen to be a fine place to make mirrors because the temperature would remain constant. Work was kept up feverishly to doctor the figure on the eight-inch so that Mars could be observed while near the earth. Nothing but failure resulted, due to the fact that the glass disk was too thin. It showed signs of flexure.

A relative now wanted me to make a seven-inch reflector for him. Here was an opportunity to try fresh glass and to profit from the mistakes made on the eight-inch. Armed now with the book "Amateur Telescope Making," the second project bid fair to be a success, but the first disk cracked while heating it to cement a handle on the back. Another disk was ordered immediately.

The grinding proceeded very satisfactorily and soon was done. The mirror was ground to a focus of 58½ inches. Some scratching was encountered in the polishing, and fine grinding again was resorted to twice to remove the scratches. Upon investigation, the source of the mischief was found to be some grit which had become mixed in the rouge. Polishing was resumed, followed by figuring. "Hyperbolae," "turned-down edge," and "zones" gave trouble and several laps were made in correcting these errors. Finally the mirror was parabolized successfully, placed in the tube and tried on celestial objects for several nights. Views of the moon with a quarter-inch eyepiece were good—much to my joy. Accordingly the mirror was sent away for silvering.

THE tube of the telescope was made of number 22-gage galvanized iron, reinforced by a ring of strap iron at each end, riveted on the inside. A one-inch right-angled prism was used for a diagonal. The telescope was finished just in time, before the annual return of farm work intervened.

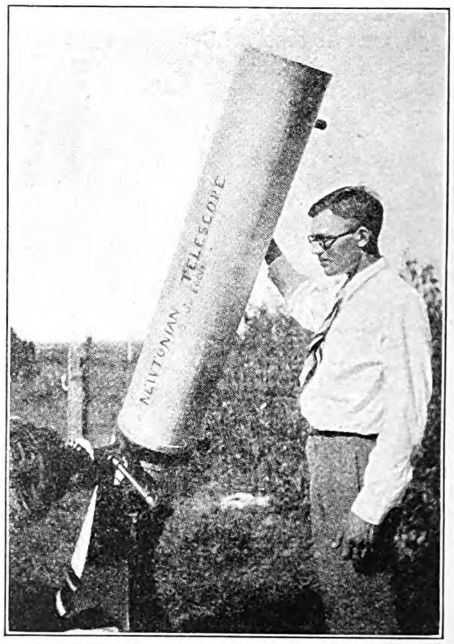
In May, 1927, I set out to enjoy the fruits of my labor. The telescope outstripped anything I had previously looked through. Views of the moon and planets with high powers were splendid. With low powers star fields and clusters were most beautiful. From time to time neighbors came to enjoy a look.

One rainy day in August the telescope was packed and shipped to my uncle. I had become so attached to the instrument that I felt the loss keenly.

Soon afterward I ordered disks of glass to build a nine-inch reflector for myself. During a rainy spell in September the rough grinding was done and several weeks later the subsequent work was resumed. A total of 24 hours were required for the grinding process, including careful washing of stand and tools between grades. An 80-inch focal length was aimed at, which later was found to be three-fourths of an inch less. All the grinding and polishing were done by hand. I did not have the time, money, nor inclination to build a machine for these operations. No wooden handle was ever cemented to the back of the speculum.

MY five-year-old brother took keen interest in the project and begged to help. I let him renew the charges of carborundum and water. This saved me the trouble of laying the speculum down and picking it up each time. His enthusiasm and willingness were a source of great joy and inspiration to his big brother.

My father assisted me most generously with the mounting. Ingeniously he fashioned a neat and sturdy one according to my plans from parts of old farm machinery, using only the

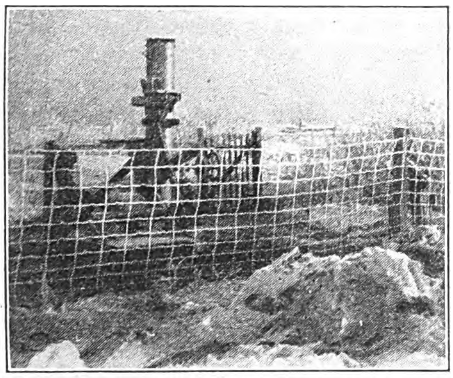


The author standing beside his nine-inch home-made reflecting telescope described in this article tools found in the average farmer's repair shop. Later the performance of the mounting was found to be most gratifying, even when using a power of 400 diameters. The worm-screw slow motion in right ascension, and the turning of the polar axis in its bearings, were uniform and smooth.

The declination axis was cut from one-inch shafting taken from an old straw-spreader. A hardened steel shaft from an old Buick car served for the polar axis. The worm-wheel was made from a spark lever arc of an old car, by carefully filing the notches until they became teeth. The worm-wheel arc is readily clamped to the polar axis for slow motion.

The mounting is of the German type. My father and I forged the yoke from tough, heavy wrought iron. The upper end of the polar axis was threaded and screwed tightly into the yoke. Great pains were taken to fix the polar axis at exact right angles to the declination bearings, the latter being cleanly bored with a hand drill-press, and then treated with fine emery cloth. The polar axis bearings likewise were made with especial care. One could not ask for smoother motion. The polar axis bearings are fastened to the base of an old cream separator whose metal base in turn was bolted to a pier of reinforced concrete.

THE telescope tube, seven feet long and 11 inches in diameter, was made of 20-gage galvanized iron, at a tinner's shop, for a sum of six dollars. Later, at home, two strong bands, one at either end, were riveted by my father on the inside of the tube, giving added rigidity and strength. He also made a cell support in the tube and fitted the back of the cell with three adjusting screws for "squaring on" the speculum.



When the telescope is not in use the tube is capped and the instrument is left out of doors in the snow and rain without injury

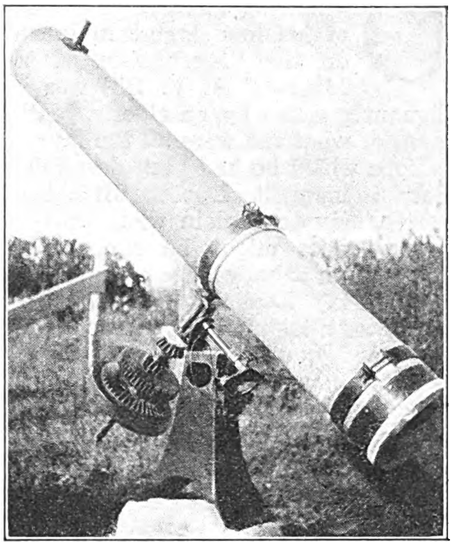
The nine-inch mirror rests on a ten-inch disk of walnut two inches thick, and the wood in turn is joined to a fixed metal disk base by the three adjusting screws. This metal disk fits snugly between a tube reinforcing ring in front and three equidistant arcs of strap iron behind. Three evenly spaced gaps were cut on the circumference of the metal disk. By turning the metal disk so that the three gaps come into a congruous position with the three arcs of support the entire cell with mirror slips out of the lower end of the tube. This arrangement allows quick removal and replacement of the cell with its mirror. Dead-black slate cloth was glued to the inside of the tube with shellac to prevent internal reflection of light.

The arrangement used for fastening the telescope tube onto the declination axis will be quite well understood from the photograph. An iron band two inches wide and one quarter inch thick acts as a slip ring. The grip on the tube may be loosened by the handwheel and the tube rotated into any desired position. An iron block tapering off at either end was riveted to this ring. A hole was bored in the block and tapped, and the end of the declination axis was threaded and screwed tightly into this block. This arrangement proved to be quite rigid as well as convenient.

A SMALL optical flat, three eighths of an inch thick and 1½ by 2 inches, intercepts the light and directs it to the eyepiece. It was mounted so as to permit adjustment, and supported by a thin strip of strap iron extending diametrically across the tube.

Considerable trouble was experienced in figuring the mirror, because of the use of too many long strokes in shaping the first polishing lap which was slow in hardening. The first knife-edge test showed the r^2/R value to be one half inch! Serious complications followed in reducing this, and several laps were made and cut up while correcting various errors. The work, consequently, was greatly prolonged. At last the mirror was parabolized to two thirds the theoretical value, in order to compensate for the rapid fall of temperature at night, which is typical of western Kansas in seasons of good seeing.

The optical performance of the telescope is most gratifying. The "double-double" system of *Epsilon Lyrae* is a favorite test for light-grasp, resolving power, and seeing. The components of the two doubles are $2''.3$ and $3''.0$ apart, respectively. During good seeing these doubles are thrown wide apart, and each spurious disk is very small and clean-cut when using a one fifth inch Ramsden (positive) eyepiece. During moments of extra good seeing arcs of the first diffraction ring are observable, using the full 9-inch aperture. Between E_1 and E_2 are several faint stars. The two stars marked 12.0 and 12.5 magnitudes in Webb's "Celestial Objects for Common Telescopes" were conspicuous. Two fainter stars marked 13.8 and 13.9 magnitudes were just seen and held under favorable conditions. In addition I have seen many very delicate rills and countless craterlets on the Moon. In the autumn of 1928 I was able to observe seasonal changes on Mars and saw a few canals.



Detail of the mounting, made from parts of an old straw spreader, a Buick shaft, cream separator, and several other pick-me-ups

The making and use of my nine-inch telescope has been a source of great pleasure to me, and the entire cost in money, excepting for the eyepieces, amounted to 36 dollars.

The entire telescope, excepting the eyepieces, is left out-of-doors in my "telescope garden." When not in use the tube is held in a vertical position, a tin cap is placed over the end, and a solid dummy eyepiece is substituted for the eyepiece. Thus closed, the tube is practically air-tight. The telescope has withstood the onslaughts of blizzards, driving rains, hail, and dust-storms without the slightest damage. Yet it can be set in operation in two minutes and closed up in five minutes, thus greatly encouraging observation.

A five-inch single-lens non-achromatic refractor of 6½ feet focal length was also made in the early part of 1928. Of course the color is bad and the definition poor due to diffusion. With a two-inch eyepiece it is fairly satisfactory, however.

The following autumn (1928) a Cassegrainian mirror was ground for the nine-inch. Two five-inch specula with focal lengths of 20 and 75 inches, respectively, were also under construction at that time, but early in January of 1929 I was granted work at the Lowell Observatory, and a little later was assigned to the new 13-inch Lawrence Lowell Telescope to search for "Planet X" (Pluto). Consequently my mirror work came to a close, and these mirrors still are unfinished.

Experiments With "Wonder Creatures"

By FRANK E. LUTZ, A.M., Ph.D.

Curator of Insect Life, American Museum of Natural History

ON inviting questions at the end of his first American lecture on the "Mechanism of the Muscle," A. V. Hill was indignantly asked by an elderly gentleman, of what use were all the investigations which he had been describing. For a moment Doctor Hill tried stumblingly to explain what practical consequences might be expected to follow from a knowledge of how muscles work. Realizing suddenly how thankless a task it was to prove to his indignant questioner that the work he was doing was useful, Doctor Hill turned to him with a smile, and finished,

"To tell you the truth, we don't do it because it is useful, but because it is amusing."

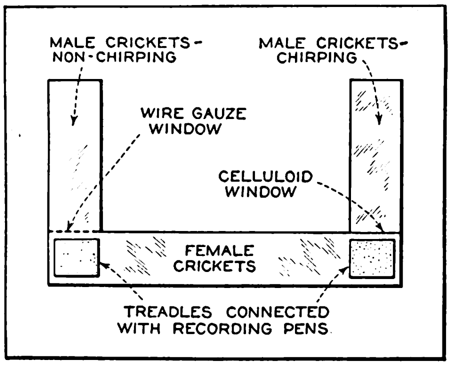
"And if that is not the best reason why a scientist should do his work," says Doctor Hill, "I want to know what is. Would it be any good to ask a mother what practical use her baby is?"

This article is to give you a peep at some of our "babies," glimpses of some of the experiments we have been trying at the American Museum's Station for the Study of Insects in the Harriman State Park and at the private laboratory of Alfred L. Loomis in Tuxedo. They are "babies" in the additional sense that none of them have gone far enough to mature into a definite scientific report.

MOST of the more than half a million different kinds of insects live their lives without a sound that we can hear. A few, however, such as the crickets, katydids, and their relatives, with an originality that is the more striking as we consider the multitude of conservatives, have developed not only rather complicated sound-producing organs, but also apparently satisfactory ears. As is characteristic of insects, they have gone about certain functions in a way and with structures that seem to us strange. An interesting essay could be written on this latter point, telling about such things as that insects take air directly to the blood instead of the rather clumsy human method of taking the blood to inhaled air; and not the least interesting thing about it is that the insects' way seems to work better than our way. An intimation of their success will be found in the last of the experiments discussed in this article.

Several years ago, in reviewing work on insect sounds, I confessed considerable skepticism concerning the utility of these sounds to the sound producers; but the chirping of crickets gave me considerable trouble both then and after the paper was published. The chirping is done by rubbing together highly modified structures on the front wings which seem "made for that purpose." Furthermore, crickets have ears on their front legs, and definite ears are unusual among insects. Since only males chirp (although both sexes have ears) the conclusion has been that the chirping is a sex call.

Having somewhat questioned that conclusion, it seemed only fair that I should test the matter; but watching a female cricket to see if she goes to a chirping male is a time-consuming business and, so, it seemed desirable to invent a machine that would do the job as well or better than we could. Consequently we made an automatic "eavesdropper." It will have to be improved and its first reports are not to be taken too seriously.



The plan of the "automatic eavesdropper" described in the text

A box was made to contain the females. There was a window at each end where two other compartments joined it and here was food and shelter. Each window communicated with separate boxes containing males. One window was covered tightly with thin celluloid that let through the chirps but kept back odors. (Remember that insects have a keen sense of smell and many clearly find their mates by this sense.) The other window was covered with wire gauze that let through the odors and would have let through the chirps also if there had been any in the box with which it communicated. But there were no chirps in that box, because a simple surgical operation on the wings of the males there had completely "dechirped" them without hurting them more than a girl is hurt by having her hair bobbed—and the effect was much the same in so far as they were made more like the opposite sex. The females in the central box could wander about and go to either window. Would they go more often to the one where there were male chirps but no odor, or to the one where there presumably was male odor but certainly no chirps? This is where the automatic eavesdropper comes in.

On the floor of the females' box, just below each window, was a very delicate treadle. When a female came to either window, she stepped on the treadle there and, her weight depressing it, closed an electric switch that completed the circuit through an electromagnet. The magnet drew aside a pen that was otherwise tracing a perfectly straight line on a paper tape moving at a known speed. Each treadle moved its own separate pen. Clearly, all we needed to do was to examine the tape at our leisure and we could tell not only which window was visited but how often the female came, when she came, and how long she stayed.

IN "chirp but no odor *versus* possible odor but no chirp" the females visited the chirp window 290 times and the no-chirp window 307 times. There is practical equality here. When offered a choice between a blank window and one where there were males that could not chirp the score was 170 to 166. Again equality. "Chirp but no odor" won out over "blank" by 63 to 24, but the numbers are rather small and "blank" scored 65 against 48 for a window where there was *both* chirp and possible odor. Males which were offered several of the same choices paid 86 visits to "chirp but no odor" and only 40 to "possible odor but no chirp"; also 80 to "possible odor but no chirp" as contrasted with 44 to a blank window. It seems as though males are more consistently interested in both male chirp and odor than are females, the latter wandering about more or less at random; but that may be a too hasty conclusion.

A few experiments were tried with unmated females whose presumed ears had been removed by the simple expedient of cutting off their front legs. There were 27 visits by these virgins to a window where there were both male chirps and possible male odor and none

---

*Reprinted by permission, from *Natural History*, published in New York by the American Museum of Natural History.

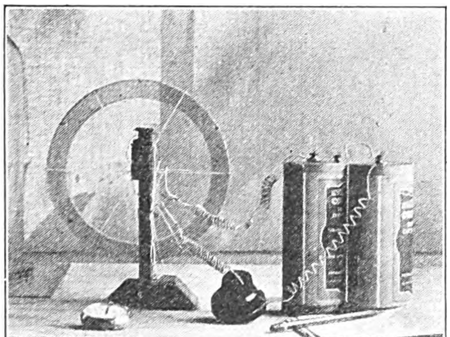
to the other window where there were no males. In another short series of trials where possible odor but no chirps was opposed to chirps but no odor the score was 14 to 11 in favor of odor, but the numbers are too small to be significant. On the other hand, possible odor but no chirps won out over a rival blank window by the rather startling total of 106 to 1.

One of two conclusions is fairly certain: either female crickets do not get wildly excited over the music of possible mates or there is something wrong with the apparatus.

THERE is a very different sort of problem which has greatly interested some physiologists and which may strike rather deeply into the mysteries of animal activities, either muscular or nervous, we are not sure which. For example, Harlow Shapley, an astronomer apparently desirous of improving daylight hours when he could not look at stars, watched ants and noted the speed with which they walked along a path at various temperatures. The warmer it was, the faster they went. A curious thing is that the relation between speed (S_1) at a given temperature (T_1) and the speed (S_2) at another temperature (T_2) closely accords with a complicated formula which represents the speeds of certain chemical reactions at various temperatures:

$$S_2 = S_1 e^{A\left(\frac{1}{T_1} - \frac{1}{T_2}\right)}$$

where e is 2.7183, the base of "natural logarithms," temperatures are measured on the "absolute centigrade" scale ("absolute zero" being about —273° C. or about —459° F.) and A is a constant that is characteristic of the reaction.



Treadmill operated by a cricket. A photo-electric cell recorded the revolutions made by the pedestrian

Some physiologists think that, by a comparison of the "temperature characteristics" of various animal activities (as shown by a curve representing the speeds of these activities at various temperatures) with the "characteristics" of various chemical reactions, we can discover what chemical reactions control these activities. Possibly we can but, at any rate, it is interesting to find out a little more concerning the influence upon insect activities of all the environmental factors, and this seemed to require a new type of apparatus in which the insect could walk straight ahead indefinitely without coming to a wall and in which the environment could be controlled.

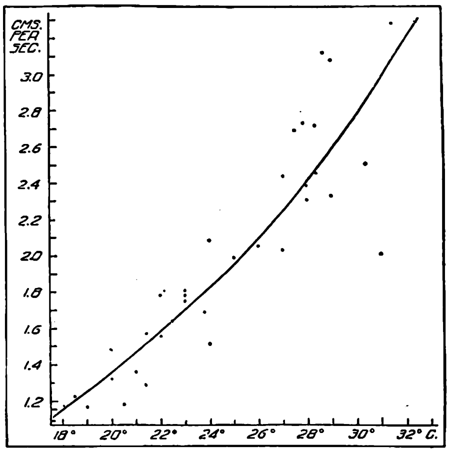
A device something like the wheel in an old-fashioned squirrel cage seemed to be what we wanted, but we wished it to be so delicately balanced and so frictionless that even a tiny fruit-fly would easily turn it. However, if we did away entirely, or almost entirely, with friction, the wheel, once it got started, would go on and on even after the insect had stopped walking. Furthermore, while we were at it, we wanted things fixed so that the wheel would automatically record both the speed and the direction of its turning. As I look back, I do not wonder at the kind, solicitous inquiries of friends concerning the "fly-wheel," and I even forgive the less kind intimations as to "wheels" in my head. The list of failures is a long one, but here is what worked and it is quite simple.

The track where the insect walks is something like an automobile tire with the insect inside of it. It is made of exceedingly thin, transparent celluloid, the "valve" being a tiny, sliding celluloid door for getting the animal in and out. The spokes of the wheel are fine silk threads; the axle, depending on the size of the wheel, is either a needle or the shaft of an almost obsolete thing, a hat pin. Over each end of the axle is an electro-magnet whose strength can be quickly and accurately varied by a rheostat conveniently located in the circuit.

NOW: An insect is put into the wheel, just enough electricity is sent through the magnets to take practically all the weight off of the bearings (a trick suggested to me by Professor R. W. Wood), and the insect can go as rapidly as it pleases but, like Alice and the Red Queen, it never gets anywhere. If it decides to stop, we can decrease the strength of the electric current; this lets the weight press on the bearings and friction stops the wheel.

Since an observer is usually on hand when the apparatus is being used, there really was not much point in having it self-recording but, compared with getting the wheel to work, that was easy, and there is some satisfaction in finishing what one starts out to do. Accordingly, a disk of opaque paper was fitted to the wheel and a series of openings was made in the disk. A photo-electric cell was put back of the disk and a beam of light was directed against its front. Every time an opening passed the beam of light, as the wheel turned, an electric impulse went through the photo-electric cell and worked a pen on a recording tape much as did the cricket treadle already described. The openings were so arranged that the turning wheel "telegraphed" a code message that told exactly what it was doing.

Having the apparatus, there was an obligation to use it and, I confess, this was more like work, although interesting. Not every insect is fit to go in such a wheel. Some sat calmly, as though thinking about something. Others had the will to walk but got tired, for the inside of a freely turning wheel is a trail that has no end. Thus, a yellow-jacket wasp that, in ordinary life, flies much but walks little, started off with an evident intention of getting somewhere in a hurry. For the first 20 minutes it kept steadily going at an average speed of about 9.5 centimeters per second. Then, temperature, light, humidity, and barometric pressure remaining the same, it began slowing up, its average speed in successive five-minute intervals being 8.3; 7.7; 7.4; 7.3; and 6.2 centimeters per second. At the end of the three hours and a half it was still at it but going only 3.9 centimeters per second, having had the longest walk of its life—about two thirds of a mile.



The higher the temperature the faster the milliped walked. "What it all means is another question"

GROUND beetles (Carabidæ) are much more used to walking than are wasps. In fact, they rarely fly. A specimen which Richard Iverson timed for two hours with the wheel in the open laboratory started off with a speed of 5.3 centimeters per second. Its average speeds in 19 of the 20 five-minute intervals for the last hour of the run were: 5.4; 5.3; 5.1; 4.9; 4.8; 5.9; 6.0; 5.9; (Dick took a five-minute rest); 6.0; 6.2; 5.8; 5.7; 6.2; 6.1; 5.5; 5.6; 6.0; 5.2; and 4.3. Apparently it could keep that up longer than we cared to watch and record. Our automatic disk contraption would have been handy in this case.

The creature that best served our purpose was not, strictly speaking, an insect but *Spirobolus marginatus*, the large brown milliped ("thousand-legger") of the late-summer woods. It is heavy enough to turn the wheel without the help of magnets; it is a consistent walker; and there is an absolute fascination in watching the perfect rhythm of those many legs hour after hour. Let us examine the effect of two environmental factors upon its speed of locomotion.

A *Spirobolus* was started off at a temperature of 32.5° C. (90.5°F.); then the box which contained the wheel was gradually cooled to 18° C. (64.4° F.); and finally warmed again to 30° C. This took about four hours and a half, the creature walking most of the time. Distance traveled, together with elapsed time, was electrically recorded on a rapidly moving tape. If you are used to reading graphs, the one on page 271 will clearly tell the story. The dots on the graph indicate the average speed of walking (see left-hand margin) at various temperatures (see bottom margin) and the slightly curved line is that given by the formula noted above when the constants are speed of walking (centimeters per second) equals

$$2.238\, e^{6351 \frac{(\text{Temp.}-300)}{(300 \times \text{Temp.})}}$$

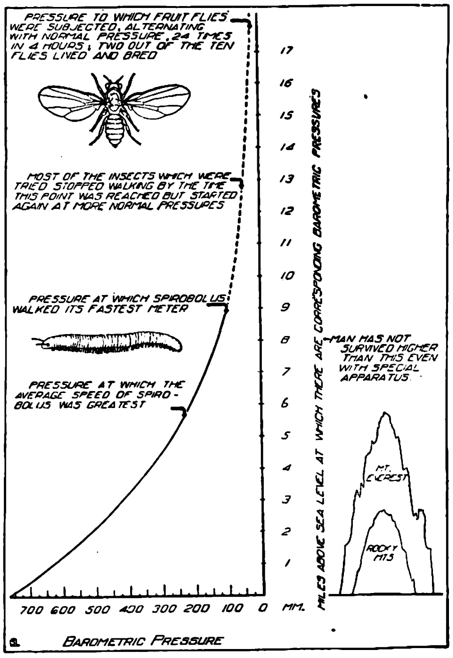
when temperature is given on the "absolute" centigrade scale. It is quite evident that "the warmer, the faster." What it all means is another question.

RATHER more startling experiments, perhaps largely because they were in an almost unexplored field, were the effect of changed air pressures, and this requires a bit of comment on the side. At sea level the air above us weighs so much that it balances the weight of a column of mercury about 760 millimeters high; in other words, the barometric pressure is about 760 millimeters at sea level. As we go up in a balloon (mountains are not high enough for present purposes) the pressure decreases, but not in simple proportion to the altitude. "Sounding balloons," carrying recording barometers but not a human being, have attained about 19 miles above sea level. But even that is not high enough for our present purposes. Since we do not know what the air pressure is 30 miles above sea level, about the best we can do is to take a very simple formula which seems to be "in the direction of the truth" even though it is known to be inaccurate. It is that altitude in miles about equals

$$10.33 \log_{10}\left(\frac{760 \text{ mm.}}{\text{Observed Pressure}}\right)$$

It may be simpler to look at the curve in the drawing above which gives, on the bases of known facts and of this formula, altitudes in miles for various barometric pressures.

For this experiment *Spirobolus* was put in a wheel; the wheel was put in a bell-jar; and air was pumped out of or let into the jar according to whether we wished to decrease or increase the atmospheric pressure. It was absurdly easy to give the creature all of the air-pressure thrills of a super-balloon ride to, say, 15 miles above sea level (air pressure of about 27 millimeters) and return in less than three minutes. Of course, since it is well to investigate one factor at a time, temperature, light, and humidity were kept as nearly constant as possible, and for that reason we can speak here of only the effects of air pressure and decreased oxygen supply.



The effect of decreased barometric pressure on several animals tested. The vertical column of numerals has reference to miles above sea level at which there are corresponding barometric pressures. The insect is a much "tougher" organism than the mammalian primate known as *Homo sapiens*

Suppose a man were being treated in this way. Even if the change were made slowly, his gait would be wobbly and his breathing very labored at a pressure of 400 millimeters of mercury, and the aviator Gray died, whether accidentally or not, when it was about 150 millimeters.

Since we wished to time the speed of walking at various pressures, *Spirobolus* was subjected to graded series of them. Observations were made during the first hour at 740, 500, 400, 300, 250, 200, 150, 100, 75, 50, 40, 30, and about 22 millimeters pressure in succession. In order to have a constant degree of humidity and also to prevent drying of the milliped by excessive evaporation, we had water in the jar and, since the vapor pressure of water at ordinary summer temperature is about 22 millimeters, that was as far as we went, and it seemed far enough for the present. At that, there was practically no air left in the jar. Then we came by rather short stages back to normal; then went to 100 and back to normal; and repeated this "round trip" three more times—all in two hours and a half.

Instead of walking more slowly as the air became rarer, *Spirobolus* increased its speed, all of its many legs functioning in absolute rhythm. This increase kept up on the average until the air was about two thirds gone, corresponding to pressures at an altitude of, say, six or seven miles; then it began to slow on the average and stopped (but not for good) when there was practically no pressure left except that of water-vapor. As a matter of fact, however, the fastest one-meter dash that it did was at an air-pressure of only 105 millimeters (representing, say, an altitude of about nine miles), making the meter in 59 seconds or a rate of about 1.7 centimeters per second. Of what stuff are these creatures made, at any rate?

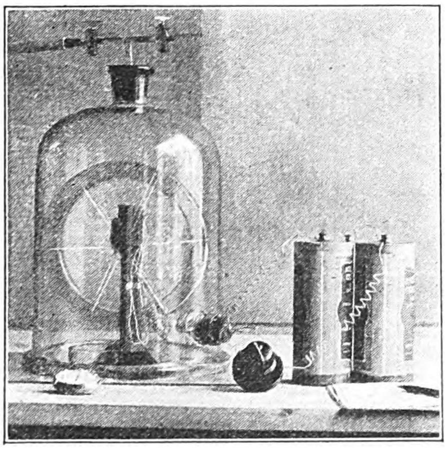
WE are all familiar with the tiny, red-eyed fruit-flies that come about over-ripe bananas and the like. Ten of these flies were put in a bell-jar with water and the air exhausted to the vapor-pressure of water in 90 seconds. The flies stopped moving. Valves in the apparatus were then opened wide and the pressure almost instantly returned to normal. Within four minutes all ten were walking about as though nothing had happened. The same procedure was repeated again and again. After the eighth trial one fly did not walk within seven minutes and I did not wait for him but went on with the one- to three-minute swings from normal to "none" and back again. After the 20th trial only six of the ten stalwarts were walking and I took time out for tea.

After tea we (the flies and I) made four more round trips and then only a male and a female of the original ten were still alive. There seemed no point in pushing the experiment to their death and, besides, I wanted to see if they were really as well and hearty as they seemed to be. So, I put them in a cage with a nice ripe banana, where they started breeding the next day. Careful microscopic examination of their children, grandchildren, and great-grandchildren failed to reveal indications that anything unusual in fruit-fly affairs had happened.

Human endurance would fall so far below that of insects in such a test that no comparison can be made. An express elevator in the Woolworth Building or the dropping of a cage in a deep mine are slow coaches going a short block compared to the ride these flies took 24 times in four hours, but in what follows we tried to reach the limit of even insect endurance—and failed as far as air-pressure is concerned.

It is well known that, in order to produce X rays, the air is almost completely removed from the X-ray tube and then an electric discharge of very high voltage is made to jump the gap between two electrodes in this "vacuum." But the so-called vacuum, while nearly complete, is not entirely so; there are still enough ions left to carry the electricity from one electrode to the other. Furthermore, it is possible, by means of a pump which Mr. Alfred L. Loomis has in his bio-physical laboratory at Tuxedo, to exhaust the tube so completely that the X ray dies out and even 30,000 volts will not force a discharge across the gap. Instead of an air-pressure of about 760 millimeters of mercury, as we have in normal atmosphere at sea level, the pressure now in the tube is of the order of one 10,000th of one millimeter. It is probably lower than the vacuum of interstellar space. What would happen to a "frail" butterfly or bee if subjected to such a vacuum and then suddenly brought back to normal pressures?

THE answer is complicated by a factor already mentioned, one which we found was more important than sudden and great changes in air pressure. This factor is that the pump which removes the air also removes the moisture; and insects which are kept in a pressure much less than the vapor pressure of water would quickly dry up and die of desiccation. Water can not be supplied to them in this apparatus, because some of it would evaporate so quickly that what remains would be frozen to solid ice and, in fact, part of the slowing effect of high vacuum on insects may be due to a marked lowering of their temperature caused by evaporation from their bodies. However, let us see what happened.



The treadmill placed inside a bell jar connected with a vacuum pump

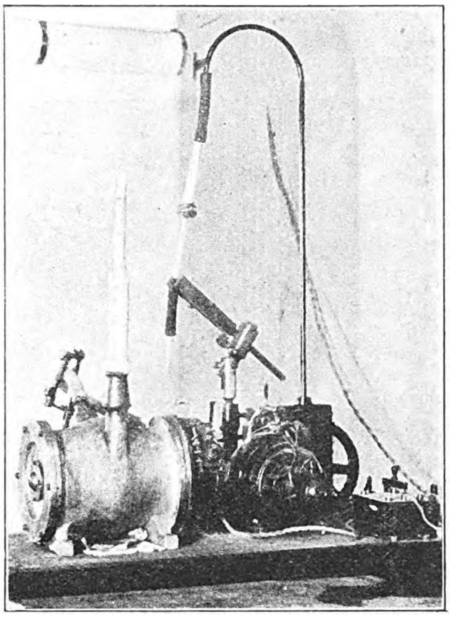
Three small bees belonging to two genera of the sort that live a solitary life, instead of in colonies, two mound-building ants, a beetle related to fireflies, and an immature grasshopper, were put in a tube and the ends of the tube were melted so that it was welded into the apparatus. (Ordinary joints would not hold.) Since moisture would ruin the pump and since moisture was sure to come from the insects, that part of the tube between the insects and the pump was packed in a mixture of solid carbon dioxide and acetone in order to freeze the water out of the air while on its way to the pump.

The pump was started and the next three minutes were busy ones. First the vacuum-tube glow appeared, but before the end of the second minute it had died out, showing that a non-conducting vacuum had been reached. This was held for 60 seconds, a rapidly growing pile of snow in the chilled connection being the moisture sucked out of these "frail" creatures, and then the glass tube was broken at one blow and the insects were returned to normal conditions from their journey into a "complete vacuum." Not one moved then, but two hours later all were active and apparently normal. A little later one of the ants showed some signs of trouble but whether it was due to the vacuum, the drying, or to some more natural cause I do not know. The next day that ant was dead but, when released, the other ant and all of its companions each according to its kind flew, hopped, or walked away.

THE same experiment was tried with a bumble-bee and two kinds of butterflies, except that the insects were in a vacuum of less than one millimeter pressure for four minutes and the extreme of 1/10,000 millimeter was kept up for 90 seconds. In about ten minutes after the tube was broken, instantaneously returning them to normal pressures, the bee and one of the butterflies began to show signs of life. Five minutes later both were walking and the other butterfly was feebly moving its legs and mouth-parts. By the next day the bumble-bee was active as ever but the butterflies had died. Possibly they were unable to withstand the conditions of the experiment, including the excessive drying, and possibly they died from other, more natural causes, but it did not seem necessary to try the experiment again.

There was no longer room for doubt that insects and their near relatives are creatures that can not only exercise vigorously at air-pressures which no man nor any of the animals related to him could survive; creatures that can not only completely recover within a few minutes from sudden and rapidly repeated transfers from normal pressures to almost none and back again; but they are creatures that can survive the most complete vacuum that man can produce with exceptionally perfect apparatus. How do they do it; why can they do it?

All that we can say is that insects seem to be better made than we are. They have invaded almost every bit of the livable world, including hot springs and the highest mountains, the Arctic and the tropics, in water and on water, underground and above ground, in plants and animals and on them. Only the ocean is avoided by them. Their structure and mode of living have stood the test of time practically unchanged since the Carboniferous period. Possibly Maeterlinck was right when he called them "beings so imcomparably better armed and endowed than ourselves, concentrations of energy and activity in which we divine our most mysterious foes, the rivals of our last hours and perhaps our successors." On the other hand, as has been pointed out in "The Friendly Insects" (*Natural History*, Vol. XXVI, p. 147), relatively few kinds of insects seriously injure us and we owe much to many kinds. Possibly, with increased knowledge of insect habits, we may be able to swing the balance still more in our favor.



The high vacuum pump at the Loomis Laboratory. See the text

WHAT good are such experiments as these? Possibly collecting interesting information about the masterpieces of Creation is of no greater value than collecting human masterpieces of art; and possibly writing about Nature is no more useful than writing music; but, until some one is wise enough to be able to predict the worth of any bit of pure (as contrasted with "applied") science, we can at least say that it "amuses" those who do it and interests many who read about it. "Pure" science is science which has not yet been applied.

The Largest American-Made Telescope Mirror

READERS who are devoted to to science and the arts doubtless will recall that, in January, 1928, much publicity was accorded by the scientific and daily press to the successful casting of a two-ton disk of optical glass at the United States Bureau of Standards in Washington.

This disk, 71 inches in diameter and 12½ inches thick, had been poured in May of the previous year. The glass reached the mold at 2500 degrees Fahrenheit, was securely covered (the mold itself was in an insulated pit beneath the floor) and permitted to cool within a week to 1100 degrees Fahrenheit. It was held at that temperature four days, then cooled 4½ degrees per day until it reached 860 degrees, was held at constant temperature 45 days for annealing, and then allowed very gradually to cool to outside temperature, which required 130 days.

Only then might the covering be removed to ascertain whether the disk were broken and worthless or perfect. Dramatic moment! Some wag said that, as the decisive time approached, some of the anxious spectators nearly died of heart failure, but the disk came out uncracked. This was the first large American telescope disk ever cast and its successful completion rightly put a feather in the cap of the Bureau of Standards, particularly of Dr. A. N. Finn, the glass technologist at the Bureau. Optical tests for strains and symmetry of annealing indicated that the disk was optically as well as physically a success, and the whole proceeding thus constituted the beginning of a sort of declaration of American optical independence.

The disk was shipped to J. W. Fecker of Pittsburgh, the successor to the late John A. Brashear whose fame as a maker of large telescope mirrors is a tradition. The sequence of six recent progress photographs reproduced in the present pages was kindly furnished by Mr. Fecker, who with his men has done the further work which they show.

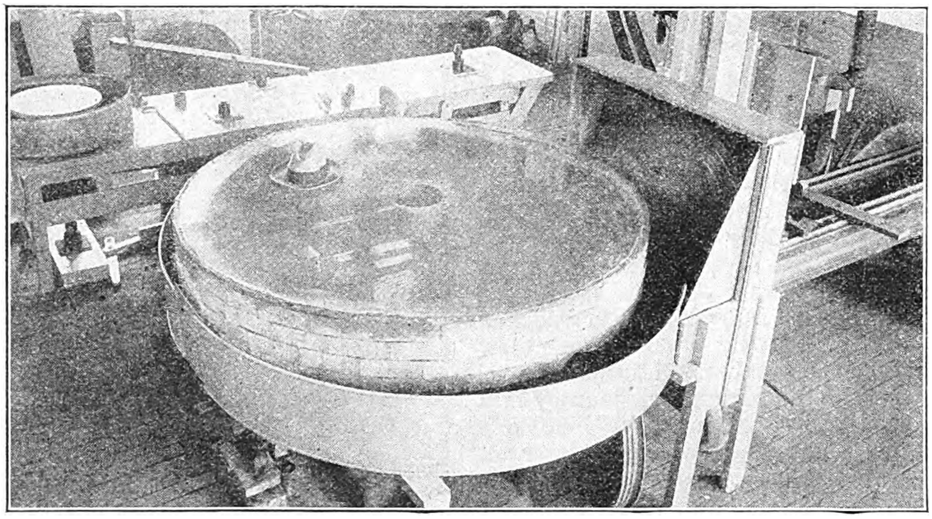


Figure 1, Above: **The raw glass disk of the 69-inch mirror. The geometrical pattern on its edge is due to the bricks of the underground mold**

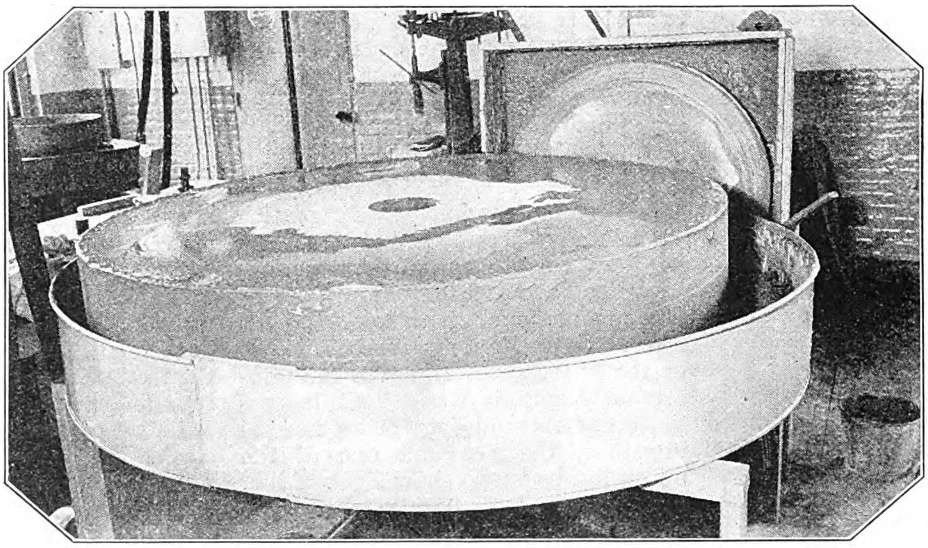

Figure 2, Right: **Rough grinding the edge with water and emery (note pot at right, on the floor) as the disk is slowly revolved**

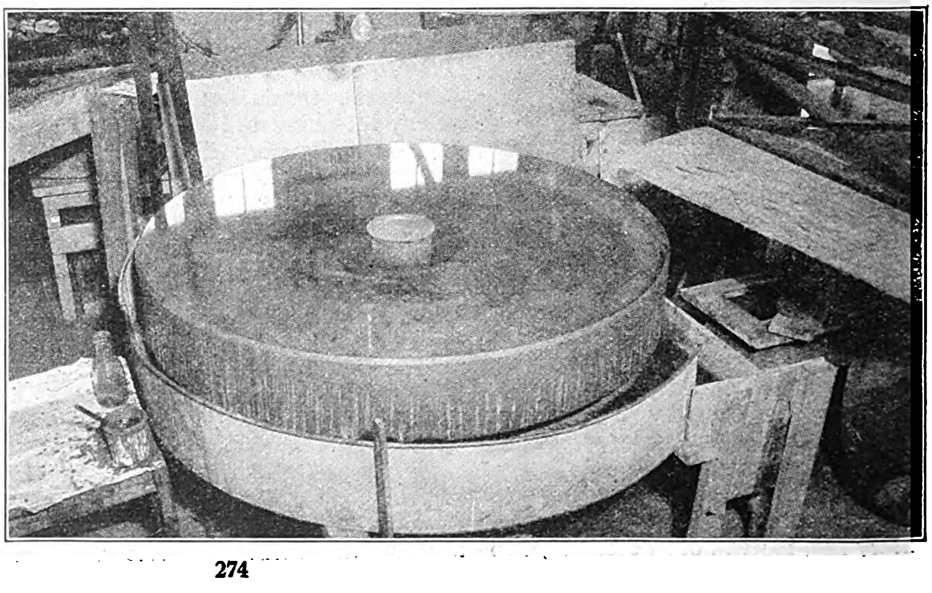
Figure 3, Below: **The edge has been ground and the back surface ground and polished approximately flat. The disk is ready to be turned over and ground to thickness, preparatory to grinding the concave curve in the reverse side**



In Figure 2 the glass is slowly revolving while a disk of iron bears steadily against its edge, with wet abrasive doing the work of removing the irregularities. Figures 3 and 4 are sufficiently explained in the legends. In Figure 5 the disk, now reduced to $9\frac{5}{16}$ inches thick, has been ground to a concave (approximately spherical) curve having a depth of 0.95 inch, and less than one thousandth of an inch will be removed in all subsequent operations.

Apparently, then, the job is about complete. But is it? "In its present state," Mr. Fecker writes, "the mirror is about 20 percent completed." It is this last thousandth of an inch which contains most of the real grief in making a telescope mirror.

Even a thousandth of an inch is an extremely rough, coarse measurement in this work and a millionth of an inch is much closer to Mr. Fecker's final criterion of perfection. The degree of accuracy required by the purchaser in this case was one tenth of a wavelength of yellow light, or one 500,000th of an inch. In large work of this kind it is the practice to work within a specified tolerance, such as this, but Mr. Fecker carries the refinement to a still higher degree of accuracy. This final process, call "figuring," usually requires endless hours of the most skilled retouching, all performed underground in a constant temperature.

It is hoped that some time in 1931 the finished mirror will be functioning in the large telescope at Ohio Wesleyan University, which was made possible by the life savings of the late Hiram Mills Perkins and his wife Caroline Barkdal Perkins, the donors.—*A. G. I.*

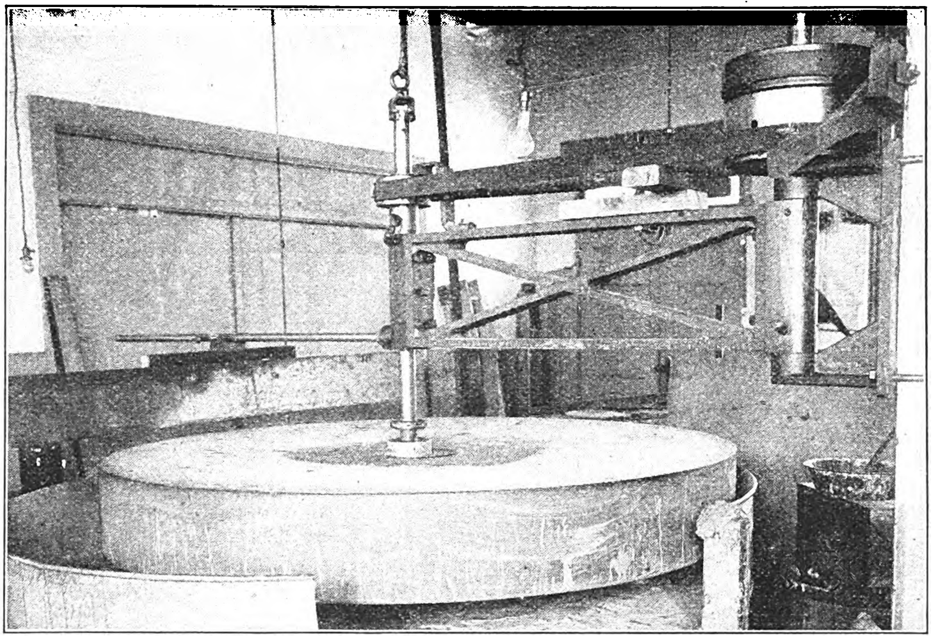


Figure 4, Above: **Grinding the hole true and concentric with the periphery of the mirror. As the disk slowly rotates the vertical, adjustable (note arm), revolving tool, belt driven, enlarges the hole**

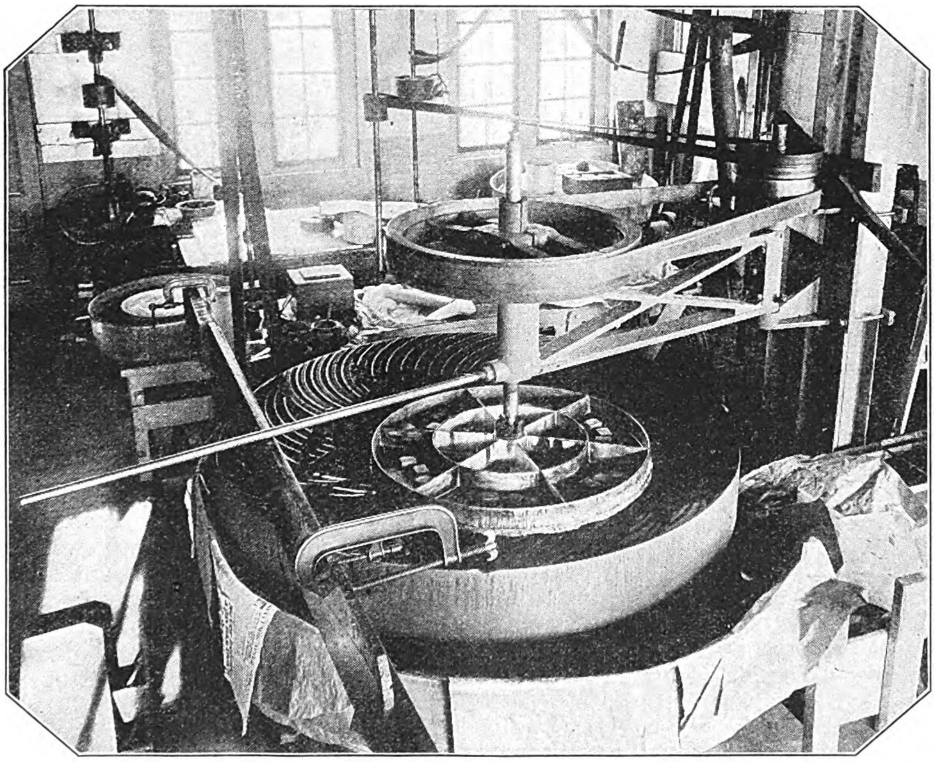

Figure 5, Left: **Polishing the concave surface of the mirror, using a pitch polisher and rouge abrasive. This brings the mirror to approximate spherical form ready for final delicate correction**

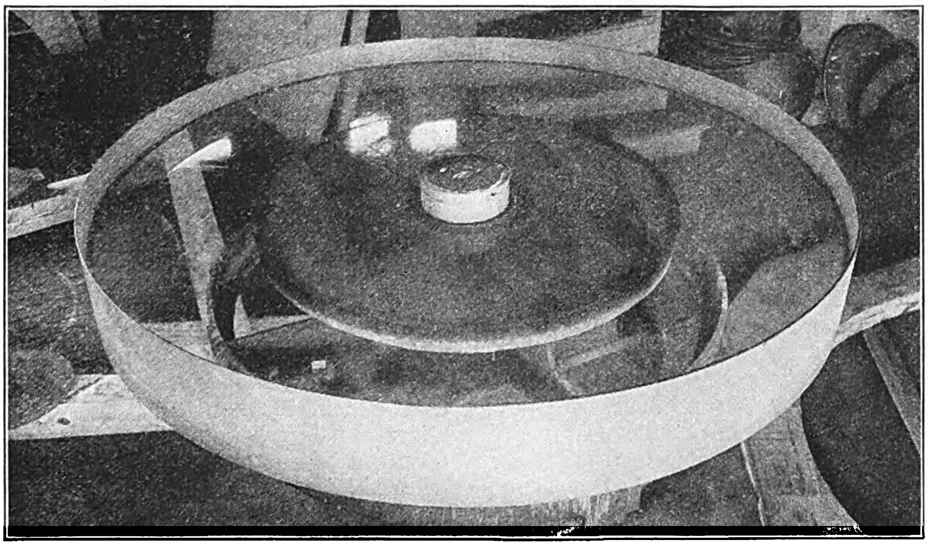

Figure 6, Below: **Ground and polished on both sides, ready to be put into its metal backing or "cell," removed to another machine in the constant temperature room underground and given final correction or "figuring"**

The Development of the Columbia River

By CHARLES F. A. MANN

AFTER over a half century of incessant effort by the citizens of Multnomah County and Portland, Oregon, assisted by United States Army Engineers, toward the establishment of a deep channel in the 110-mile stretch of the Columbia River that lies between Oregon's famous port and the Pacific at Astoria, the final and most important chapter of all is about to be written down—that of scraping off the last five feet of river bottom in the present 30 by 300-foot channel, in order that a deep-water canal 35 feet deep and 500 feet wide will be a stable part of the Columbia River.

Word reached residents along the lower Columbia late in 1929 that the Board of Army Engineers had approved and recommended the project to Congress, involving an initial expenditure of only 1,366,000 dollars with an annual maintenance charge of 665,000 dollars. Five feet does not seem much, but when one realizes that 85 percent of all imports of the Pacific Coast ports move in ships of greater draft than can be cared for in the present 30-foot channel, the importance is at once appreciated. Portland, together with its neighboring Columbia River ports of Vancouver, Washington; St. Helens and Rainier, Oregon; Kalama and Longview, Washington, draining vast quantities of lumber, paper, pulp, and fruit into the markets of the world—presents the paradox of a great seaport being able to export but do little importing.

THE Columbia River ranks as one of the great rivers of the world, draining some 300,000 square miles of territory in seven states and British Columbia, which is a region of heavy precipitation. It flows from glacial headwaters in the remote Columbia ice fields in north central British Columbia for 1200 miles to the Pacific.

Because of its gigantic proportions, the development of the Columbia for power and navigation, and use of its waters for irrigation, has been very slow. The great interior stretches of the river flow through vast, sparsely inhabited arid plains and past weird rocky cliffs where once countless lava flows and uplifts tore gashes and even changed the course of the river entirely. There is approximately 8,000,000 horsepower of primary and double that amount of secondary, or summer hydroelectric power available in the Columbia River. Only in the fall of 1929 were plans made for the first power plant ever to be placed on the river. It will be a 100,000 horsepower plant at Priest Rapids, in central Washington.

Because of its glacial origin, the Columbia carries vast quantities of sharp sand in its waters. In addition to this, when the hot summer sun melts the glaciers in the Columbia ice fields each year, the river floods with unusual rapidity, raising the level from 20 to 75 feet in various parts of its course. With a normal flow of about 70,000 cubic feet per second the river rises at certain times to a maximum of 1,400,000 cubic feet per second. Thus two great problems confront engineers who set out to conquer the river: silting and flooding in peculiar combination.

Scarcely 30 miles above Portland—140 miles inland from the ocean—the Columbia takes its last plunge over the Bridge of the Gods practically to tidewater. From there on, the river, known as the Lower Columbia, changes its character. It becomes wide, often sluggish, with shifting channels and innumerable sandbars. Rolling, green hills and fertile river plains in the wide lower river valley form the banks. It is in these quiet waters that the people of Portland and the lesser ports are directly interested.

Long ago navigation on the upper river, above Portland, gave way to the parallel railroad tracks on each bank, which are not affected by floods or silt and need fear no rapids, yet are able to take advantage of the matchless grade through the mountains that never is greater than 0.2 percent all the way from Spokane to Portland. This factor, together with the limitless possibilities of growth in the tributary area of Portland, long ago made one vital factor of great importance to the citizens of Oregon's metropolis: to make the Columbia River into a navigable channel. In final terms their problem was about as follows:

1. To get a deepwater channel to the Pacific.
2. To create a deep harbor in the shallow Willamette River, on the banks of which the city of Portland rises, 12 miles in from the Willamette's confluence with the Columbia.
3. To build two jetties at the mouth of the Columbia in order that the river might carry its silt far to sea, leaving ample depths over the bar at all tides.
4. To keep all bridges high above the Portland harbor and permit nothing but suspension spans with at least 200 feet clearance over the Columbia.

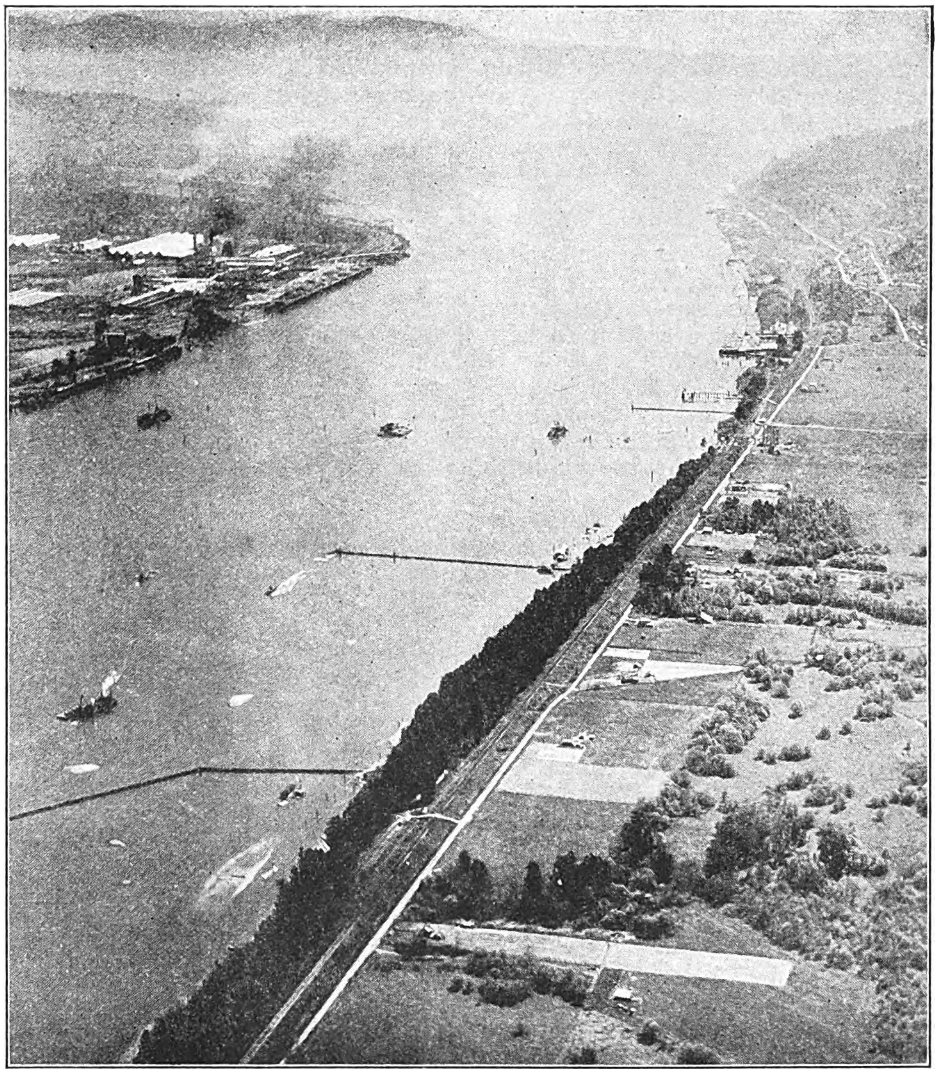
FIRST efforts by Portland citizens to get a deep channel in the Columbia began more than half a century ago. In order to clarify the method of carrying out the long series of river improvements, it is well to divide it into sections. The first section concerns the work of the Engineer Corps, United States Army, which has complete charge of the Columbia from its mouth to its confluence with the Willamette River. The second concerns the work of the citizens of Portland and Multnomah County, that of developing Portland Harbor without financial assistance from the Government through the Port of Portland Commission, and the development of public terminals through the Portland Commission of Public Docks. To the end of 1928, the United States Government had spent about 16,000,000 dollars on the two jetties at the Columbia's mouth, and 11,000,000 dollars on the 100-mile stretch of the Columbia River; the city of Portland had spent approximately 25,000,000 dollars divided about equally between harbor development and a public terminals system.

In the original state of the river, a minimum depth of about 15 feet was found, and around 20 feet at the Columbia Bar at the river's mouth. When work was first started by the Government a half century ago, the first problem to be solved was that of making the river scour its own bed free over the bar. The original plan for these jetties was first approved by the Government in 1884, but it was not until a quarter of a century later that they were finished. The south jetty is seven miles long and the north jetty two and a half. These have effectively changed the channel over the bar to a depth of 46 feet for a width of about 2500 feet and 40 feet for about 7000 feet width at mean low water. The original depths of the river were from 19 to 21 feet over a width of six miles.

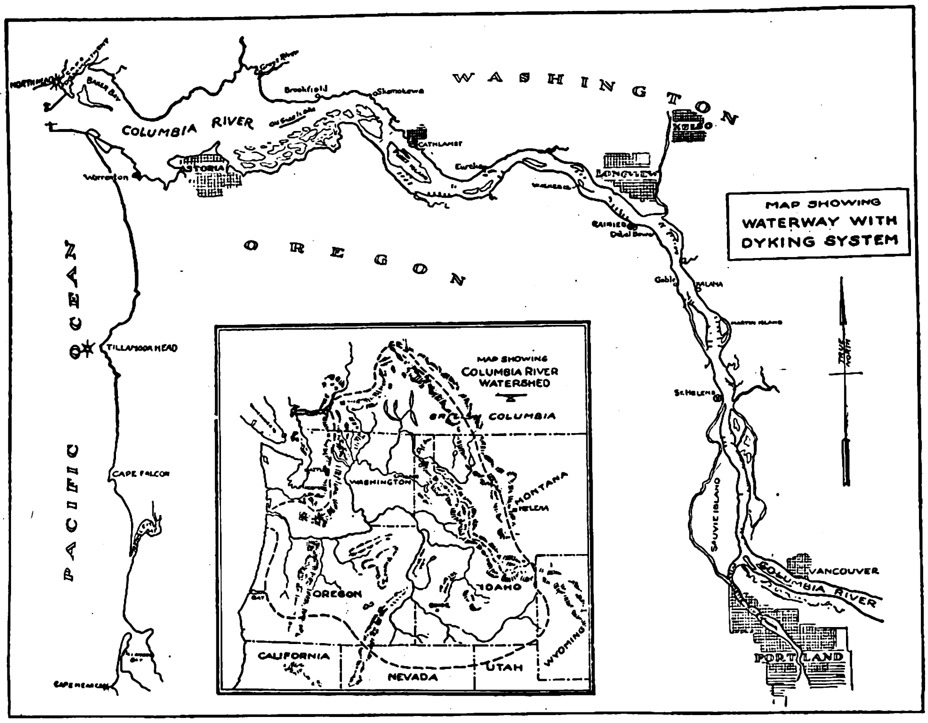
In the 100-mile stretch from Portland to Astoria, the Columbia develops shoals in about 25 places after the annual freshet in June. These are known as bars and, between them, deep pockets of safe water are found. So regular are these bars that year after year they are found in exactly the same places and after being measured are attacked by dredges and pumped away.

Ever since the long line of surveys was begun on the lower Columbia in 1878, the plan has been to make the river scour its own bars free of silt, the deposit of which varies from three to twelve feet each season, in exactly the same way as the big jetties at the mouth do. Accordingly, the primary problems of the Army engineers were reduced to two: dyke construction and supplementary dredging where dykes would not do the job.

BY watching the river closely after each flood, they have found where the shoaling takes place. As a result of this, more than 70 dykes projecting into the river at various angles have been built, which act as a contraction to the stream flow and keep the mass of mud and silt moving along the bottom. Supplementing this, after each flood from June to October, a fleet of dredges attacks the bars and brings them back to normal depth. The Portland Port Commission lends the War Department two dredges for a period of three months each year, the government paying nothing but operating expenses, to assist the regular Army dredges in speedily bringing back the proper depths before the



Three new dykes at Ranier, Oregon, at wide part of river where silting takes place. Notice how sand has been deposited on downstream side of dykes



deep-draft grain ships begin to move in October. This accounts for the abnormal rush to bring the channel back to proper depths that takes place each summer. The Willamette River does not silt in summer, but during heavy rains, it floods vast quantities of mud down from its valleys, which must be removed. Silting in the Columbia amounts to about 5,000,000 cubic yards per year.

AFTER years of effort, the effect of the permeable dykes has become apparent. The channel is now stabilized and the success of the timber and rock wing dyking system has been proved. The entire project is a part of successive projects for 20, 25, and 30-foot depths approved by Congress in acts of 1892, 1902, 1905, 1913, and the foundation work of the 35-foot depth project about to be started, in 1919. With faster and deeper ships, increased dyking has had to be done to compensate for the increased cross-sectioned flow incident to dyke construction of earlier dates which deepened the channel.

In order to execute the 35-foot project, about 18,000,000 cubic yards of silt will have to be removed. In addition, 18 new dykes will have to be built and 28 extended farther into the river, amounting to 44.7 miles of Columbia channel and 11.5 miles in the Willamette. The annual appropriation of 665,000 dollars will serve to dredge away 7,000,000 cubic yards of silt and to repair dykes.

At Portland, we find the oldest quasi-public organization in the northwest, the Port of Portland Commission, at work with a fleet of four dredges, moving millions of yards of mud out of the Willamette, building its famous Swan Island Airport in the middle of its harbor out of waste silt from its dredges, filling in valuable real estate areas in the harbor, operating drydocks and towboats, and in sole charge of the entire harbor, without governmental aid in any form. Organized in 1891, the Port Commission began dredging away on its harbor, then mainly a muddy puddle between the two halves of the city. One old steam pipeline dredge—the famous *Portland*—worked 30 years at the task. Four others, ending with the 2000 horsepower twin-turbine steam dredge *Tualatin* and the giant *Clackamas*, a 3400 horsepower Diesel-electric dredge of tremendous capacity, were built. The *Clackamas* was the last dredge built by the Commission and, at the time of her building in 1925, was the most powerful in the world. She is capable of moving 20,000 cubic yards per day at a cost of about three cents per yard, and cost 850,000 dollars to build. During the two years in which the Swan Island Channel was changed to the west side of Swan Island and the famous airport built out of the waste from the dredges, the Port Commission dredges moved 39,000,000 cubic yards of material with an over-all cost of about 2,500,000 dollars. The real estate obtained by filling tide lands reduced the net cost of the entire project and gave the Commission an airport, a yacht harbor, and a new channel, all for less than 800,000 dollars! This still ranks as one of the most important dredging projects in the world.

WITH the last and most important step of all about to be taken, that of the 35 by 500 foot channel to the sea, the efforts of 50 years will at last bear their best fruits. Probably no more important piece of engineering has been done in this country than the building of a fine inland seaport on the erratic Columbia. With the hinterland yet comparatively untouched, and an enthusiastic group of boosters besieging Congress for 350,000,000 dollars to irrigate 2,000,000 acres of the Columbia Basin, the waterway will grow in importance as the years pass. Credit for the two big divisions of Columbia River development goes to Colonel G. R. Lukesh, of the Army Engineers at Portland, and James H. Pohlemus, Manager and Chief Engineer of Portland's famous Port Commission.

Another phase of the work, although not immediately concerned with channel development, is the vital problem of bridges in which approximately 50,000,000 dollars have been invested. Eight large spans cross the Willamette and two cross the Columbia carrying rail and highway traffic northward from Portland into Washington. A 6,000,000-dollar cantilever span across the Columbia between Longview and Ranier was opened in January, 1930; and a 5,000,000-dollar suspension span has been planned to cross Portland Harbor at St. Johns.

A Reclining Chair Night Coach

WHEN a person has to travel only part of the night, it hardly pays to take a berth in a sleeping car; some travelers cannot afford even the luxury of an upper berth. To all such, a new type of car has been introduced by the Baltimore & Ohio Railroad Company for their night trains between New York and Washington. These cars were built in the Mount Clare shops, Baltimore, Maryland. "Twin seats" in day coaches are in use on other railroads, but these new cars have many points of novelty.

THE exterior of the car shows no change, but in the interior there are many departures from normal practice. By means of cranks, each seat can be inclined independently. The arm-rests of the reclining seats are of sponge rubber composition, soft and comfortable. The middle armrests are collapsible and disappearing so they can be removed if desired, to allow children to lie down. Foot-rests are also provided, adjusted to the proper angle so that when the seats are in a reclining position, the posture of the occupant is conducive to rest. Thermostatic control is provided on each side of the car to insure even temperature throughout, and in addition there are ceiling and window ventilators. The decorations are plain and the car is finished in "living-room" style. In addition to ceiling lights, small individual night lights are provided so that those who wish to read may do so. There are separate smoking rooms for men and women, with comfortable arm chairs. The great novelty is the lunch room at one end, where simple refreshments can be obtained at all times during the long and wearisome night.

Measuring the Distance to the Stars

By HENRY NORRIS RUSSELL, Ph. D.

Chairman of the Department of Astronomy and Director of the Observatory at Princeton University

Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

SIR ROBERT BALL, who illuminated his admirable lectures with recurrent flashes of his native Irish wit, used sometimes to say, "Astronomy consists of sitting up all night and doing arithmetic all day." No truer picture of the life of the working astronomer was ever compressed into a sentence. All that need be said in addition is that some astronomers specialize in the sitting up, some on the arithmetic, while some divide their energy between the two.

An excellent example of the third sort of work is found in the measurement of the distances of the stars. This has become in recent times distinctly an American field of work and may well claim our attention for a few moments. The principle involved is the simplest. Look out across the room through a window at the world without, then move your head a few inches from side to side. As you do so the window bars will seem to shift to the right as you move to the left, and *vice versa*. It is exactly such a shift of nearer objects, compared with those at a distance, which we use to measure the distances of the planets and the stars, only we call it by the Greek name of "parallax." Obviously, the nearer one sits to the window the more the window bars will seem to move across the landscape (for the same motion of one's head) and, if one can measure the apparent shift, the simplest sort of geometry gives their distance. Exactly the same principle is used in the range finders which are so important in military and naval gunnery.

TO apply this principle astronomically we must have two things: a shifting base moving by known distances, and a distant background against which we can measure the parallactic shift. When we are working on the moon or the nearer planets we change our base simply by making observations from different parts of the earth, or by the cheaper process of letting the rotation of our planet carry us around it. When we must deal with the stars we need a far longer base line. Fortunately we have one, provided by the earth's motion in its orbit, which takes us alternately 93,000,000 miles on one side of the sun and on the other, and so gives us a base of double this length. Even with this long base the parallactic shift is measureable only for a small minority of the stars. The rest are so far distant that their displacement is imperceptible.

This is no unmixed evil, for we may employ the multitude of faint stars which cloud the heavens as the background, the standard of reference; which is the other prime necessity of

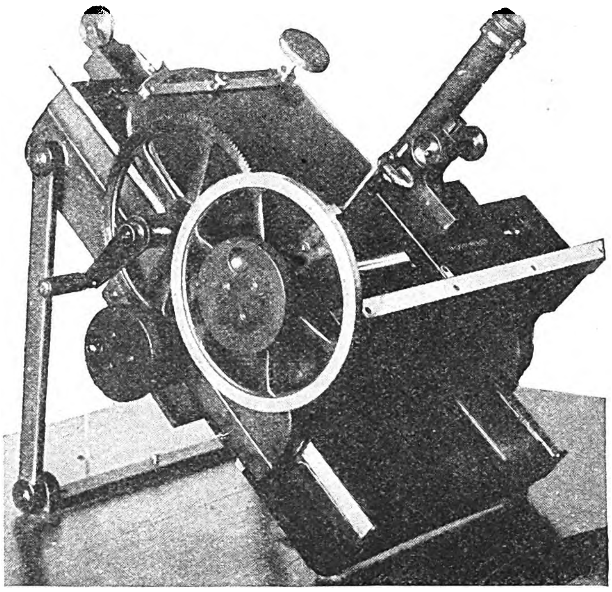

Figure 2, Right: **Gaertner machine for measuring parallax plates. A microscope, movably mounted above the plate on a very accurate, horizontal low-pitch screw, is spotted over the star's image, with the aid of its cross hairs. The accurately divided index head at end of screw facilitates measurement to 1/25,000 inch**

the method. Theoretically it is not quite an ideal standard, for even these remote stars must show a small parallactic shift compared with an absolutely fixed background. But, practically, this makes no trouble, for we have means, based largely on the sun's motion in space, of finding the average amount of this tiny shift and can then allow for it.

When it comes to the application of these principles to the actual measurement of star distances we meet with various difficulties. The first is that the stars do not stay still to exhibit their annual shift, but move across the heavens. By extending our observations over two or three years, however, we can easily find out the rate of this "proper motion" for each star and allow for it. More serious is the fact that the shift due to parallax is very small, so that our observations must be extremely accurate. This difficulty again has been fairly well overcome by the use of large telescopes and, above all, by the photographic method of observation.

ONE of the most unexpected discoveries of modern precise astronomy was that it is possible to make more accurate observations with a given telescope by photographing the stars and measuring the positions of their images on the plates than by measuring the stars directly with a micrometer attached to the telescope. Until the thing was actually tried no one had any idea how precisely the photographic film preserves the record of the position of the images which impress themselves upon it. In ordinary modern practice the average error of position of a single star image is less than a 10,000th part of an inch. Considering the vicissitudes through which the gelatine film has gone during the processes of development, fixation, and drying, this is really extraordinary.

However accurately the plate records the positions of the star images, it must be measured under the microscope, employing some form of micrometric device (for example, as in Figure 2), and it may still seem strange that this two-stage process yields better results than does the micrometer directly applied to the telescope. The most probable explanation is that, owing to the irregularities of atmospheric refraction, the star images in the telescope are continually oscillating and dancing about. In visual observation the observer sets his spider thread on the images and catches them at some one moment. The plate automatically averages the effect of the oscillations of the image during the whole length of the exposure (usually several minutes) and thus gains a considerable advantage. When it comes to measuring the positions of several stars in the same field the photograph has the still greater advantage that its record is simultaneous for all, while the visual observations must be successive and are subject to different errors in each case.

Photographs, therefore, have quite ousted all other methods in parallax work, but the observer is only at the beginning of his troubles when he has set up his telescope and got his lenses into proper adjustment. In the first place his instrument should follow the diurnal motion of the stars in the heavens so perfectly that the image of a given star throughout the whole time of the exposure falls exactly on the same spot upon the plate. Even the best driving clocks do not quite meet this severe requirement, and of course they can not follow at all the irregular motions of the images caused by refraction. To meet this need the parallax observer has the plate holder mounted on the telescope in such a way that it can be moved up and down or right and left by two delicate screws. (Figure 1 at D and R; also Figure 3.) Just outside the plate holder and clamped to it is an eyepiece (E, Figure 1), adjustable in such a fashion that the observer may bring into it the image of some faint star. Before he begins his exposure he brings this star on the cross hairs of the eyepiece. Then, watching with the eye of a hawk, he notes the slightest deviation of this image and brings it back by turning one or both of the screws which move plate holder and eyepiece together. An experienced observer in this way may get rid of most of the "errors of guiding" which otherwise might vitiate the positions of his star images. As a result of this care the images will all be small, clean and round. If by any mishap they are not, the plate will be rejected and not measured.

TO get good images, however, we need not only careful guiding but correct exposure. Under-exposed images are gray and diffuse; over-exposed large, fuzzy, and ill-defined—and neither sort can be measured accurately. When the star whose parallax we are seeking is faint, this causes no extra trouble. A trial plate or two shows what length of exposure is necessary to get good images of this "parallax star," and among the other stars which appear on the plate it is practically always possible to find enough of about the same brightness to serve as the "comparison stars" which furnish the requisite background.

But the parallax star may be a bright one—perhaps even Sirius itself—while the only available comparison stars are a hundred or even a thousand

Photo by Dr. James Stokley. Science Service

Professor Frank Schlesinger, Director of Yale Observatory, whose parallax work was done at Yerkes and Allegheny Observatories

times fainter. Obviously, some means must be found to cut down the light of the one without obscuring the others. This is usually done by the aid of an "occulting disk" an inch or so in diameter (Figure 1, O). This consists of two parts which can be set so as to leave a narrow open sector of any desired width from 1 degree to 180, while blocking out the rest of the circumference. This disk is mounted close to the front of the part of the plate where the image of the parallax star falls and is rotated rapidly by a tiny motor or by clockwork. If the opening in the sector covers only 1/50th of the circumference, the parallax star will be given intermittent exposures which will total 1/50th that given the fainter comparison stars which receive a continuous exposure.

WITH this apparatus the image of even a very bright star may be reduced to apparent equality with those of its faint neighbors without losing the advantage resulting from the averaging effect of a large number of exposures under different conditions of trembling of the images. This method has been completely successful, with the result that observations of stars as bright as Sirius made with its aid are found to be as accurate as those of faint stars which do not need it.

Still another danger, and the most subtle, remains. The images of the stars are raised in the heavens by refraction, and more for white stars than for red ones (by the same influence which produces the "green flash" at sunset). If our parallax star and comparison stars are not of the same color (as very often happens) this will shift the one relatively to the other. So long as this spurious shift is always in the same direction and of the same amount it will not trouble the parallax observer, but if it is in different directions at the same time of his different observations it may become confused with the true parallactic shift in such a way as to vitiate his results. To be safe, therefore, he must observe any given star always when it is in the same position in the sky, preferably on the meridian, so that the error due to refraction may always be the same.

When all these precautions are taken, a set of from 12 to 20 photographs made at the proper times during an interval of two or three years, will give a determination of the parallax with the probable error less than 0''.01, which exceeds in precision any other angular measurement.

Parallax work is a strenuous occupation. To get the shift in one direction the stars must be photographed in the evening as soon as it is really dark—which is easy; but every such plate must be matched with one showing the opposite shift taken at some other time of the year and in the morning hours just before dawn. To carry on the careful work of precise "guiding" without a moment's relaxation of the tension through these weary hours is "sitting up" with a vengeance, even if the observer has left the instrument to another worker during the middle of the night and sought a well deserved rest—and it is rarely that the size of an observatory staff permits such a relief.

Measuring the plates, after they have been developed and passed as fit for it, is a job for the daytime and for a good light, and consumes a great deal of time. Indeed, one good telescope in a fairly favorable climate and with assiduous observers can secure plates two or three times as fast as these observers could work them up. Fortunately the measurement, like most routine work, can be entrusted to assistants and this is true *a fortiori* of the computations, which are simple but interminable when thousands of plates have to be discussed.

The pioneer of this photographic method was the great Dutch astronomer Kapteyn, who first pointed out the importance of accurate guiding and the way to avoid the errors due to refraction. The methods which are at present employed are mainly due to Schlesinger of Yale, who first used the rotating disk upon bright stars and devised the very convenient methods of calculation which are now employed by almost all workers in the field.

Most of these workers are Americans. First in productivity is Professor Mitchell, Director of the Leander McCormick Observatory of the University of Virginia, who recently has been the guest of his colleagues at other observatories in celebration of his completion of determinations of parallax for no less than a thousand stars! (See page 247.) This record is the more noteworthy since it comes from an observatory possessing a telescope of moderate size, as great instruments now go, and very modest resources. Moreover, the telescope is a visual one and therefore slow in photographic work. Only the persistent devotion for a long term of years of the director and a loyal corps of colleagues could have secured this remarkable result.

NEXT in order comes the Allegheny Observatory where, at first under Professor Schlesinger and later under Professor Curtis, more than 850 parallaxes have been determined. Smaller but very considerable lists, each about 300, have been observed at Mount Wilson, Yerkes, Greenwich, and the Sproul Observatory of Swarthmore College. The promising and almost untouched field of the southern hemisphere is now being worked both at the South African station established for the purpose by Yale under the direction of the veteran Schlesinger and at the Cape Observatory.

Arduous as the work is, and dull as some parts of it may seem to one who merely reads about them, it has a curious fascination.—*At anchor, off Mitylene.*

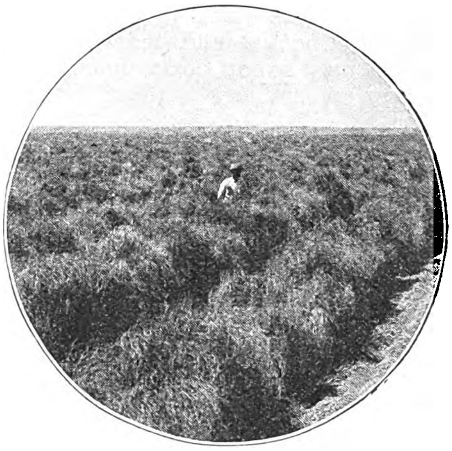
Marsh Delta Lands Become Rich Farms

ONE of the most fertile regions in California is the Delta area (usually called the "Delta lands") in northern California, just a few miles west of Sacramento, the capital city. The tule marshes along the Sacramento River were long considered worthless but have been developed in recent years into most fertile farm and orchard land. Until the engineers constructed levees, drainage canals, pumping plants, and other flood protection, the Sacramento and San Joaquin Rivers spread out over the entire area during annual spring floods, depositing new layers of silt. Water for irrigation now comes from the rivers and the surplus water is drained and pumped back into them. Soil rich with the humus of centuries, abundant water, and a splendid climate all unite to make this one of the most fertile spots in the United States. The crops are very diversified and include asparagus (a 10,000,000 dollar crop). The rivers and paved highways serve to bring all the crops to market or to the great canneries at strategic points.

Gyp corn, a dwarf type, grows to nearly double height—seven feet



Asparagus is a splendid crop in Delta lands, worth $10,000,000

Celery is grown on seven thousand acres in the Delta lands and much of it is crated in the field itself

Cutting asparagus in the irrigated fields. Much of our best canned asparagus comes from this locality

Our Army's New Super-Weapon*

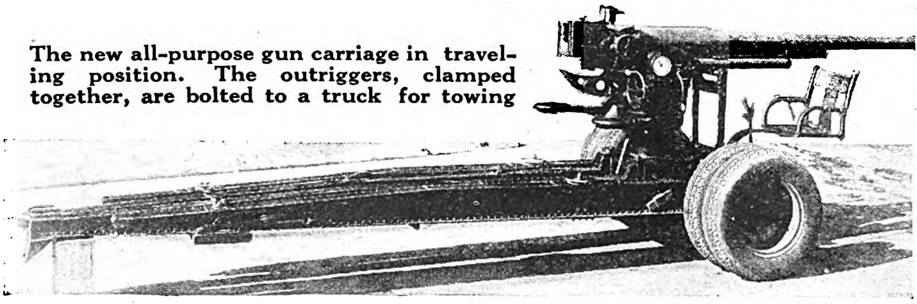
Chief, Design Section, Watertown Arsenal, Watertown, Massachusetts

DEVELOPMENTS during and since the war are tending to render the existing field artillery matériel obsolete. It is a well known fact that new field guns and carriages of the division, corps, and army types have been built since the war which are greatly superior to the war types in that the guns give greater ranges. However, the matter is more serious than that, since none of the war types and few of the post-war types of artillery will meet the new demands which will be required of them in future wars.

High-speed targets in various forms are gradually entering the field of fire of all types of field guns, such as the new high-speed trucks used as prime movers for artillery and for carrying infantry, and tanks having cross-country mobility and speeds heretofore unthought of. But even more menacing than the high-speed tanks and trucks are the many types of aircraft, carrying bombs and machine guns, which may swoop down upon the infantry or artillery without warning.



The new all-purpose gun carriage in traveling position. The outriggers, clamped together, are bolted to a truck for towing

It is well known to all field artillery officers and other officers, and civilians as well, who have given thought to the problem, that the present types of field artillery, as exemplified, for example, by the famous French 75-millimeter gun, are wholly incapable of dealing with these high-speed targets. Few of the carriages for these guns permit sufficient elevation for firing at aerial targets, or have sufficient speed in traversing or elevating.

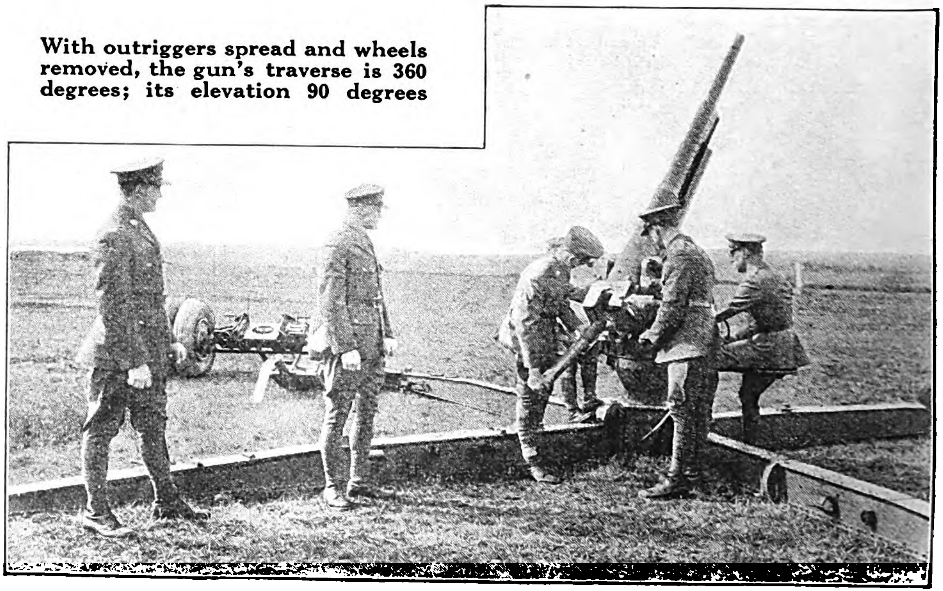
Unfortunately, not only the guns and the carriages but also the fire-control instruments which have been developed for use of field artillery, are wholly unsuitable for use against high-speed moving targets. The fire-control instruments used by a field artillery battery have been developed on the principle of keeping this equipment as light and as simple as possible. Practically all firing data must be computed slowly and laboriously by the personnel of the battery. It will be at once evident that such methods are found lacking when attempting to fire guns continuously at moving targets.

With luck, a battery of divisional guns might destroy a high-speed tank, but there could be no assurance of the same result using the present types of field carriages and fire control. It would be absolutely impossible to bring effective fire upon an airplane traveling at a speed of 100 miles per hour or more, and to attempt it would be purely a waste of ammunition. The present methods of fire control are being adhered to although the increased ranges of the post-war guns necessitate refinements in fire-control instruments and methods.

Furthermore, practically all existing field artillery carriages, up to this time, are defective from the standpoint of modern high-speed transportation in that they cannot be hauled at speeds greater than about 15 miles per hour without seriously damaging the gun carriages and their mechanisms. All the artillery of the World War period was limited in this respect since it had been designed with the idea of using horses or the slow-speed tractors available at that time for tractive forces. Since the war, trucks have been built which are capable of hauling gun carriages at high speed. Commercial development makes it imperative that gun carriages of the future be so constructed that these high speeds can be taken advantage of, not only on good roads, but when the gun carriages are trailed across country.

THESE new conditions, thus briefly outlined, call for field artillery of a new type. The present ideas concerning fire control must be revised and the fire-control equipment of the battery must be augmented so that these batteries can bring effective fire against stationary ground targets, and can also be used effectively both against rapidly moving ground targets and, with equal accuracy and facility, against high-speed targets in the air.

A new type of field-gun carriage which has been developed with the idea of meeting the new requirements referred to above, was completed recently at Watertown Arsenal. This carriage mounts the high velocity 75-millimeter gun (muzzle velocity 2175 foot-seconds) which gives a maximum range of 15,000 yards with a 15-pound

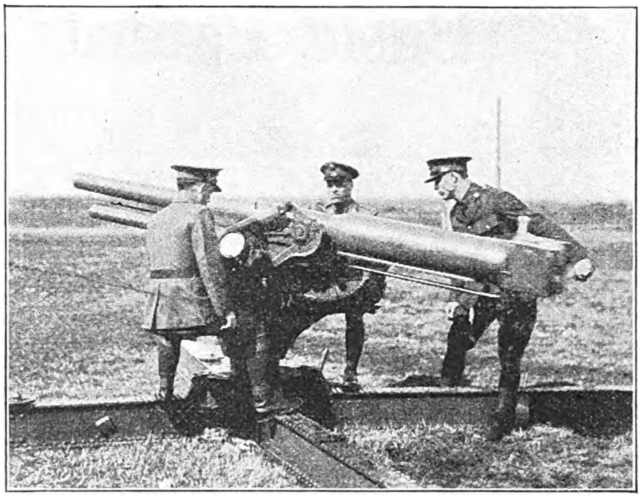


With outriggers spread and wheels removed, the gun's traverse is 360 degrees; its elevation 90 degrees

---

*Reprinted through the courtesy of *Army Ordnance* projectile for high or low altitude.

The new carriage has been equipped with wheels mounting balloon tires and having roller bearings at the hubs. The design is such that either single or dual tires can be mounted. The newly developed puncture-proof inner tubes are used. While the dual wheels and tires increase the weight of the gun carriage about 400 pounds, it is believed that tests will show the advantages of having the additional tire contact area. Furthermore, the two additional wheels and tires may be considered as spares, in which case, if one of the tires were punctured, the vehicle would not have to stop. The increased ground contact area will make it possible for the vehicle to pass through sand and soft mud. The construction is such that the gun carriage proper is carried on the wheels and axle as a spring load.



Firing position of the 75-millimeter gun, 360-degree traverse and 15-degree elevation, in full recoil

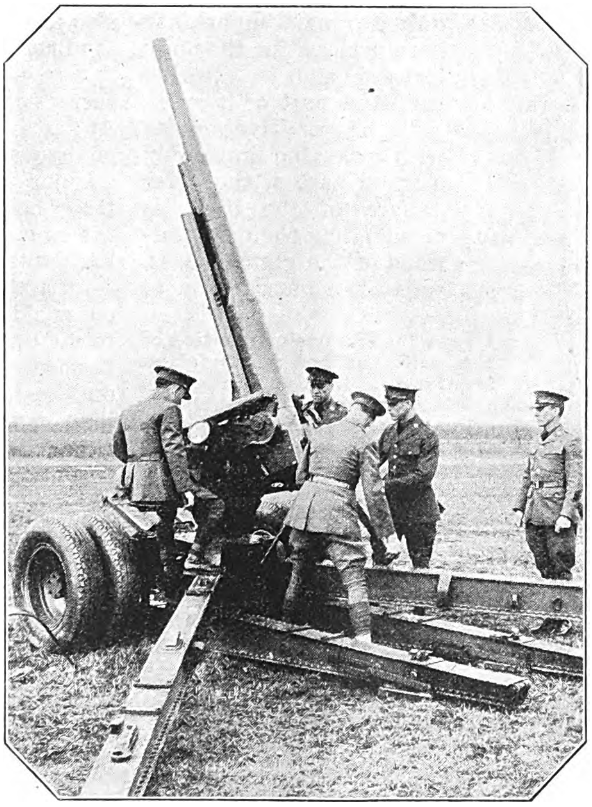
The gun can be fired by opening out the rear trails and supporting the front part of the carriage by means of the two spare trails. Two outriggers with built-in screw jacks are placed on the ground under the carriage pedestal.

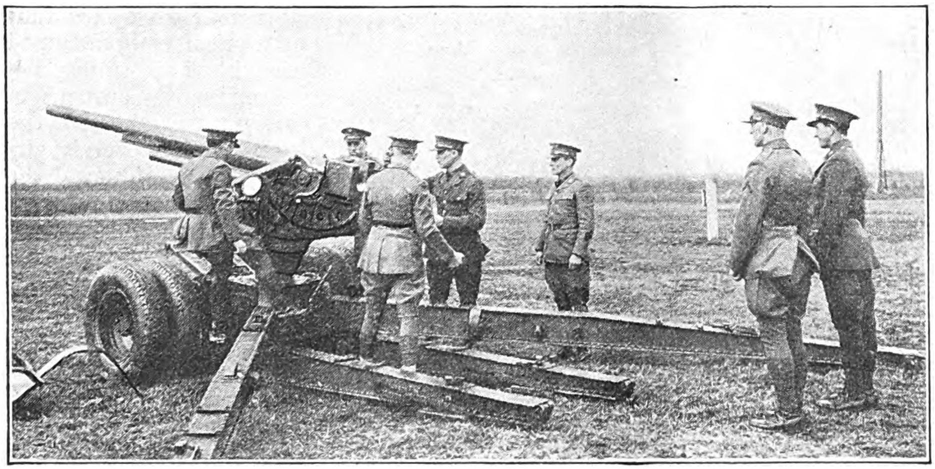
When in place, the screw jacks are tightened against the bottom of the carriage; thus the vertical component of the firing load enters the ground through these two outriggers which serve to protect the balloon tires, roller bearings, and the spring suspension from the firing load. The gun can be fired in this manner through an angle of traverse of 90 degrees and at elevations from 0 degrees to plus 80 degrees.

If all-around fire is desired, the carriage can be put in a second firing position. In this case, the two outriggers are used as levers for raising and lowering the carriage. The wheel and axle assembly can be removed quickly from the pedestal of the gun carriage and the latter lowered to the ground. The two spare outriggers are then put into place to complete the base for the carriage. In this position, the gun can be fired through 360 degrees of traverse and at angles of elevation from 0 degrees to plus 80 degrees.

In arsenal trials, using untrained men, the carriage was put in the first firing position (for 90 degrees traverse) from the traveling position in one minute, and in the second firing position (for 360 degrees traverse) from the traveling position in four minutes.

It is believed that such a gun carriage fully meets the requirements which were outlined at the beginning of this article. The weight of the gun and carriage in the firing position is 5800 pounds, or nearly twice that of the low-velocity 75-millimeter gun carriage of the World War type. However, assuming a four-inch penetration of the tires into the ground, the area of the tires in contact with the ground is 832 square inches as compared with 194.6 square inches for the French 75-millimeter field gun, M 1897, equipped with steel tires, and the ground pressure is 6.9 pounds per square inch as compared with 13.7 pounds per square inch for the French gun. Thus it will be seen that the new carriage will undoubtedly possess greater cross-country mobility than the lighter carriage.





In center of page the mount is arranged for 90-degree traverse and 60-degree elevation for anti-aircraft firing. At bottom of page, the gun has a 90-degree traverse and an elevation of 15 degrees for firing at speedy land targets. In both cases, the balloon tires, the roller bearings, and the springs are protected against shock of recoil by the special type of construction

This low weight for a high velocity, all-around-fire carriage with dual balloon tires, brakes, and spring suspension, is made possible by taking advantage of steels of high physical qualities, of a new welding process which has been developed at Watertown Arsenal, and by making parts of the carriage, where possible, of strong aluminium alloys having one third the weight of steel. This carriage is equipped with the anti-aircraft type of elevating and traversing mechanisms, employing roller bearings throughout. All blacklash is eliminated, making it possible to lay the gun with an accuracy of ½ mil on either elevation or azimuth.

Fitting of fire control equipment to this new gun mount is still in the experimental stage and somewhat too technical for discussion here.

Basic Patents in Evolution—III

By WILLIAM K. GREGORY

Professor of Vertebrate Paleontology, Columbia University. Curator, Departments of Anatomy and Ichthyology, American Museum of Natural History. Member of the National Academy of Sciences

(Concluded from September)

TURNING now to the history of the pelvis and hind limbs, we have already noted that in many respects their origin was similar to that of the pectoral limbs, that is, they first appeared as keels or ridges supported by basal rods and operated by extensions of the segmental muscles of the body-wall (Figure 13). Much later they became paddle-like and finally when bent downward (Figure 14) were able to support the weight of the body and to co-operate with the pectoral limbs in pushing the body forward. But the pelvic limbs and the pelvis itself differed widely in their functional associations with surrounding parts and consequently they acquired conspicuous anatomical differences from the pectoral limbs. In the first place, the pelvis corresponds only to the inner or primary shoulder-girdle and it never had any system of sheathing plates attached to it. Secondly, the pelvis was associated with the lower ends of the digestive tract and of the tubes that discharged either eggs or living young in the female or the sperm of the male (Figure 13).

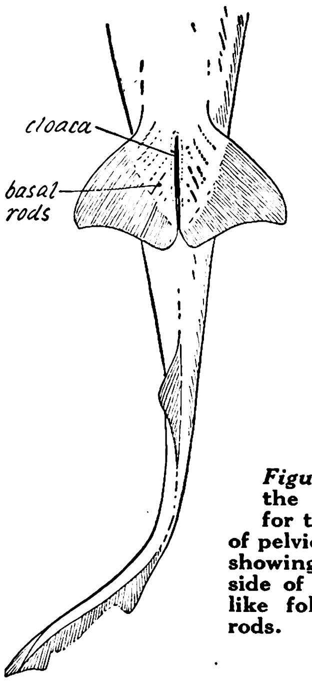


Figure 13: **The basic invention of the pelvis or bony foundation for the hind limbs. Under side of pelvic region of primitive shark, showing the pelvic fins on either side of the cloaca; they are keel-like folds supported by skeletal rods. Drawing from specimen**

THUS the pelvis arose around the cloaca or common opening of the digestive and reproductive tubes and served as a base or platform of the following sets of muscles: first, those that ran forward along the lower surface of the abdomen; second, those that ran backward along the outer and under sides of the tail (Figure 15); third, for a cone-shaped mass of muscles based on the pelvis and converging outward and downward to form the thigh muscles.

The ilium, or upper branch of the pelvis, at first grew upward between the muscles of the back in front and the tail muscles behind. As it grew upward it passed to the outer sides of the ribs, which were at first entirely free from it. Gradually, however, certain of the ribs became tied by connective tissue and ligament to the inner side of the ilium and when this happened an indirect connection was established between the hind limbs and the backbone. Thus the hind limbs soon acquired great importance both in thrusting the body forward and in steering the front part of it.

In the primitive reptiles with sprawling limbs only a small part of the outer surface of the ilium is occupied by the deep portions of the gluteal mass, which ran outward on to the top of the femur. But when the limbs were drawn in toward the sides of the body in the primitive mammals, the gluteal muscles acquired great importance in holding the body upon the femur when the opposite leg was lifted off the ground. Hence, that part of the outer surface of the ilium which gave rise to these muscles became enlarged in accordance with their increasing importance (Figure 14, D, F, G, H, I).

In the early mammals when the knees were drawn forward the ilium also grew forward almost parallel with the backbone (Figure 14, E), to which it was now attached by means of the sacral vertebrae and their ligaments. At first in the mammals the upper part of the ilium was trihedral, that is, triangular in cross-section, its three surfaces being occupied respectively by the muscles of the upper side of the backbone, by the iliacus muscles in front and by the gluteal muscles on the outer side. When the primates began to sit upright (Figure 14, G), resting themselves on their folded-up legs and on the lower ends of the pelvis, the iliac muscles served to check them from falling backward, while the gluteal muscles prevented them from falling forward. Hence with the increased size of these two sets of muscles the blade of the ilium began to grow outward in a transverse plane, the chief successive steps in this broadening process being recorded in the lemurs, monkeys, apes and man (Figure 14, F, G, H, I).

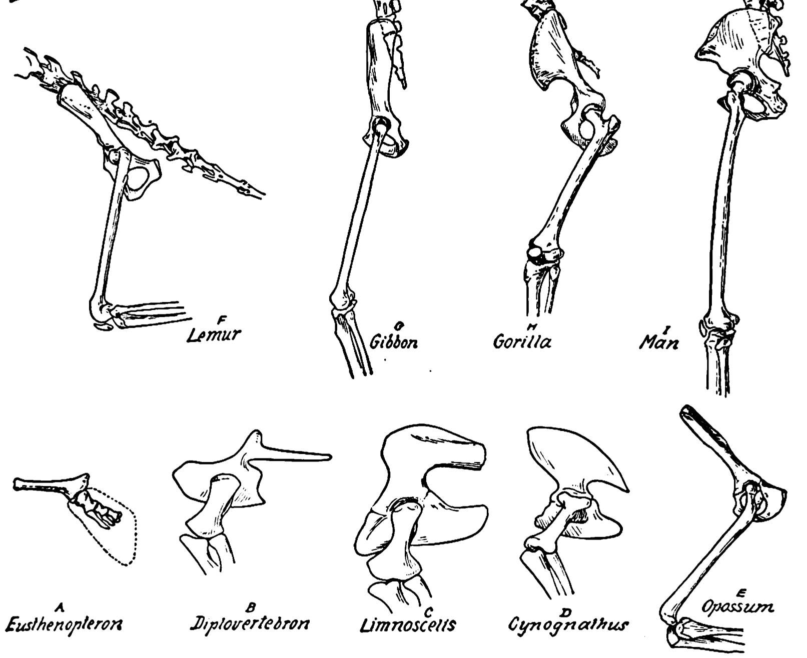

Figure 14: **Series showing progressive outward growth of ilium from fish to man. (A) Lobe-finned ganoid (*Eusthenopteron*) of the Devonian period; (B) *Diplovertebron*, early tetrapod; (C) primitive reptile (*Captorhinus*); (D) advanced mammal-like reptile (*Cynognathus*); (E) primitive mammal (opposum); (F) primitive primate (lemur); (G) gibbon; (H) gorilla; (I) man. This series of drawings was made chiefly from models and specimens in the American Museum of Natural History at New York**

In the first section of this article we saw that in a primitive quadruped the body is slung between two suspension towers, which are the pectoral and pelvic girdles. The gibbon of the East Indies (Figure 16) has succeeded in turning this suspension bridge up at right angles to its original horizontal position and in balancing it on its rear tower, represented by the pelvic girdle. In other words, in the gibbon Nature has already worked out the basic invention for upright or bipedal progression on the ground. This great step in advance is seen first in its viscera, which approach the human type in a number of ways, and, secondly, in the details of construction of its pelvis.

But how did the gibbon learn thus to run on its hind legs? The answer of comparative anatomists is that the first step was the habit of sitting upright and the second was the habit of brachiating, or climbing with the arms raised above the head and the body suspended beneath the branches. The habit of sitting upright, as we have seen, conditioned the first steps in the remodelling of the pelvis, especially the flattening of the ilium in the transverse plane. The habit of brachiating conditioned the extension to and upon the upper border of the ilium of certain muscles of the loins and abdomen, which thus found themselves in a better position to support the viscera, pelvis, and hind limbs when the body was suspended from the arms. But the gibbon is no longer content merely to climb deliberately with his forearms; he makes enormous leaps from one branch to another one in the distance, and in taking off for the leap he can extend his thighs backward so that they may be nearly parallel with the backbone; whereas in a quadruped, with its backbone in the horizontal position, the thigh is but rarely extended so far backward. The result of this habit of the gibbon is that when it comes down on the ground to walk it has no difficulty in extending the thighs downward parallel to the backbone.

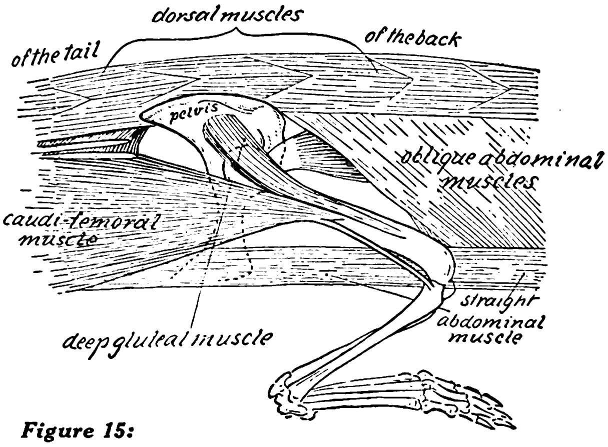

Figure 15:
Pelvic musculature of a crocodile. After Romer, 1923

Figure 16: **The ape that solved the problem of walking upright. Skeleton of gibbon from the East Indies**

But is there any reason to suppose that our own remote ancestors, which from all the evidence of comparative anatomy were admittedly related to the anthropoid stock, learned to walk upright on the ground only after a long course of instruction in brachiating in the trees? The answer is, yes, since the human skeletal and muscular systems, as well as the brain and viscera, still retain abundant traces of a brachiating, arboreal stage that immediately preceded the stage of upright walking on the ground.

In the first place, the entire shoulder-girdle, arm, and hand of man are far more nearly approached by those of the brachiating anthropoid apes than by those of any other known animals living or extinct, and the same is true when we compare the pelvis and hind limbs of the two groups. It is truly surprising that, although the pectoral limb of the anthropoids is chiefly an organ of locomotion, while that of man is used almost exclusively for carrying or manipulating objects, in spite of this great functional difference the anatomical resemblances between the forearm of man and those of the gorilla and the chimpanzee are such as to amount almost to identity, while the differences are limited chiefly to differences in the lengths of the corresponding segments of the hand and arm. Thus the hand of the chimpanzee, for example, is much longer than that of man, at least in proportion to the body size, while its thumb is notably degenerate in size; yet the humerus, radius, and ulna closely resemble those of man and the same is true of the bones and muscles of the hand. These fundamental resemblances between man and anthropoid are well brought out in Figures 17 and 18.

Objection to the derivation of man from brachiating ancestors has been made on the ground that the habit of brachiating in the anthropoids has led to the use of the hands merely as hooks and to the consequent degeneration of the thumb; also that the mobile hand of man with its well developed thumb could never have been derived from a brachiating type. The answer to this line of argument may be sketched* as follows: first, that it is not necessary to attribute to the common ancestors of man and the anthropoids the extreme specializations of either of their descendants—and indeed all the available evidence indicates that while the thumb of the chimpanzee has been reduced, that of man is a progressive structure which has experienced an increase in adjustment with its increased functional importance. Secondly, the evidences of both hand (Figure 17) and foot (Figure 18) indicate that the remote ancestors of man were primates of arboreal habits, with hands and feet more like those of the gorilla and the chimpanzee than like those of ordinary monkeys; also, these are the only known kinds of hands and feet that would work well with the particular forms of shoulder-girdle, arm, pelvis, and hind limb, which upon quite other grounds there is good reason to attribute to the common ancestors of the anthropoids and man.

In short, from the point of view of comparative anatomy, these and many other resemblances between man and the anthropoids are due neither to chance nor to "convergent evolution," because they are too numerous and too detailed. They can mean only that both man and anthropoid have descended from a common ancestral stock which was already brachiating, yet was perhaps somewhat less specialized in this way of climbing than is the chimpanzee.

In conclusion, the chief "basic patents" in the locomotor apparatus in the long ascent from fish to man appear to have been as follows:

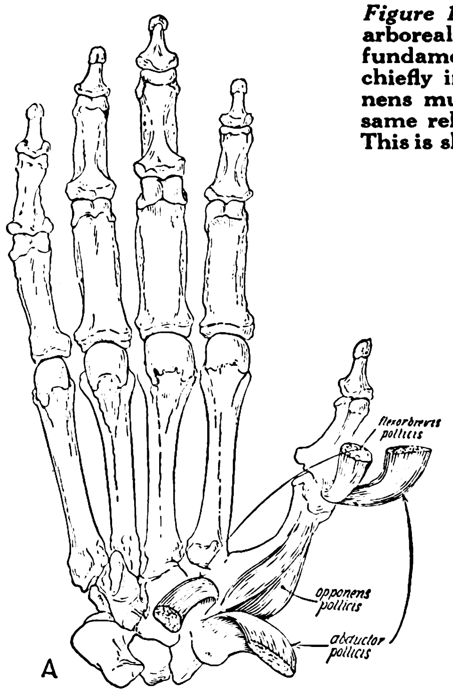
(1) The appearance of the striped muscle fiber, under the control of the nervous system. This is the stage attained by many invertebrates.

(2) The building up of these muscle fibers into zigzag muscle segments separated by tough partitions of connective tissue. This is the stage attained by *Amphioxus*.

(3) The assumption of a streamline body-form, propelled by lateral undulations caused by the rhythmic

---

* For a fuller presentation of the evidence, see the author's papers in the Proceeding of the American Philosophical Society, 1926, Vol. LXVI, pp. 439-463; 1928, Vol. LXVII, No. 2, pp. 129-150; No. 4, pp. 339-376.



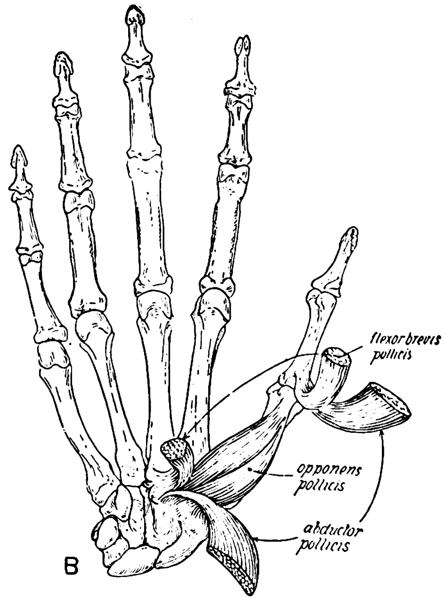


***Figure 17:* The testimony of man's hand as to his arboreal origin. Man's thumb, it will be seen, is fundamentally similar to that of the gorilla, differing chiefly in its relatively greater length. The opponens muscle is present in the gorilla and has the same relations to surrounding muscles as in man. This is shown in the drawings. (From Gregory, 1928)**

contraction of the muscle segments. This is the stage attained by *Amphioxus* and the oldest ostracoderms.

(4) The development of an axial skeletal system laid down at the points of greatest stress at the intersection of the primary and secondary septa, between the muscle masses. This is the stage attained by the shark.

(5) The development of an appendicular skeletal system, beginning in the form of keel-like projections of the body-wall, supported by segmental cartilaginous rods, as in the oldest sharks; from these rods evolve gradually the skeleton of the paired fins, the shoulder-girdle, and the pelvis, successive stages being seen in the different sharks.

(6) The operation of the paired fins by muscles that were originally derived from the segmental muscles of the body-wall but which soon became organized into a definite system consisting of a dorso-medial group above and behind the pectoral paddle, and a ventro-lateral group below and in front of the paddle. A similar system develops simultaneously in the pelvic fins. Different stages in this development may be observed in the sharks, lobe-finned fishes and early amphibians.

(7) The development of freely movable paired paddles with a fan-shaped skeleton from the keel-like ridges already mentioned. Stages of this development are observable in sharks and lobe-finned fishes.

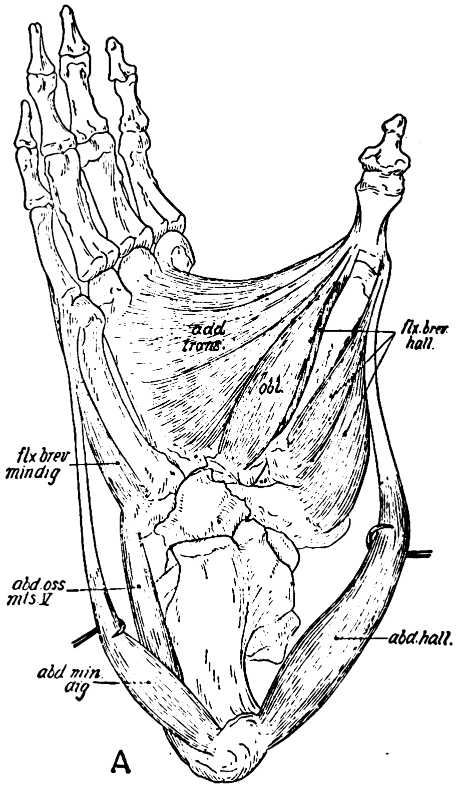
(8) The remodeling of the paired fins and shoulder-girdle of some early lobe-finned fishes after they had "learned" to turn the fins downward and to use them to assist in wriggling along on land.

(9) The development of the "double suspension bridge," by which the weight of the body was supported between one U-shaped and one V-shaped sling made from the pectoral and pelvic girdles respectively. This is the stage of the oldest known tetrapods.

(10) The development of a connection between the V-shaped pelvis and the backbone. This stage was attained by later tetrapods.

(11) The raising of the body off the ground and the drawing inward of the feet, elbows and knees. This stage was initiated in the mammal-like reptiles, perfected in the mammals.

(12) The invasion of the trees and the establishment of the habit of sitting upright. This stage is observable in the lemurs and monkeys.



(13) The development of the habit of brachiating, or climbing with the arms extended above the head and the body suspended from the arms, by which were acquired very many prerequisites for erect, bipedal progression on the ground. This stage is seen in the gibbon.

(14) A marked increase in size of body, which became too heavy for comfortable climbing in the trees, and the gradual abandonment of tree-living in favor of upright, bipedal progression on the ground. This stage is today observable in the gorilla and was with high probability passed through by our own ancestors. The gorilla, however, is now becoming secondarily quadrupedal.

(15) A profound readjustment of the viscera and of many parts of the skeleton to secure more favorable arrangements for supporting the body in the upright position. The early stages in this transformation have already been passed by the gibbon, chimpanzee, and gorilla. The later stages are now observable in man.

Although many details as to the "basic patents" that led up to man's present locomotor apparatus remain to be worked out, it is unlikely that we can be very far off in the foregoing sketch of the main stages, because much consistent evidence of the evolution of the jaws, teeth, skull, brain, and so forth is already on record.

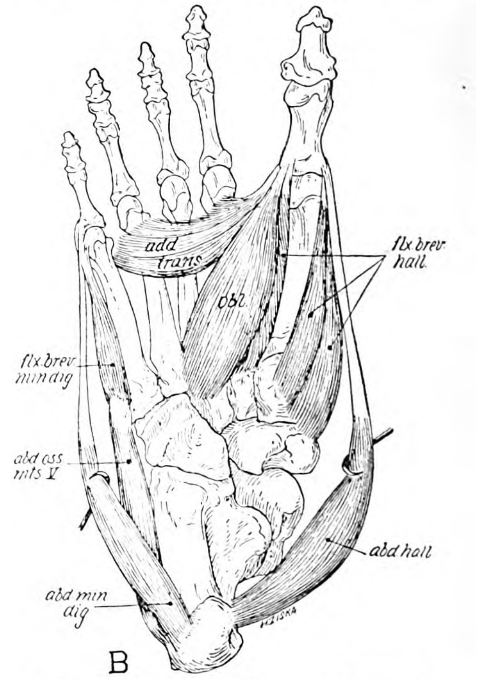


***Figure 18:* The testimony of man's foot as to his arboreal origin. Externally the sole of a human foot superficially resembles that of a bear, but internally its construction is an evident modification of the "biramous" type, with a grasping great toe. In spite of the almost exclusive use of the human foot for walking on the ground, the great toe is operated by muscles that evidently correspond closely with those of the gorilla foot, as is shown. Ctesiphon was an ancient city of Mesopotamia, about 25 miles southeast of Bagdad. The principal remains are a magnificent arch of the Sassanian period. The Neo-Persian Empire was founded in A.D. 226 and was destroyed by Arabs in 637. A tremendous battle was fought here on November 21, 1915

Ctesiphon, A Magnificent Fragment

IN the autumn of 1928 a German archeological expedition began to excavate the site of Ctesiphon, the capital of the Sassanid Empire. Here was a great battleground where the conflict raged on the Euphrates and Tigris between East and West, between the Orient and Hellenism. For a thousand years Seleucia was an outpost of conquering Greece in the East while Ctesiphon was the center of Sassanian royal power. Both were symbolic of the two conflicting worlds. Our esteemed contemporary *Antiquity* publishes an interesting account of the painstaking excavations and the results thus far obtained. Our readers probably will be most interested in the gigantic barrel-vaulted hall of the royal palace of Ctesiphon. The date is probably somewhere between 531 and 579 A.D.

The main front of the edifice is 312 feet long, the height is 115 feet and the depth is 175 feet. The great hall has an elliptical barrel vault 86 feet wide and 163 feet long and is open in front. The springing of the vault is 40 feet from the ground. The brick courses are horizontal and project inwards as they rise, so that the actual width of the vault portion is only about 71 feet. The crown of the vault is nine feet thick. It was probably built with centering. Being located on an alluvial plain no stone was available so brick was employed.

The best view of the noble ruin is from the air and now that the authorities of Iraq permit archeological investigations and air flights we may look for further discoveries made by means of aerial photographs.

The New Fifty-foot Stellar Interferometer

By F. G. PEASE

Mount Wilson Observatory

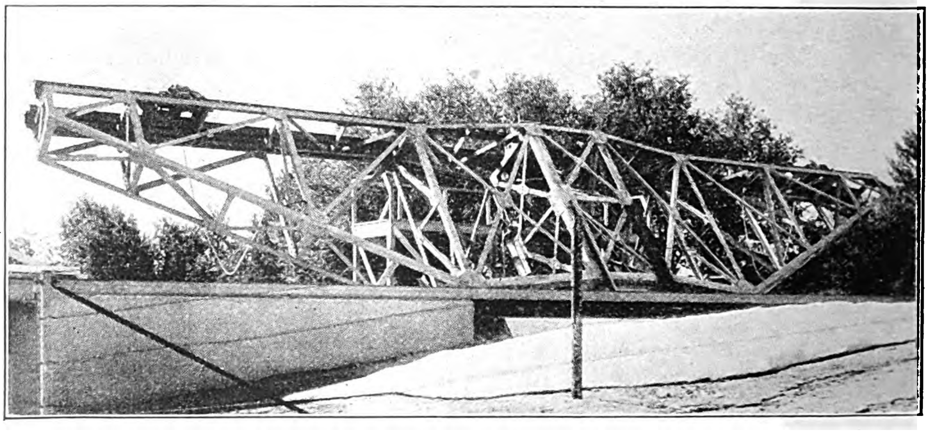
THE star image formed at the focus of a telescope is not a point but consists of a bright central disk surrounded by several dark and bright rings known as the diffraction disk. No known star except the sun has an angular diameter large enough to appear as a real image in existing telescopes, that is, its actual disk can not be seen, consequently one can not measure its diameter with an ordinary micrometer.

Fizeau pointed out that it might be possible to measure the true angular diameter of stars with a stellar interferometer. This instrument utilizes the principle of interference long familiar to physicists wherein two pencils of light radiating from the same small source are brought together again, forming a series of bright and dark bands called "interference fringes."

In the stellar interferometer the star image has the same appearance as it does in an ordinary telescope except that it is crossed by a series of parallel dark bands, that is, the interference fringes. Each point in a star produces one of these interference patterns. If the star is very small in angular size the fringe patterns all lie directly on top of one another and are clear and sharp. If a star of larger angular diameter is chosen each point in it produces a pattern which is displaced a little with respect to the original one, thereby reducing the clearness or visibility of the fringes. A still larger star may be selected in which there may be so many overlapping patterns that all the dark bands disappear and just the ordinary image remains. Two radio sets receiving from the same studio will blend well, but two sets receiving from adjoining studios emitting different modulations, even though the wavelength be the same for both, will not blend but will have only sound as a result.

IN the stellar interferometer we take advantage of the disappearance of the fringes to measure the star's diameter. Mathematicians have computed that when this occurs $a = 1.22\frac{\lambda}{D}$ where a is the angular diameter of the star in radians and λ the wavelength of the light and D the separation of the centers of the two pencils of light.

Since no existing telescope was large enough to give complete disappearance of the fringes Michelson devised a periscopic attachment consisting of four plane mirrors mounted on a stiff frame which is placed on the end of the telescope. Two outer mirrors inclined at 45° face upward, and throw the light to two inner mirrors which are inclined at 45° facing downward, directing the light into the telescope. The outer mirrors move simultaneously on slides to equal distances from the axis of the telescope.



The bridge of the new nine-ton instrument from the north side

The distance to the star from the focus of the telescope over the two paths must be the same to within a very few wavelengths of light, otherwise the fringes will not appear at all. Owing to flexure of the telescope, atmospheric variations, and slight errors in setting the mirrors it is convenient to use an optical compensator just in front of the eyepiece, with which the distance may be equalized.

As an illustration of the practical application of the interferometer method let us turn the 100-inch telescope with its full aperture on Rigel and no interferometer attached to it. We see in the eyepiece a bright image without surrounding rings, since the atmosphere rarely permits their presence in the 100-inch. Placing a canvas over the end of the tube and cutting a hole in it seven inches in diameter whose center lies 47 inches from the axis we see an image very much fainter but larger in size showing diffraction rings.

CUTTING a similar hole in the canvas diametrically opposite, that is, with centers of the openings 94 inches apart, we see an image twice as bright crossed with parallel dark bands. With good atmospheric conditions the image appears single but if the seeing is poor the two images vibrate about a common center. Let us now turn to Betelgeuse. To our surprise we see the bright diffraction image but the fringes are not sharp and distinct. Covering these last two openings and cutting in their stead two others 45 inches apart the fringes become almost as prominent as on Rigel.

READERS who keep up with science doubtless will recall the striking confirmation, made in 1920 by means of the Michelson-Pease interferometer, then new, of the prediction that many of the stars were immense beyond conception. The giant star Antares, for example, was found to be 400,000,000 miles in diameter and Betelgeuse 250,000,000 miles. The brilliant work was what might fairly be called a legitimate scientific sensation.

What the interferometer really did was to measure the diameter of a star, not in miles, but in fractional degrees of arc. The diameter in miles was then derivable from this by trigonometry, since the distance to the chosen stars ("parallax") already were known. How the interferometer actually measures the angular diameter of a star can not be explained here. The interested reader is requested to see Russell, Dugan and Stewart's "Astronomy," pages 740-748, which covers it adequately and understandably in theory and practice.

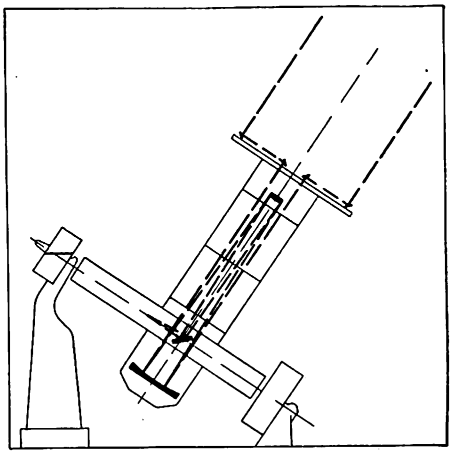
To measure more stars a larger instrument has been needed. Now, ten years later, it has been built and Dr. Pease, who had much to do with its design and construction, was invited to describe it for our readers.

—The Editor.

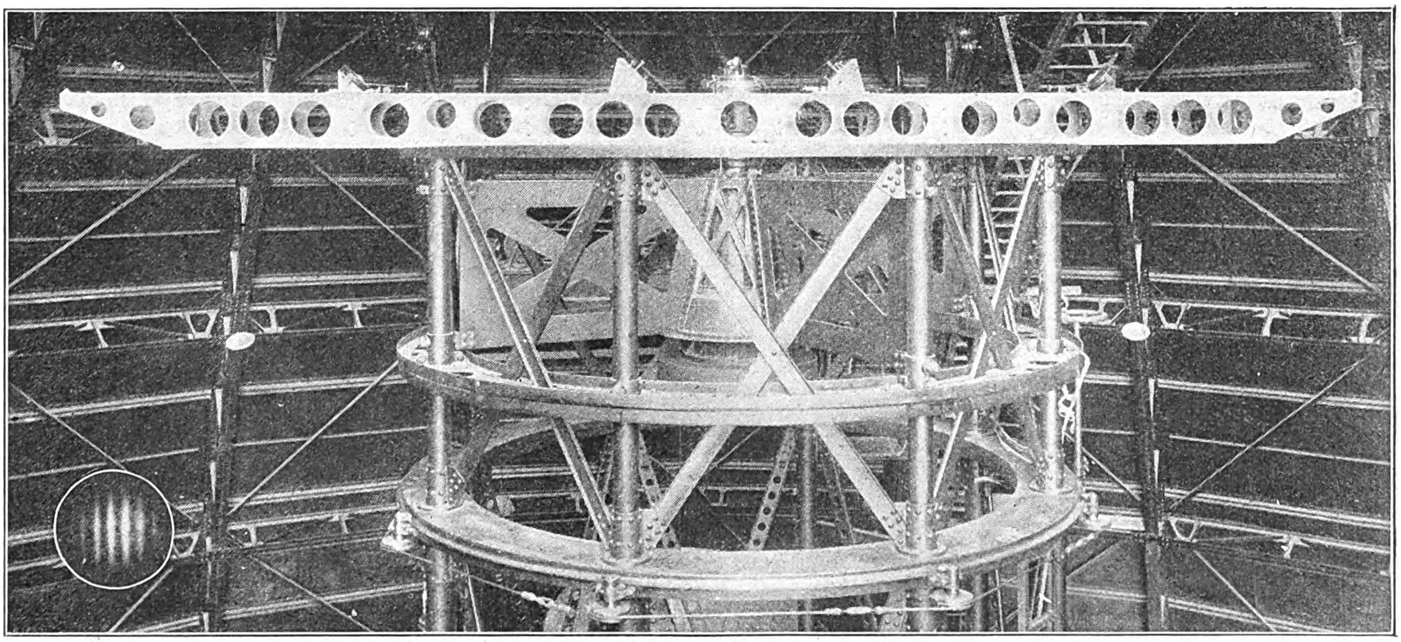
We next place the large steel beam carrying the four diagonal plane mirrors on the end of the 100-inch tube, using the crane, since it weighs about 800 pounds. The canvas will be left over the end of the tube, as the light from the inner mirrors will pass through the openings 45 inches apart. We next set the outer mirrors 110 inches apart and turning to Betelgeuse again, we adjust the compensator until the fringes appear. We have to look very carefully for them because when they do appear they are very weak, the dark spaces having almost disappeared. Shifting the outer mirrors to 120 inches we are unable to see any fringes regardless of how long we search for them. Turning the telescope to Rigel the fringes are found almost immediately and appear as crisp as they did when the apertures were closer together.

Taking the separation of the mirrors D as 120 inches, or 305 cm, and λ as 5.75×10^{-5} cm, we find that α equals 2.3×10^{-7} radian or $0.''047$ arc, the angular diameter of the star. The angular diameter of Betelgeuse appears to vary irregularly; there are days when the mirrors must be moved 14 feet apart in order to cause disappearance of the fringes.

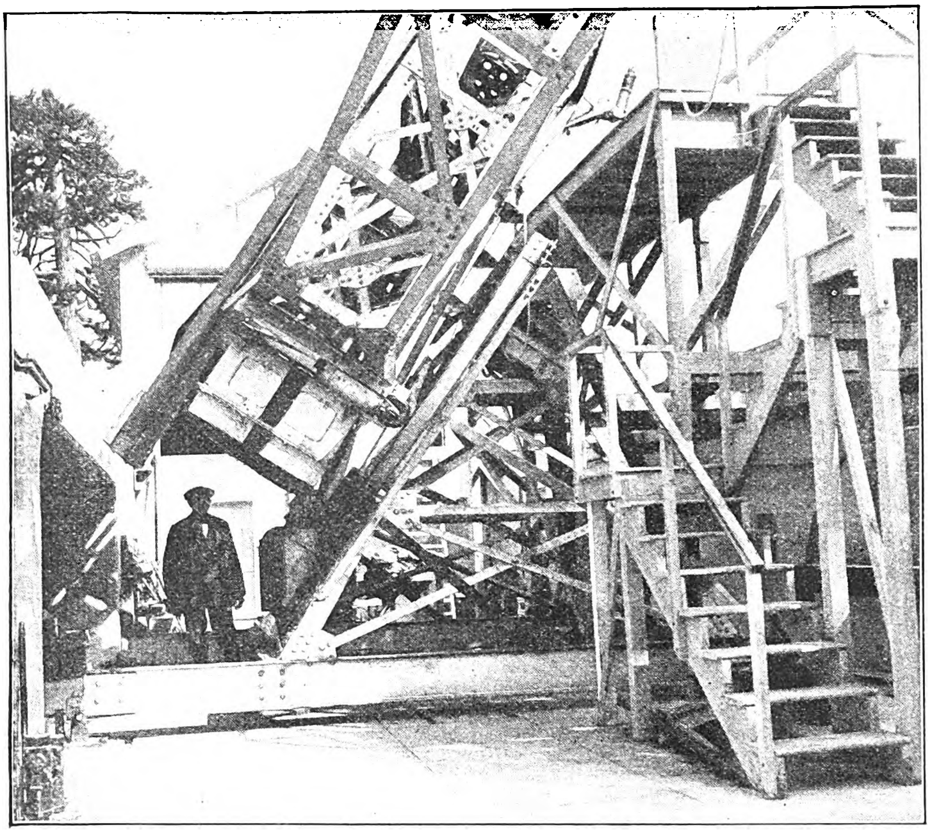
The minimum angular diameter measurable with the 20-foot interferom-



How the earlier, 20-foot interferometer was employed—attached to the 100-inch telescope. Two pairs of diagonal flat mirrors gave it, in effect, a spread or aperture of 20 feet, instead of the 100 inches of the telescope. The diagram shows the light path of two rays



The old 20-foot interferometer beam bolted to the end of the tube of the 100 inch reflector. The two inner mirrors remained fixed but the outer pair could be moved inward or outward. The circular holes in the bar were merely to save weight. *Insert, lower left:* Typical appearance of the interference fringes, a series of bright and dark bands



Pedestal and lower part of the "bridge." The 40-inch main mirror in its cell is above the man's head (Ladd, machinist). Opposite his shoulder is the worm and sector drive. One of the rollers is visible higher up. The slanting polar axis shows beneath the peak of the main supporting A-frame

eter is 0."024. The diameters of Arcturus and *β Pegasi*, which are slightly smaller than this, were found by plotting the visibility curve for various mirror separations and determining D from the extrapolated curves for zero visibility.

The diameters of stars measured with the 20-foot instrument were of the same order as those found by indirect methods. All of the stars measured were "late" type stars.

IN order to measure stars of "earlier" types which have smaller angular diameters it is necessary to have a larger interferometer. Accordingly the new 50-foot interferometer has just been built at the Mount Wilson Observatory, in which the apertures are larger and can be placed 50 feet apart. This instrument will measure a star diameter as small as 1/100 second of arc, about corresponding to that of a cent piece at a distance of 250 miles.

The 20-foot instrument was of such a size that the steel frame carrying the periscopic mirrors was placed on the upper end of the 100-inch Hooker reflecting telescope, the optical system of the telescope itself being utilized in forming the star images. But a 50-foot beam would be too large to place upon the 100-inch. So the new instrument is a unit in itself and is housed in a separate building, whose upper half is a metal shed which moves to the east on a trestle, leaving the interferometer standing in the open air. The building is 60 feet long, 20 feet wide and 26 feet high. The shed is moved by rack and pinion.

The interferometer consists of a large skeleton frame which we call the "bridge," mounted in cantilever fashion on the north end of a short ball-bearing polar axis. A structural steel pedestal supports the whole and carries the mounting for the worm that meshes into a sector on the bottom of the bridge. The bridge lies in an inclined plane parallel to the equator and carries the periscopic mirrors on its upper surface and the image-forming mirror at its lower end.

The bridge is a latticed steel frame 54 feet 5½ inches long. The structural members are all angle iron and vary in size from 6 x 6 x ⅜ inches to 3 x 3 x ¼ inches. The estimated weight of the bridge itself is 8000 pounds and the total load on the axis including the mirror mountings, tracks, and so on, is about 18,000 pounds.

The polar axis is of 0.50 carbon steel with an elastic limit of 80,000 pounds per square inch. It is forged and heat treated and drawn so hard that it was machined with difficulty. Each of its bearings is composed of two S K F annular bearings. To guide the bridge and prevent its vibrating in the wind two rollers nine inches in diameter with spring cylinders behind them are fastened to the bridge and travel on a circular track fastened to the north face of the pedestal.

The driving sector is a large iron casting bolted to the bottom and south sides of the bridge. It is 100.2671 inches pitch radius and has 1440 teeth. The worm is 4½ inches pitch diameter, 0.4375 circular pitch, left hand, single thread. It runs on S K F self-aligning bearings and continually dips into a bath of clock oil which is free from acids and gumming properties.

The driving clock is of the typical weight-driven conical governor type and is self winding. It stands just east of the pedestal and transmits power to the worm through a gear box. Slow motion in right ascension is by means of a motor mounted directly on the planetary gearing in the gear box. The instrument works in right ascension from 2 hours east to 2 hours west.

ONE of the illustrations shows an outline of the optical path of the interferometer. Two outer plane mirrors AA inclined at an angle of 45° receive the parallel beams of star light and reflect them to two similar mirrors BB inclined also at 45° which direct them downward to the large concave mirror C. The converging beams are then returned upward to a 45° plane mirror D, thence southward to a second plane mirror E and upward through the compensator to the eyepiece.

The flats AA, BB, and D are of Pyrex, 15 inches in diameter, D being cut away at the sides to clear BB. E is a glass mirror five inches in diameter mounted with a self-aligning mechanism which directs the beams constantly into the eyepiece tube which may be moved into various convenient positions for observing.

The concave mirror C is of Saint Gobain glass, 40 inches in diameter, 18 feet focus and lies at the bottom

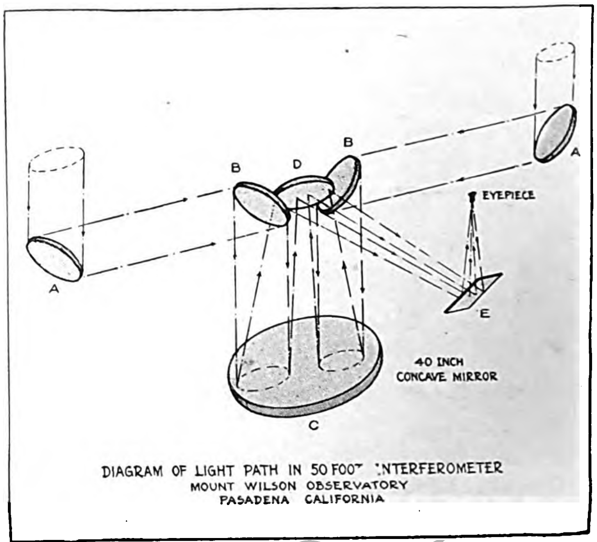


DIAGRAM OF LIGHT PATH IN 50 FOOT INTERFEROMETER
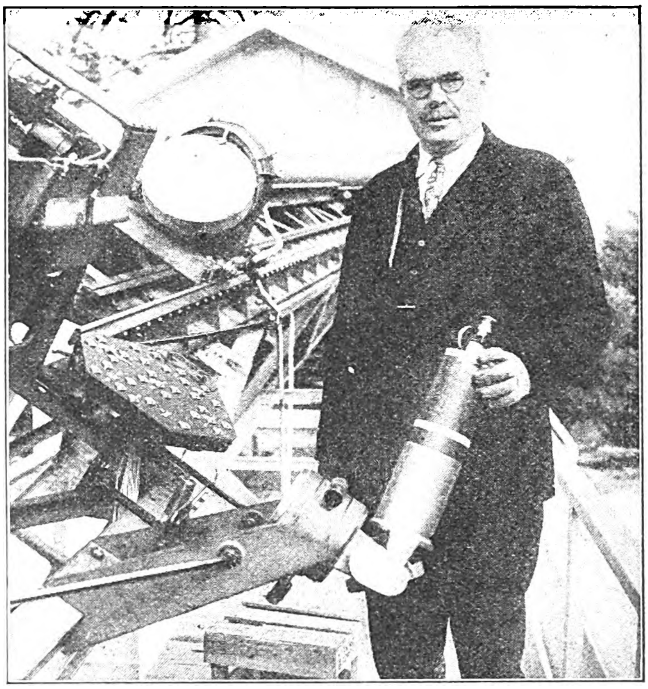
MOUNT WILSON OBSERVATORY
PASADENA CALIFORNIA

of the bridge in an iron cell insulated with corkboard. It is supported on its back by three fixed plates and one central counter-weighted plate and on its edge by four pivoted arcs.

The outer mirrors are mounted on V-wheeled carriages which are moved by motor through a herringbone rack and pinion along tracks placed on the top surface of the bridge. For the tracks heavy machined iron castings of inverted "T" section are bolted to the top of the bridge. To these are fastened steel bars bevelled on both their narrow edges. The upper edges receive the fixed V rollers of the carriages while the lower edges receive similar V wheels mounted on spring counter-weighted arms which always keep the carriages in contact with the tracks.

The carriages may be moved from 6 to 50 feet apart and their positions are read by pointers on scales graduated directly on the tracks. Positions are read through a system of mirrors by a telescope located near the eyepiece tube.



The "business" part of the bridge. The author's hand is on the eyepiece, and at his right are the control buttons. The east diagonal 15-inch flat mirror with its track and rack is visible. When the photograph was made the special mirrors and "telescope" for reading the scales and circles, described in the accompanying text, were not attached

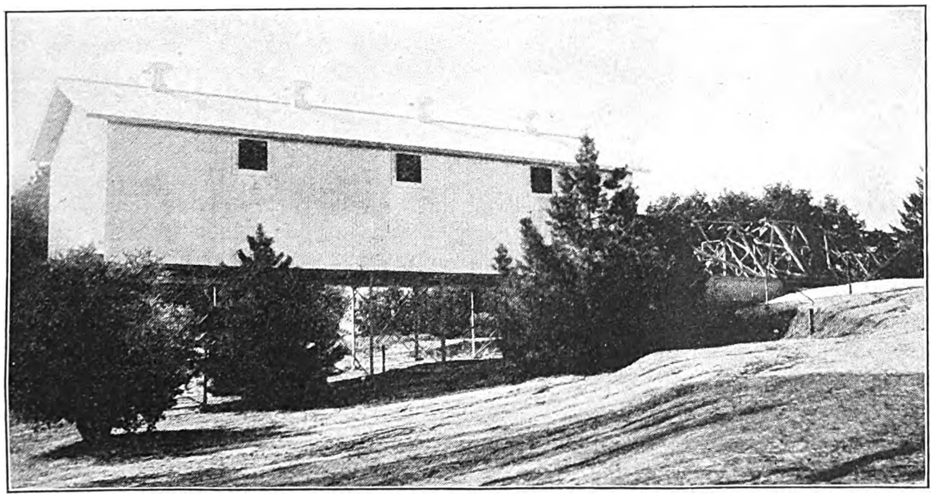
THE outer mirrors rotate for declination about centers passing through a common axis parallel to the top of the bridge. Both fast and slow motions are provided. Readings by circle and vernier are made through a system of mirrors with the same telescope used for reading the mirror separation.

The three central plane mirrors are mounted on a cast iron frame which stands on the top surface of the bridge directly above the large mirror. The central mirror is fixed; the other two can be tilted for slow motion about axes parallel to the polar axis. The east mirror is mounted on a slide capable of micrometric motion along the beam and furnishes an additional means of compensating the optical path length for variations due to flexure, differential expansion, and atmosphere.

Observations are made from a platform located south of the bridge above the polar axis. Here are placed the eyepiece, the control buttons, circle and scale lamp switches, and the telescopes for reading the circles and scales. All motions in the instrument are motor driven and are operated through relays. An eyepiece of one-eighth-inch focus is necessary to view the fringes conveniently.

The alignment of the instrument during construction was made by squaring the pedestal with the house and checking the polar axis for azimuth on the 60-inch reflector axis with level and gage. When the instrument was about finished the alignment was checked on Polaris by means of a rod carrying cross wires clamped to the bridge. Final adjustment was made by taking drift curves of equatorial stars directly reflected from an uncovered portion of the large concave mirror, computing the error and adjusting the screws at the base of the pedestal.

Drift curves were next taken of the images from the flat mirrors which were found to shift in opposite directions along the declination cross wires. Eight and ten foot straightedges were clamped in various positions about the beam and the shifts measured after moving the instrument into various positions. The addition of several ties has practically eliminated this drift.

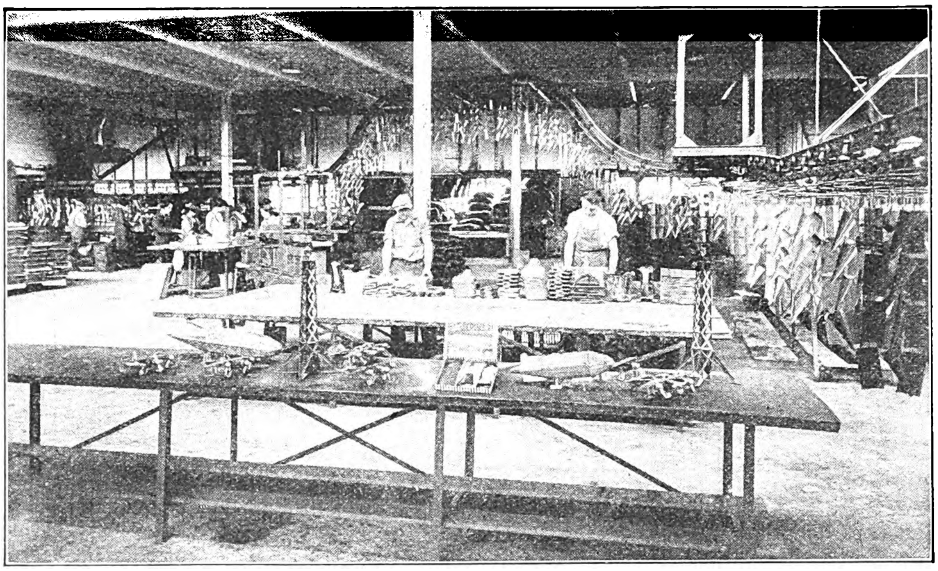


The housing or shed of metal rolled off to the east on its trestle

The first experiment made with the interferometer was to see whether fringes would show at distances greater than 20 feet. Experimental curves obtained with the 20-foot instrument showing decrease in visibility for a drop in the seeing had been plotted for stars of small angular diameter. Extrapolation of these curves indicated that for "seeing" even as low as 1 on a scale of 10, fringes should appear for distances much greater than 20 feet. At the time the 50-foot interferometer was tried out the seeing varied from 1 to 2 and it was noted with feelings of great pleasure that at the distances of 25 feet and 34 feet at which it was tried the readings coincided with points on the curves. Visibility curves of Betelgeuse and Arcturus made during seeing 1 to 2 also coincided with those made with the 20-foot beam, indicating that measures of star diameters made with the two instruments are alike.

IT is estimated that stars as faint as fourth magnitude can be measured and that complete disappearance of the fringes will take place for about 25 stars. Others whose diameters are still smaller can be estimated by plotting the visibility curve. The appearance and amplitude of vibration of the image given by the two mirrors appeared to be the same regardless of their separation, thereby giving evidence of atmospheric conditions favorable to telescopes of large apertures.

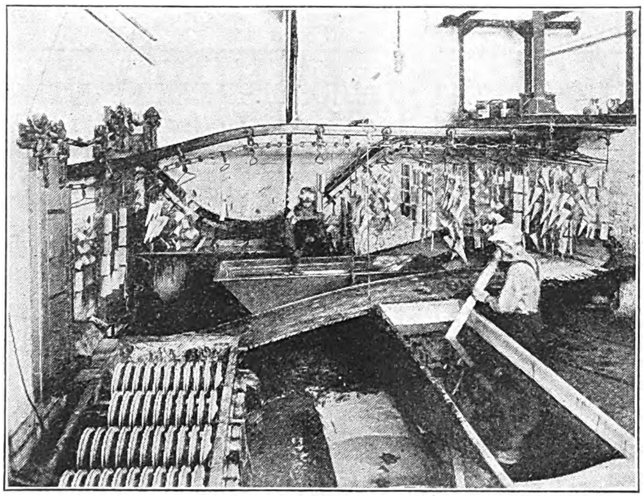
A national organization, the Lyonsport Aero Club, composed of boys owning sets manufactured in this particular plant, is equipped with aviation uniforms and winged pins which admit them free of charge to view certain war films, and also entitle them to a ground course in one of the St. Louis air colleges with a proficiency certificate of the same nature as that for adults.



A section of the electrically-operated carrier system on which metal parts are carried through enameling vats and bake oven, thence to the loading table

THIS Lyonsport Aero Club, commanded by Captain Jack Bursey, has juvenile pilots all over the world. National advertising over one of the big radio chains carries the stories of adventure to this juvenile audience of aviation enthusiasts, and spurs them on to greater work and a broader aircraft education.

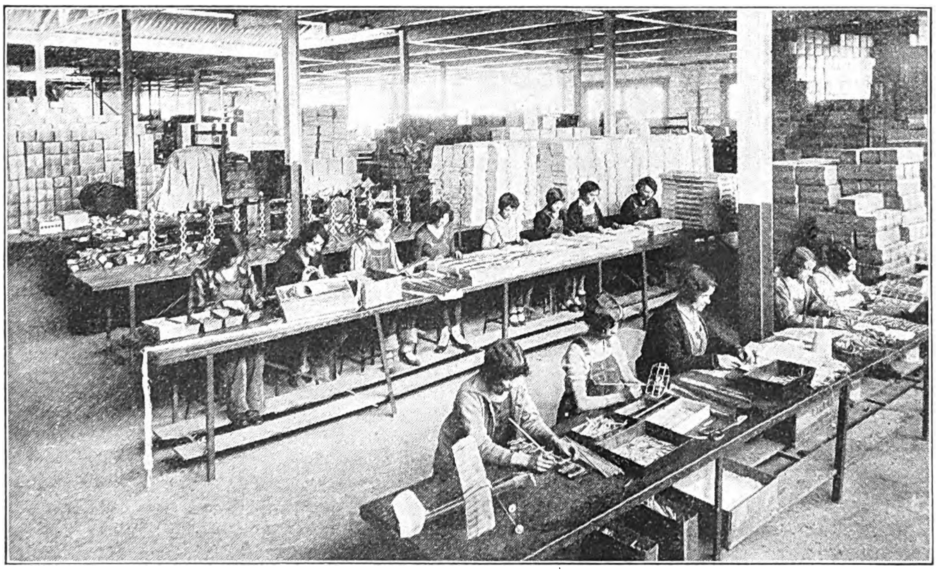
It was about 1911 that the Illinois Model Air Club was organized among Chicago high school boys. Then came the war and interest was directed elsewhere.



The paint room. The carrier dips low so that the toy airplane parts are immersed in the paint

Then Lindbergh's epochal flight in May, 1927, and overnight America became air-minded. Prior to this time, the toy aircraft industry had been very small indeed, but in the next three months it jumped to a quarter of a million dollars retail. By the end of 1928 it had climbed close to the 2,000,000 dollar mark, wholesale, while the Metalcraft Corporation, in October, 1929, wholesaled some 140,000 dollars, as has been noted, in demountable aluminum and sheet-steel aircraft parts for toy models.

Meantime the Playground and Recreation Association of America got behind a movement to arouse juvenile interest in aircraft construction, sponsoring miniature aircraft tournaments all over the country, with a National Tournament held in Memphis, Tennessee, in October, 1927. The vocational departments of many public schools had already adopted a definite program of model airplane construction, with classes, contests, and the like.



Illustrations courtesy The Metalcraft Corporation

Assembling and packing the finished parts in construction sets. The purchaser does the final assembling himself, from the parts supplied in the kit

Nor has this work been confined to any one type of plane. Flying stick types, scale models of famous ships, hydroplanes that will rise off the water, and racing planes driven by four propellers and capable of running 50 miles per hour, have been constructed.

The National Aeronautical Association has recognized two of these contests, held annually: the Mulvihill for outdoor models, and the William B. Stout for indoor models—named after the donors of the trophies.

IN June, 1928, the National Indoor Meet was held in Detroit, with boys from all over the country competing for the Stout trophy and some 500 dollars in prizes. It is significant to note that during the World's Air Fair Week, held in the St. Louis Arena during the middle of last February, a National Junior Indoor Model Airplane Contest was held; also, steps were taken for the organization of the first Junior Aircraft Convention, at which time technical subjects as applied to model airplane construction will be up for discussion.

From Florida to Newfoundland, and from New York to Seattle, these model airplane contests are being held. They are being fostered everywhere; special junior technical aircraft magazines—featuring model drawings to scale, for the boy to use in his construction work—have made their appearance.

And the whole of it points directly toward a highly specialized aircraft education for boys—not just haphazard play! The results are bound to be far-reaching in the extreme in their effects upon the aviation of tomorrow.

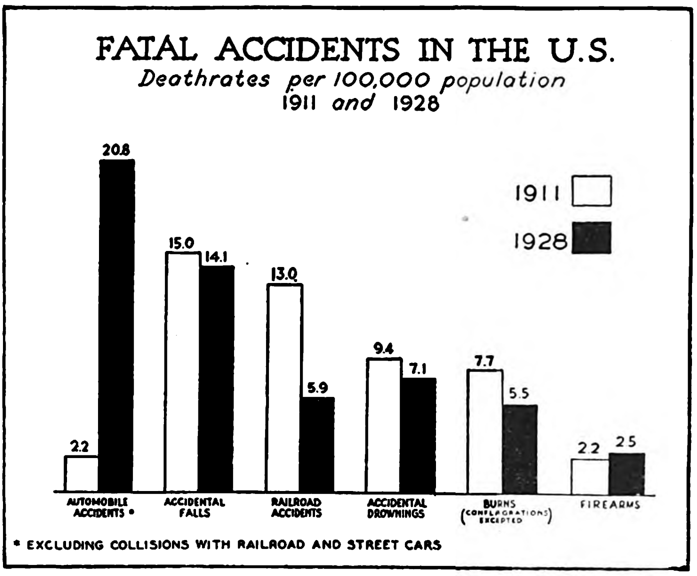
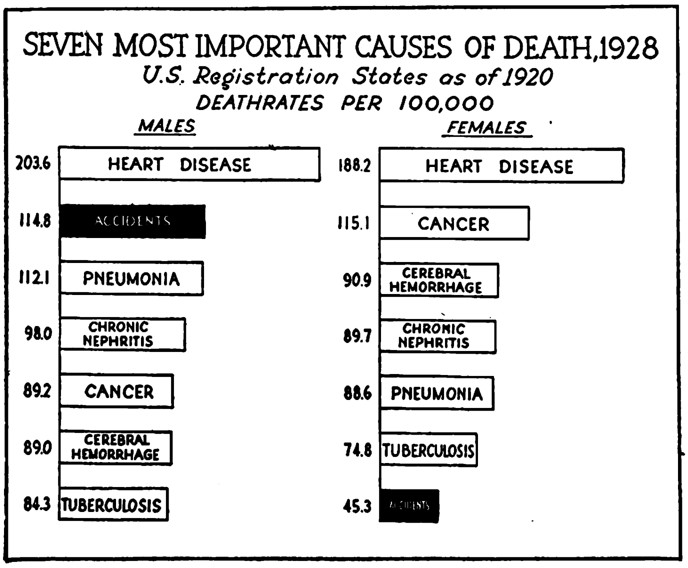
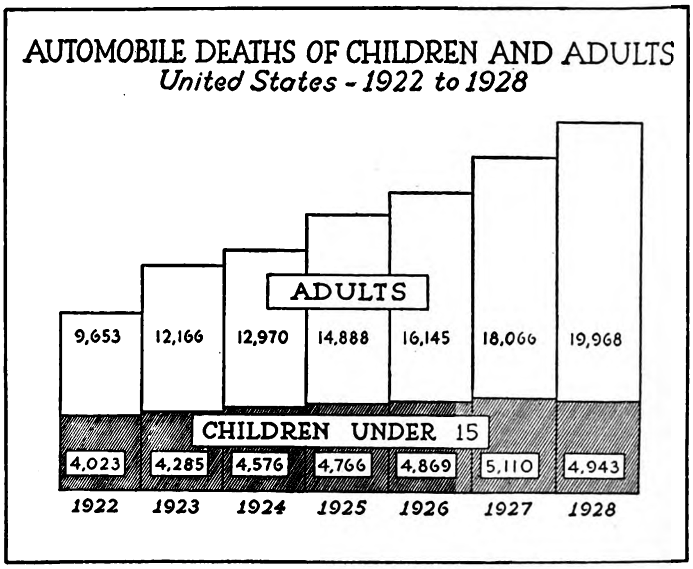
While automobile accidents soar, the death rate for non-automobile accidents is 30 percent below 1913



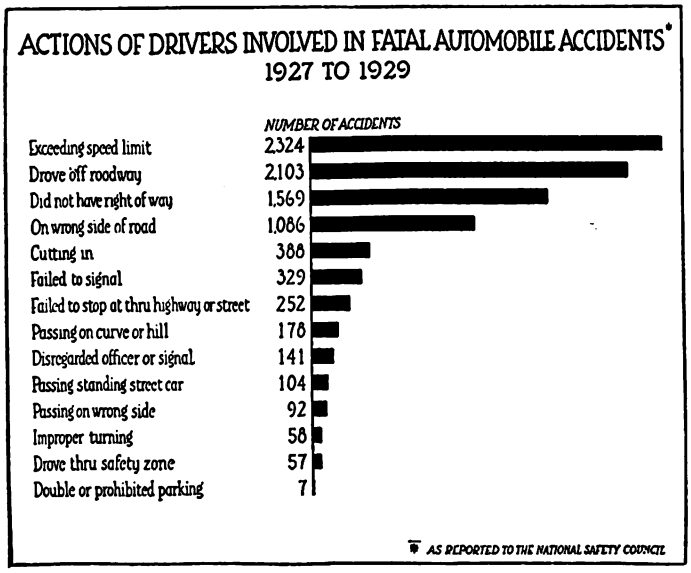
Various types of accidental death, showing a decrease during 17 years except for automobiles and firearms



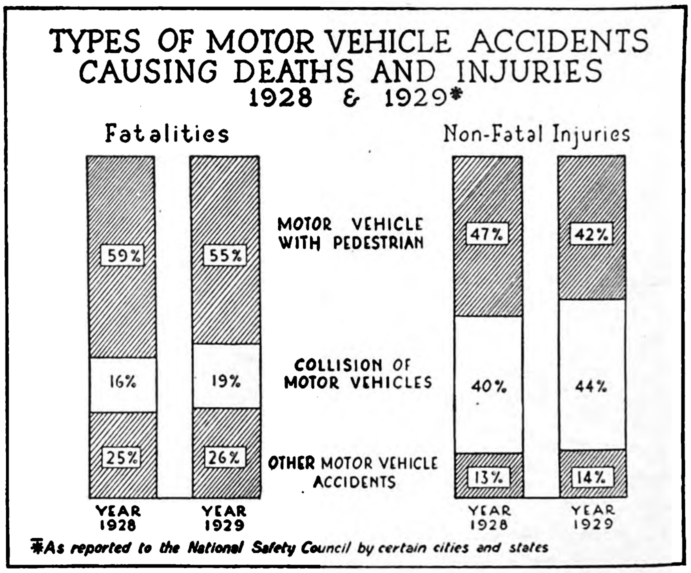
Fewer women than men suffer accidents. Accident death rates compare unfavorably with those of disease



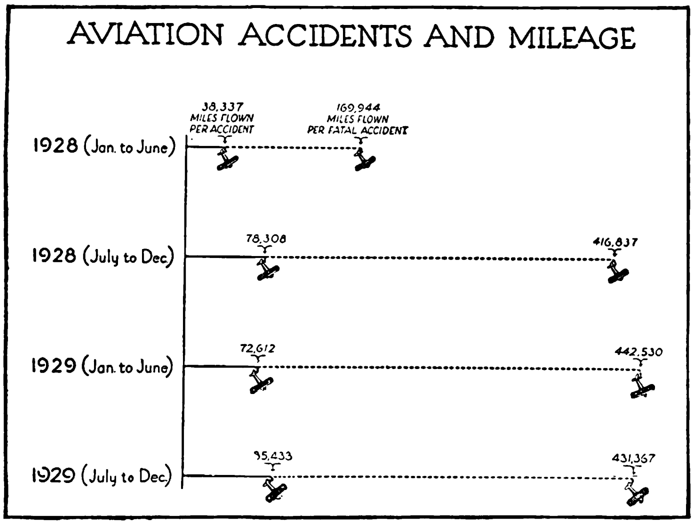
Motor vehicle deaths among persons over fifteen years old are increasing more rapidly than among children



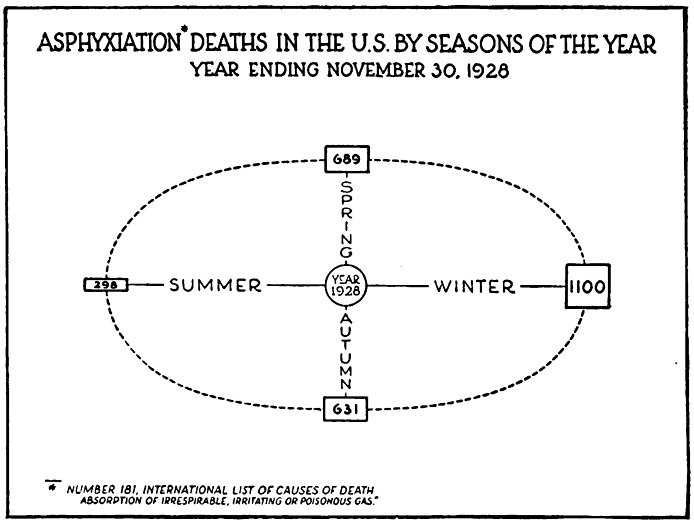
The cause of automobile accidents is worth studying. Speeding tops the list but even parking adds its quota



This interesting diagram shows that the automobile kills 13 percent oftener than it injures the pedestrian



Aviation accidents are on the increase as is described in the text. Four hundred and ninety-six deaths occurred in the year 1928 by airplane and balloon



The third largest cause of home fatalities is asphyxiation; 40 percent of such deaths occur in the winter months. The number is far smaller in the summer

The Penalty of Carelessness

An unprecedented increase in motor vehicle fatalities overbalanced the decreases in all other walks of life last year and America's accidental death toll rose to a new high total of 97,000. The private automobile driver is responsible for most of this increase and he must be curbed before a definite reduction can be realized in the national accident picture. The 1929 total for all accidents has just been made public by the National Safety Council on completion of its accident analysis for the past year. The accident fatalities for 1928 were 95,086. While total fatalities in 1929 were slightly less than 2000 more than in 1928, automobile casualties alone reached 31,000, an increase of 3000 over the previous year. These figures tend to show that motor vehicle fatalities alone are on the increase and that other types of accidental deaths are on the gradual decline.

Accidents to children are increasing far less rapidly than to older persons. In the seven-year period from 1922 to 1928, fatalities to persons of all ages increased almost 25 percent. In the same period accidental deaths of children under 15 increased less than one tenth of 1 percent. If accident prevention work among adults had been as successful as among children, approximately 20,000 lives would have been saved during the past year.

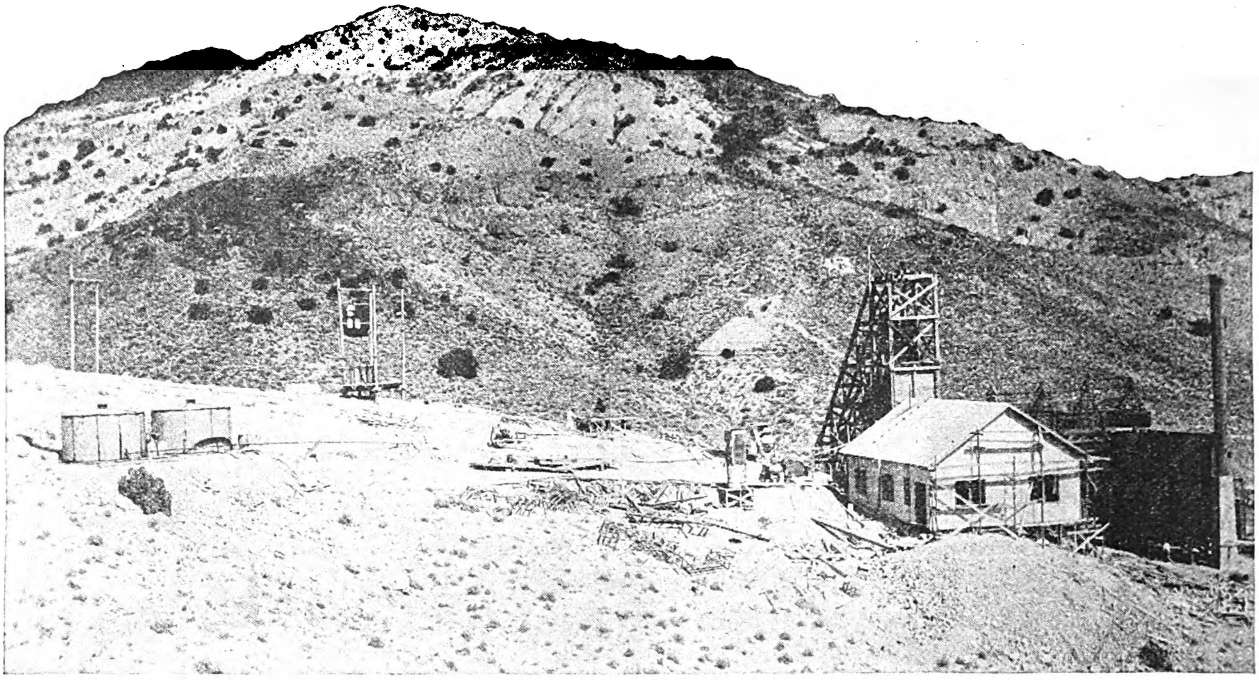
There was very little change in the railroad-automobile fatalities during 1929 and there was an improvement in the accident situation among commercial vehicle drivers. A large part of the increase therefore can be charged indirectly to careless owners of private automobiles.

The 97,000 death toll for 1929 included 23,000 fatalities in or about American homes; 23,000 fatal accidents in industry; and still another 20,000 persons who lost their lives in public accidents not involving the use of a motor vehicle. The principal cause of home accidents was falls, 9200 persons losing their lives in this manner. Burns, scalds, and explosions accounted for the next largest number of home fatalities. Asphyxiation and suffocation were the third most important causes. Carbon monoxide poisoning in closed garages was an important contributing factor. About 200 non-fatal accidents occurred in American homes for every fatal accident, it is estimated.

In addition to the annual study of accident statistics of the United States for the past year the National Safety Council conducted an interesting survey. Inquiries were sent to all governors, to the mayor of every large city, and to numerous other officials and civic leaders, asking their opinions as to the reason for increases or decreases in last year's accidents. Personal studies were made in 12 leading cities. This survey brings out some interesting facts: The states which have rigid drivers' license requirements continue to make better records, in relation to their own past experience, than the states where licenses are not required. Speed is a major consideration in the opinion of quite a number of the state and city officials and other experts. Intoxication is partly responsible for the "obsession to speed," according to the reports. Inadequate enforcement is blamed by many authorities.

There is one hopeful sign brought out in the analysis of the accident experience for 1929. If we could ignore the annual toll from motor vehicle accidents, our national experience would show that the national death rate from all other accidents had been reduced more than 30 percent since 1913.

The number of airplane and balloon fatalities in the United States has increased from 182 in 1920 to 496 in 1928. These are the Census Bureau figures. The Aeronautics Branch of the United States Department of Commerce recorded a total for the year of 485 fatalities in civil aviation. Schedule flying has the best record with a total of only 41 fatalities, or 8.5 percent of the total. According to other reports of the Aeronautics Branch, this type of aviation accounted for over 25,000,000 miles flown out of a total for all types of 79,000,000, or 31.6 percent of the total mileage. Miscellaneous pleasure flying resulted in 277 fatalities, or 57 percent of the total for all types. Of the total fatalities 227 were pilots and 258 passengers. The average mileage flown per accident and separately, per accidental fatality, is shown in our diagram. After extended and careful investigation the Aeronautics Branch announces that in 1929 about 57 percent of all accidents were due to errors of personnel; 18 percent to power-plant failures and 10 percent to some failure in the machine apart from the power-plant. Less than 5 percent were attributed to weather conditions. There was a sharp increase in deaths in airplane accidents in 1927 and a still greater advance in 1928, the latter being over 100 percent.



A quicksilver, or mercury, mine located in the hills of Nevada

The Reviving Liquid-Metal Industry

By J. K. NOVINS
